Angular Distribution of Photo-neutrons Produced by 17 Mev X-rays

By Tsunesaburo ASADA, Masayoshi MASUDA, Masayuki OKUMURA
and Juzo Okuma

Department of Physics, Faculty of Science, University of Osaka

(Received August 19, 1957)

The angular distributions of photo-neutrons from lead, copper, aluminum and beryllium have been measured by using bremsstrahlung of maximum energy of 17 Mev from a betatron. The neutron detector is ZnS-paraffin-Lucite light guide button. The results are $1+(1.29\pm0.53)\sin^2\theta$, $1+(1.6\pm0.8)\sin^2\theta$, $1+(0.17\pm0.06)\sin^2\theta$, $1+(0.30\pm0.11)\sin^2\theta$ for beryllium, aluminum, copper, and lead.

§ 1. Introduction

The photonuclear processes can be conveniently divided into two mechanisms; i.e., evaporation and direct ejection.¹⁾

The former is the one in which the γ -rays are absorbed by a collective nuclear motion which results in general heating of the nucleus and subsequent decay which can be explained by the statistical model. The latter is the transition of a nucleon in the upper shell to an unfilled state by the electric dipole absorption of γ -rays.

The evaporation process results in the spherically symmetric distribution of ejected particles and in the direct process it is expected to be of the form $(a+b\sin^2\theta)$ ¹⁾ where θ is the angle at which neutrons are emitted with respect to the incident γ -rays, a and b are constants.

In this paper, we report a measurement of the angular distribution of photo-neutrons in the energy range of "off the giant resonance" using the bremsstrahlung from the University of Osaka Betatron.

Fig. 1. Block diagram of experimental arrangement.

The results are compared with the earlier experiments^{2,3,4)} in lead, copper, and aluminum. A measurement of angular distribution of photo-neutrons from beryllium is also reported. Guth and Mullin⁵⁾ and Czyz⁶⁾ have calculated the angular distribution for the reaction

$\text{Be}^9(\gamma n)\text{Be}^8$ assuming that the Be^9 nucleus consists of Be^8 core plus a valence neutron in $P_{3/2}$ ground state. They have obtained a distribution of the form $(a+b\sin^2\theta)$ arising from electric dipole transition to S and D state, with the ratio b/a depending on the respective

transition probabilities.

§ 2. Experimental Procedure

The arrangement of experimental instruments are shown in Fig. 1. The boron enriched concrete shielding has increased the signal to background ratio by factor of 10. The targets were cut in the shape of cylinder of $1''\phi \times 1''$. The neutrons were detected by a ZnS-paraffin-Lucite light guide button⁷⁾ mounted on Du-Mont 6292 photomultiplier tube as shown in Fig. 2. This counter was arranged

Fig. 2. Detailed diagram of neutron detector.

so that it could rotate about the center post on which the cylindrical target was set. The distance between the target and the center of counter was 16 cm. The diameter of the X-ray beam was 2.0 cm at the target and monitored by an ionization chamber calibrated by the method of National Bureau of Standard.⁸⁾ The pulses from the photomultiplier tube were fed into a cathode follower pre-amplifier, a Model-100 amplifier, a 4-channel pulse height analyzer and a register. The discriminator bias was set at 15 volts as shown in Fig. 3. This indicate the efficiency of 0.3 % for Rn-Be neutrons.

In measuring the photo-neutrons, one must contend with background noises of very large intensity which originate in the target placed in the center of the X-ray beam. It is possible to obtain the required discrimination between the X-rays and recoil protons from

the fact that the specific ionization of recoil protons is much higher than that of secondary electrons. But the high intensity burst of X-rays causes high voltage scintillation pulses by the pile-up effect of electrons. It is difficult to distinguish the neutron pulses from these pile-up pulses.

Fig. 3. Differential bias curve with Emmerich button (ZnS-paraffin-Lucite light guide). Rn-Be neutron source was placed at 16 cm from neutron detector.

Fig. 4. Block diagram of counting system.

Therefore, the long expansion technique⁹⁾ was adopted for the betatron operation. The long expansion pulse of 80 μ sec results in a long X-ray burst and reduces the pile-up difficulties in measuring the low yield neutrons in the large X-ray burst. In this point of view, we changed our integrator expander for a delayed expander for this experiment. Readings were taken at 40°, 50°, 70°, 90°, 110°,

130°, 140°. The pile-up difficulties made the readings for more forward angles impossible. Moreover, the forward reading with aluminum target was unobtainable due to its low neutron yield.

Also, the pile-up difficulties could be lessened by using a thick lead window in the detector. This result is shown in Fig. 5. The target was lead and a lead sheet was inserted between the detector and the target.

For example, the counting rate was 133 per

Fig. 5. The absorption curve of photo-neutrons with lead window inserted between the counter and the target. It is shown that the 12 mm window is sufficient to avoid the pile-up effect.

1.5 min. with lead window of 12 mm thickness, while 112 per 1.5 min. with 22 mm window when the lead target was bombarded by bremsstrahlung with maximum energy of 17 Mev.

By the way, the counting rate for neutrons from the Rn-Be neutron source was 116 with 22 mm window when normalized at 12 mm window counting. This value was taken by placing the Rn-Be neutron source at the position of target without the bremsstrahlung bombardment. The both counting rate with 22 mm window agrees within the experimental error.

The similar procedures were followed in other targets and we can say with confidence that our results are free of the erroneous counts due to piled up electrons.

§ 3. Results and Discussion

The observed angular distributions for lead, copper, and aluminum have the shape of $(a + b \sin^2 \theta)$, which are the same as reported by Johanson²⁾, Dixon³⁾ and Price.⁴⁾ This is shown in Fig. 6. The value of b/a was compared with the data of earlier experiments in Table I. Since these detectors are all fast neutron

Fig. 6. The angular distributions of photo-neutrons as measured with Emmerich button type scintillation detector.

detectors, the detected neutrons are those of direct emission. Therefore, assuming these neutrons are due to the transitions from unknown upper shells, one can conjecture that the transitions from which shells are predominant by the relation $(l+2)/2l=b/a$, where l is the angular momentum of the state before

nuclear excitation. However, because of large differences between the results of earlier experimenters, above conjecture is not reliable. The photo-neutrons of lead seems to originate in the transitions from lower state than in copper. But the large value of b/a of angular distribution of aluminum can not be explained

Table I. The values of b/a .

Energy	Al	Target Cu	nucleus Pb	Be	Detector
Present (17 Mev)	1.6 ± 0.8	0.17 ± 0.06	0.30 ± 0.11	1.29 ± 0.53	Emmerich ^a
Dixon (70 Mev)	0.36 ± 0.29	0.23 ± 0.15	uniform	1.2 ± 0.4	Hornyak ^b
Halpern (70 Mev)				1.26 ± 0.11	Emmerich ^a
Price (22 Mev)		0.33	0.84	uniform	Al (n, p) ^c
Johanson (65 Mev)	1		0.8	1.5	Hornyak ^b

a) A scintillation detector with a ZnS-paraffin-Lucite light guide.

b) A scintillation detector with a ZnS-Lucite.

c) A fast neutron detector by measuring the beta activity of $\text{Al}^{27}(n, p)\text{Mg}^{27}$ reaction.

satisfactorily by the theory. The theoretical value of b/a deduced by the Courant model can fit the experimental distribution only if the majority of the observed neutrons have an angular momentum of one in the nucleus before excitation. This seems unlikely in aluminum.

The angular distribution for beryllium is a superposition of distribution resulting from photons of all energies up to 17 Mev because of the nature of bremsstrahlung. Transition from the P state to the S state, which predominate at the energies just above the threshold, give a spherical symmetric distribution and prohibited by the high energy filter with a large γ -ray absorber placed at the center of X-ray beam. High energy photons cause transitions to the D state with a resultant rise in the angular distribution at 90° . However the value of b/a seems to prove this fact, the constancy of b/a in varying the excitation energy up to the 70 Mev suggests us that the calculation of Guth and Mullin can

not be applied to the experiment of this energy region. The Be^9 nucleus is divided into the neutron and proton clouds at this energies. The mechanism of photodisintegration which looks more is the one given by Titterton¹⁰) that Be^9 may disintegrate by photon absorption into a two alpha particles and a neutron in the following manner, $\text{Be}^9(\gamma, \alpha)\text{He}^6 \rightarrow \alpha + n$, but we can not conclude the reaction mode with this experimental data.

The Phase Transformation of Solid Normal Hexadecanamide

By Tosio SAKURAI and Masaya YABE

Institute of Science and Technology, University of Tokyo

(Received September 4, 1957)

A phase transformation of normal hexadecanamide ($C_{16}H_{31}CONH_2$) in which the crossed hydrocarbon chain configuration changes into the parallel-chain one is investigated by means of X-rays, thermal analysis, infrared absorption and proton magnetic resonance absorption. Based upon the knowledge of the crystal structure and X-ray observation, a mechanism of successive reorientation of the hydrocarbon chain at this transformation is proposed. The twisting vibration of the hydrocarbon chain is found to play an important role for this transformation.

§ 1. Introduction

In the previous report¹⁾²⁾ it was found that the normal fatty acid amides $CH_3(CH_2)_nCONH_2$ with even carbon number have an unusual crossed-chain configuration. Lingafelter and Turner³⁾⁴⁾ investigated the same series of amide from propane amide to tetradecanamide and hexadecanamide independently of us. Their results essentially agree with ours. It was also found¹⁾ that heptadecanamide and hexadecanamide have another phase with parallel-chain configuration, and hexadecanamide has a phase transformation at which the crossed-chain configuration changes into the parallel-chain configuration.

At this transformation point, reorientation of the paraffin chain occurs. The reorientation of the paraffin chain was observed at the transformation of some triglycerides⁵⁾. In this case the reorientation occurs through a liquid-like phase. But in the present case, the reorientation occurs in the crystalline state at a temperature more than twenty degrees below the melting point. Although a large number of works about the phase transformation of long chain aliphatic compounds have been published, this kind of phase transformation is completely new, and detailed investigation seems to be very interesting.

Although the nature of the phase transformation is already stated briefly in the previous report,¹⁾ its important points will be reviewed in § 2, because it is complex and there is something new in it. The mechanism how the molecule reorients at the transformation point is one of the most interesting points of the present work. From the knowledge of the crystal structure and X-ray observation at

the transformation point, it is shown that the hydrocarbon chain is brandished around the terminal amide group which forms the strong hydrogen bond network with surrounding molecules. The behavior of the hydrogen bond is investigated by infrared absorption. Thermal properties indicate that large entropy change occurs at the transformation point and internal vibration of the molecule plays an important role. Results of the proton magnetic resonance absorption are consistent with the above view and show the marked motional narrowing corresponding to the molecular reorientation and the internal vibrations.

Sample used throughout the present work was the same as that used in the previous ones.

Fig. 1. Diagram of the phase transformation. Arrows show the direction of the transformation.

× represents crossed-chain configuration,
// represents parallel-chain configuration.

§ 2. Nature of the Phase Transformation

Following the nomenclatures in the previous paper¹⁾, the phase of the crossed-chain configuration is called phase A, those of the parallel-chain configuration are called phase B and B'. The relation between these phases are shown in Fig. 1.

When hexadecanamide is crystallized from a solution at or near room temperature, phase *A* appears, and when it is cooled from its own melt phase *B'* appears. This phase transforms into another phase *B* on cooling at about 56°C. When phase *A* is heated, it changes into phase *B'* at about 80°C, but on cooling it never returns to phase *A*. Arrows in Fig. 1 show the direction of the transformation. $\times$ represents the crossed-chain configuration and $//$ represents the parallel-chain one. Every attempt to reverse this process, namely from *B'* to *A* by slow cooling or maintaining the sample just above or just below the transformation temperature for a long time has failed. At room temperature, both phases *A* and *B* persist at least for three years.

Another phase named *B''* appears in some special case. It resembles phase *B* and appears either on cooling from its own melt or heating phase *A*. But, as it comes out accidentally and the systematic investigation is therefore very difficult, the problem of this phase is out of the main scope of this paper.

§ 3. Crystal Structures

Phase *A* is monoclinic and the space group is reported to be $P2_1/a^{11}$. Phases *B* and *B'* are triclinic. Piezoelectric effect of phase *B* is absent, therefore the space group will be $P\bar{1}$.

Their unit cell dimensions were determined by a conventional single crystal rotation camera. The camera radius, about 35 mm, was calibrated by the diffraction lines of copper and calcite. Results are tabulated in Table I.

Table I. Unit cell dimensions

Phase	<i>a</i>	<i>b</i>	<i>c</i>	α	β	γ
<i>A</i>	9.790 Å	5.535 Å	32.43 Å	90°	104.4	90°
<i>B</i>	5.185	5.509	45.403	115.8	110.3	113.3
<i>B'</i> *	5.168	5.492	45.474	117.1	109.7	110.9

* Values for *B'* was determined at about 82°C.

The values for phase *A* are slightly refined than the previous ones. Phase *A* contains four molecules per unit cell and phases *B* and *B'* contain two molecules per unit cell.

3 a. Phase *A*.

The detailed structure analysis of tetradecanamide was already performed by Lingafelter and Turner⁴, and from the investigation of the subcell structure it is known that the structure of hexadecanamide is nearly the same as that of tetradecanamide.¹¹ Therefore no attempt was made to get the detailed structure.

The packing of the hydrocarbon chain is best understood from Fig. 2 of the previous paper¹¹. If we consider a plane containing *b* axis and the chain axis (defined as the row plane by Lingafelter and Turner), molecular axis in one row plane are all parallel. But the chain axes of two neighbouring row planes are almost perpendicular to each other. Therefore the crystal is composed of two kinds of row planes. If we name these planes *S*₁ and *S*₂ respectively, *S*₁ and *S*₂ planes are stacked alternately in the crystal. The plane of the

zigzag chain is almost perpendicular to the row plane.

3 b. Phase *B*.

Small needle-shaped crystals of phase *B* were obtained by cooling the sample from its own melt. The needle axis was taken as *b* axis, and the intensity data of the *b* axis projection were obtained by Bouman type camera. Multiple-film method was used, and the photographic density was measured by the microphotometer. As the crystal used was very small, no absorption correction was applied and corrections for Lorentz and polarization factors were applied in the usual way.

In the present structure, two molecules are in the unit cell and are situated centrosymmetrically. An approximate value of the distance between CH₂ groups in a molecule is easily obtained from the subcell structure. From Patterson synthesis the direction of the molecular axis is shown to deviate a few degrees from the *c* axis of the crystal. Therefore one main unknown parameter is the separation of two molecules. Thus by varying this parameter, several trials were made to

get the best agreement between observed and calculated structure factors of $(00l)$ reflections. After these parameters were determined approximately, the signs of structure factors were calculated, and a Fourier synthesis was performed. The result is shown in Fig. 2. Due to the effect of the large temperature factor, neighbouring CH_2 groups are not separated.

Fig. 2. Phase B. Projection along the b axis.

But it is clear that the chain axis is not quite straight but bends in this projection. This means that twisting of the molecule occurs. A similar case is reported by Sydow⁶⁾ for fase C' of n -hendecanoic acid. In that case, the helical twisting is observed, and the temperature factor reaches to $9.8 \text{ \AA}^2$ at a temperature five degrees below the melting point.

Final atomic position and calculated and observed structure factors are tabulated in Table II and Table III. For the structure factor calculation, atomic structure factors for valence state⁷⁾ were used and CH_2 groups and NH_2 group were treated as single atoms having the structure factors $f=f_C+2f_H$ and $f=f_N+2f_H$ respectively. No significant difference occurs by exchanging the positions of the oxygen

atom and the nitrogen atom. The temperature factor is taken to be $5.3 \text{ \AA}^2$. The reliability index R is 30%.

As the shape of the crystal is very fine needle, projections along other axes are very difficult to get. But, if the tetrahedral angle and the ordinary single bond length are assumed for the $\text{C}-\text{C}$ bond, the angle between the $\text{C}-\text{C}$ plane and ac plane can be calculated. This angle varies gradually for successive $\text{C}-\text{C}$ plane as shown in Fig. 3. Thus

the total twisting of the molecule reaches 12 degrees.

Twinned crystals are often obtained. This twin has the *b* axis and the *c** axis in common. It is interesting to note that this twin is closely related to the imperfect structure which is obtained after *A* to *B'* transformation. (see § 4 Fig. 4c).

3 c. Phase *B'*.

No special difference in the intensity dis-

tribution between phases *B* and *B'* is observed except the decrease of the intensity of the higher angle spots of phase *B'* due to the large temperature factor. Therefore, the atomic positions are almost the same in both phases.

3 d. Phase *B''*.

Although the systematic investigation of phase *B''* is not successful, the Bouman photographs around the *b* axis shows that not only the lattice constants but also the relative intensities are closely similar to those of phase *B*. They are shown in Table IV. The differences appear in the odd *h* reflections, which means that the molecular configuration is closely similar to that in phase *B* except that *x* coordinates of phase *B''* shifts $\frac{1}{2}a$ compared with that of phase *B*. This phase might be the phase *II'* reported by Kurokawa⁸. But, as the powder pattern of phase *B''* could not be obtained, direct comparison was impossible. The best indication of phase *B''* is the appearance of the strong ($\bar{1}017$) reflection, which is very weak in phase *B*.

§ 4. Mechanism of the Reorientation of the Molecule

At the *A* to *B'* transformation point, long molecule must be subjected to the large reorientation in the solid state. Three important results concerning this problem were already pointed out in the previous report¹. Namely, when a single crystal of phase *A* is heated,

Fig. 4. (a) *ab* basal plane of phase *A*. (b) Relation between phase *A* and phase *B'*. (c) *ab* plane of phase *B'* after transformation. Black and white bars in (a) and (c) represents the projection of the hydrocarbon chain.

- 1. it splits into a few crystals of phase *B'*,
- 2. the direction of the *c** axis is conserved,
- 3. the direction of the *b* axis (the needle axis of the crystal) is conserved.

But, after repeating such experiments with many crystals, it was found that although the second result is always correct, the first and the third results must be modified in the following way.

When a good single crystal of phase *A* is heated, the axis of phase *B'* is apt to appear in the direction of the needle axis. But, in some cases the axis or the [1 1 0] appears in the direction of the needle axis. Among the fifteen crystals tested, ten possessed *b*, four possessed *a* and one possessed [1 1 0] axes as the direction of the needle axis.

When the original crystal of phase *A* is imperfect, powder-like rings appear. In this case discrete (0 0 1) reflections are still observed. From these results following mechanism is suggested. As the *c** axis is conserved, *ab* basal plane is conserved and the reorientation occurs between these planes. The separation of these planes ((0 0 1) spacing) is 31.5 Å for phase *A* and 32.5 Å for phase *B'*. Therefore the molecule tilts from *ab* basal plane about 45° and 46° respectively. Fig. 4a represents this *ab* basal plane of phase *A*. Bars represent the projection of the hydrocarbon chain. Chains represented by black bars are situated on the plane *S*₁ and those represented by white bars are on the plane *S*₂. Fig. 4b represents *ab* plane of phase *A* and phase *B'* at the transformation point with the same origin and the same direction of

the *b* axis. The lengths of these axes have the following relations. The *b* axis of both phases *A* and *B'* are almost the same, and 2*a* sin *γ* of the phase *B'* is almost equal to the *a* axis of phase *A*. Therefore, when the *b* axis is conserved during the transformation, one of the row planes say *S*₁ of phase *A* needs not to be subjected to the appreciable change and only a slight gliding along the *b* axis is sufficient. On the other hand, molecules on *S*₂ must experience the large reorientation. But the molecule packed in the crystal leaves no room for such a large reorientation. Thus the transformation seems to be triggered by the reorientation of one molecule at the boundary of the crystal. If the reorientation of a molecule once occurs, neighbouring molecule on the same *S*₂ plane follows the first and the reorientation propagates in the crystal. This model is consistent with the observation under the polarizing microscope¹⁾. The end group of a molecule on *S*₂ plane is linked to the molecules on *S*₁ by hydrogen bonds and the direction of this hydrogen bond network is conserved. Therefore the hydrocarbon chain is brandished around the end group.

The triggering occurs either in *S*₁ plane or in *S*₂ plane with equal probability. If both kinds of triggering occur at different parts of the same crystal, resultant phase split into several crystals with different directions of the *a* axis, as shown in Fig. 4c. Bouman photographs shown in Fig. 5 of the previous paper clearly corresponds to this structure. This is the most common case. But if reorientation of the triggering molecule occurs

in some different way, succeeding molecules will follow the first and the resultant B' phase has different axial direction.

When the original crystal is not perfect, mainly composed of the layer like crystal packed in the same orientation, the direction of the axis of each layer after the transformation is controlled by each triggering molecule, thus the resultant crystal is composed of small crystallinities with different orientations and the powder-like pattern appears.

Fig. 5. Infra red absorption spectra.
(a) Phase A. 29°C. (b) Phase A. 73°C.
(c) Phase B. 35°C. (d) Phase B' . 94°C.

§ 5. Infrared Absorption

From the discussion in § 4, it is clear that the hydrogen bonds between terminal amide groups have an important role for the phase transformation. But in X-ray analysis it is not easy to deduce the exact form of the hydrogen bond. Therefore infrared spectrum of N-H stretching vibrations was examined.

$\text{H}-\text{N}-\text{H}$ bending vibration is very near to the $\text{C}=\text{O}$ stretching vibration and it proved to be very difficult to separate them.

Absorption spectrum is recorded by com-

mercial Parkin Elmer spectrometer. The sample is sandwiched between rock salt plates, and heaters are attached on both sides of the plates. The temperature is measured by the thermojunction inserted into a small hole drilled into the rock salt plate. The measured temperature seems to be slightly lower than the temperature of the sample itself. Therefore it is corrected by assigning the melting point of the sample to the temperature at which the abrupt change of the observed infrared spectrum occurs. Typical absorption curves are shown in Fig. 5. In Phase A small side peak appears in the 3370 cm^{-1} band, and in phase B' the 3195 cm^{-1} band broadens slightly. But in other respect, both the frequency and the intensity of the absorption band are nearly the same for all phases. The frequencies against the temperature is tabulated in Table V. At the melting point, this absorption band suddenly disappears.

Table V. Stretching vibrations of the N-H bond.

Phase	Temperature	1	2
A	29°C	3370 cm^{-1}	3195 cm^{-1}
A	73	3370	3195
B	35	3365	3195
B	47	3365	3195
B'	62	3365	3195
B'	82	3370	3195
B'	102	3370	3200

The relation between the stretching frequencies and the bond distances of the hydrogen bond is given by Nakamoto et. al.⁹⁾ From Fig. 1 of their paper, N-H...O distance of amide is evaluated to be 2.97 Å. This value agrees well with that obtained by Lingafetler and Turner⁴⁾ for tetradecanamide. Therefore it may be concluded that the hydrogen bond length is not changed during the phase transformation.

§ 6. Thermal Properties

6a. Differential thermal analysis.

Differential thermal analysis was performed by the method developed by Vold¹⁰⁾. In this method, the sample and the reference material, packed into cylindrical containers of the same shape are heated and cooled in the same furnace. The condition of the heat transfer is made as equal as possible for both sample

and reference material. The sample temperature and the temperature difference between the sample and the reference are measured. These temperatures are recorded against the time, and if the transformation is the first order, not only the transformation temperature

but also the latent heat should be obtained. Whether the transformation is the first order or not, is determined from the shape of the curve. In the present case cetane was used as the reference material.

A virgin curve shown in Fig. 6a indicates that the *A* to *B'* transformation is the first order. In cooling curve or reheating curve this latent heat disappeared completely, and only the small anomalous specific heat near 56°C which corresponds to the *B* to *B'* transformation was observed. In phase *B'* the temperature difference from reference material was observed. This means that the specific heat of phase *B'* is large compared with the other phases. These results are consistent with the specific heat measurement of the *B* to *B'* transformation¹¹.

From the average of the two independent observations using the different quantities of sample, the heat and the entropy of the transformation are obtained and listed in Table VI.

Fig. 6. Curves for differential thermal analysis. (a) Virgin curve. (b) Repeated curve.

Table VI. Thermal data.

	latent heat	entropy change
<i>A</i> to <i>B'</i> transformation	4.0±0.3 kcal/mole	12.4±0.9 cal/deg. mole.
Melting	15.7±0.3	46.6±0.8

6b. Temperature factor. Temperature factor for phase *A* is taken to be 3.4 Å² (in the previous paper¹¹) and that for phase *B* is 5.3 Å² both at room temperature.

By comparing the powder photographs at different temperatures it was immediately noticed that although the lines for phases *A* and *B* are not greatly affected by the temperature change, the intensities of higher angle lines of phase *B'* decrease rapidly on elevating the temperature. Therefore our main concern was directed towards phase *B'*.

Now the observed intensity *I*(*T*) of the powder pattern at the temperature *T* will be expressed in the form

$$I(T)=I_0(T)\exp(-2B(T)\sin^2\theta(T)/\lambda^2),*$$

where *I*₀(*T*) is the intensity for a structure with atoms at rest at their equilibrium posi-

* The current notation *B* is used for the temperature factor. Their may be no fear of confusion with phase *B*

tions at the temperature *T*. In the present case *θ* does not change appreciably with temperature. Therefore, when the intensities of the powder lines having the same index are compared at different temperatures, say *T*₁ and *T*₂, and if *I*₀(*T*₁) and *I*₀(*T*₂) is the same, the temperature factor difference can be deduced. The powder pattern changes gradually from phase *B* to *B'*, and their intensity change can be followed throughout both phases. But, as the maximum attainable temperature difference is only about 40 degrees for each phase, an accurate result can not be expected.

Powder photographs were taken by ordinary powder camera with simple attachment to adjust the sample temperature. Multiple-film method was used and the photographic density of the film was measured visually and by the microphotometer. Exposure time for each temperature was kept constant, but owing to the fluctuation of the output of the X-ray source, resultant exposures could not be made quite the same. The correction was made in

the following way. When $\ln I(T_1)/I(T_2)$ are plotted against $\sin^2 \theta$, and extrapolated to $\theta=0$, it must be zero if the exposure is the same. If it differs from 0, a suitable correction factor is applied.

After the correction was made, $\ln I$ was plotted against the temperature. In the present case, not only I_0 changes with temperature, but also the lattice constant change. Ththerefore some lines overlap each other and some lines, overlapped at room temperature, separate into several lines on raising temperature. Data for these lines were omitted and those for very weak and very strong lines were omitted too. In this way among more than 35 lines observed in the powder photographs, only seven lines were selected. Logarithmic intensities of them were plotted against the temperature (Fig. 7). Even for these lines I_0 and the temperature factor B may change from line to line. However, Fig. 7 shows that $\ln I$ is linear against the temperature and have a knick near 60°C. The temperature factor difference between 60°C

and 20°C for phase B and that between 100°C and 60°C for phase B' are obtained for each line (Table VII). The mean values are 0.7 and 4.2 respectively. As the temperature factor of phase B is 5.3 at room temperature, that of phase B' exceeds 10 at 100°C.

Fig. 7. Variation of the relative intensities of the powder pattern against the temperature.

Table VII. Temperature factor differences.

Line	Bragg angle at room temp.	$B(60^{\circ}\text{C})-B(20^{\circ}\text{C})$	$B(100^{\circ}\text{C})-B(60^{\circ}\text{C})$
1.	13.8 degree	0.8 A^2	2.9 A^2
2.	19.2	1.3	2.9
3.	20.3	0.6	4.3
4.	22.1	0.7	5.6
5.	23.6	0.8	5.5
6.	25.6	0.7	
7.	28.1	0.5	
Mean		0.8	4.2

6 c. Thermal expansion.

Generally the thermal expansion of the crystal is closely related to the thermal vibrations of atoms in the crystal. Therefore from the results in §6b the large thermal expansion is expected for phase B' .

Lattice constants are measured for various temperatures. The volumes of the unit cell and the density are tabulated in Table VIII.

The mean volume expansion coefficients of phases A and B have the values of 5.8×10^{-4} and 5.1×10^{-4} respectively, as is usual for ordinary long chain compounds. On the other hand, the volume of the phase B' changes

irregularly and expand more rapidly at higher temperatures.

Table VIII. Volume of the unit cell and the density.

Phase	Tempera- ture	Volume of the unit cell	Calculated density
A	26°C	1702 A^3	0.997 g/cm ³
A	80	1756	0.966

B'	82	860	0.986
B'	86	876	0.968

§ 7. Proton Magnetic Resonance Absorption

Preliminary measurements of the proton magnetic resonance absorption were kindly performed by H. Komatsu. The method is almost the same as that used for the study

able motional narrowing occurs. In order to get the intermolecular contribution, the low temperature study seems to be very desirable.

Fig. 8. Thermal expansion.

of normal alcohol¹³. The line width (the peak to peak distance of the derivative of the resonance curve) is plotted against the temperature (Fig. 9).

In phase *A*, when the temperature is raised, a small central peak appears, but the peak to peak distance of the main line does not change up to the transformation. At the transformation point, the broad absorption line almost disappears and only the sharp peak is observed. This seems to correspond to the reorientation of the molecule at the transformation. In phase *B*, the line breadth almost remains constant up to the *B* to *B'* transformation point and then decreases appreciably above the transformation point, showing larger degrees of freedom in phase *B'* compared with that in phase *B*. In phase *B'*, the line breadth decreases gradually on raising the temperature. This corresponds to the large temperature factor shown in § 6 b. The second moment of phase *A* and *B* at the room temperature is 16 Gauss².

According to Andrew¹³, the second moment of the normal paraffin with carbon number *n* is $(18.5 + 19.1/(n+1)) + 7.8$ in so far as the molecule can be assumed to be rigid. The term in the bracket is the intramolecular contribution, and the last term is that of the intermolecular contribution. In the present case, intermolecular contribution of the phase *A* will be less than the ordinary parallel-chain configuration. But the observed value is less than the intramolecular contribution. Therefore, even at the room temperature, consider-

Fig. 9.

§ 8. Discussion of the Results

The fact that almost all the known crystal structures of the normal aliphatic compounds possess the parallel-chain configuration shows that the parallel-chain configuration has more stable van der Waals energy than that of the crossed-chain configuration. This point is already discussed by De Boer¹⁴. On the other hand, from the results of the infrared absorption, length and energy of hydrogen bond do not seem to differ for both phases. Where do the large latent heat and entropy change at *A* to *B'* transformation come from then?

One of the important contributions will be the thermal vibrations of the hydrocarbon

chain. As we saw in §6 and §7, thermal vibrations of the molecule increase remarkably in phase B' . Therefore, when phase A transforms to B' , molecular vibrations are excited abruptly, and the large entropy change is observed. Thermal vibrations in the crystal consist of the vibrations of the molecule as a whole and the internal vibrations. In ordinary molecules, the contributions of the internal vibrations to the temperature factor are very small. But in the long chain molecules, some modes of internal vibrations extend to the very low frequencies and contribute remarkably to the total temperature factor. According to Pitzer¹⁵⁾, if the hydrocarbon chain takes plane zigzag form, the lowest frequency band of internal vibrations corresponds to the out-of-plane vibrations of CH_2 groups and is extending from 0 to 220cm^{-1} . These vibrations cause the twisting of the molecule. The force constant of these twisting vibrations will be largely affected by the surroundings of the molecule, because the twisting is caused by the rotation around the C-C single bond and intramolecular force resisting this rotation is very weak. Now in the crystal structure of phase B shown in §3, twisting of the hydrocarbon chain is really observed at its equilibrium position. This means that intermolecular force to suppress the twisting is weak in this structure. Therefore, when temperature is raised, the twisting vibrations are excited and give the large temperature factor for phase B' .

The B to B' transformation has a special character that, at this transformation point, not the physical quantities themselves, but their temperature coefficients change. This phenomenon may have some relation to the melting of these normal aliphatic compounds. Internal vibrations of the molecule are affected by the packing of the molecule in the crystal. When the amplitude of thermal vibrations increases, the force packing the molecule at the equilibrium point will change, and when the amplitude becomes very large, the instability of the crystal lattice occurs. Explanation of the melting of the solid from this standpoint is already expressed by many authors¹⁶⁾¹⁷⁾ for ionic crystals. According to Lindemann the mean amplitude of vibrations at the melting point is 0.075 times the inter-

atomic distance, and Thompson found that the instability occurs when the increase in inter-ionic distance, as compared with that at 0°K , is between 6 and 7%. Although the binding force for the hydrocarbon chain is quite different from that for the ionic crystal, still it may be said that, when the amplitude of the thermal vibration reaches a certain extent, the melting occurs. When the way of packing is similar, the mode of internal vibration of the hydrocarbon chain having the same chain length will be similar for different compounds. Now, two molecules of amide are connected by the hydrogen bond and form a dimer. Therefore the chain length of the hexadecanamide roughly equals to $43\text{\AA}$. Other aliphatic compounds with the same length, for example palmitic acid (dimer) or *n*-tetratriacontane, melts near 60°C . Therefore, the crystal should become unstable at this temperature if only the van der Waal forces are taken into account. The B to B' transformation really occurs near this temperature. But, in the case of amide, the melting does not occur because the strong end group interactions connect molecules. The increase of the atomic vibrations above this point is naturally understood, however. The real melting occurs by the breaking of the hydrogen bond. This corresponds to the sudden disappearance of the N-H stretching frequencies in the infrared absorption spectra and to the large latent heat of fusion and seems to be consistent with the fact that the melting point of the amide depends neither on the carbon number nor the crystal structure.

On the other hand, for phase A , the way of packing of the hydrocarbon chain is quite different, and similar effect to the B to B' transformation does not occur. Thus the large entropy change due to the twisting vibrations occurs when phase A transforms to phase B' .

§ 9. Acknowledgements

Authors express their sincere thanks to Prof. Y. Kakiuchi for his kind guidance, Prof. H. Kambe for his aid for the differential thermal analysis, Mr. H. Komatsu for his aid in proton magnetic resonance absorption measurements and Prof. K. Kuratani for his advice in the measurement of the infrared absorption.

Variation of the Hall Coefficient of Mg-Cd Superlattice Alloys with Degree of Order

By Kiyoshi YONEMITSU and Takao SATO

Department of Physics Tokyo Metropolitan University Tokyo

(Received June 22, 1957)

Temperature dependence of Hall coefficient of three superlattice alloys of Mg-Cd system, Mg_3Cd , MgCd and MgCd_3 , was measured to find the effect of order-disorder transformation upon it. At the transformation temperature, the Hall coefficient of these alloys showed a discontinuous increase in positive direction, while the electrical resistivity, which was measured simultaneously, decreased discontinuously at that temperature.

It is discussed that the change of Brillouin zone structure due to the order-disorder transformation of these alloys might be considered to be the origin of such a change of the Hall coefficient.

§ 1. Introduction

It was suggested by Slater¹⁾ that electronic energy may play an important role in the order-disorder transformation of superlattice alloy, and from this point of view, qualitative discussion was made by Nicholas²⁾ about band structure of CuAu , CuPt , and Ag_3Mg . To proceed further along this line, it may be useful to know the information about the change of electronic structure when the order-disorder transformations of these alloys take place.

In 1938, Muto³⁾ has predicted that some change in Hall coefficient and magnetic susceptibility must be observed in the transformation. The prediction was proved to be true by Komar and Sidrov⁴⁾. They measured the Hall coefficient of Cu_3Au at room temperature

after quenching it from high temperature and found that a discontinuous change occurred when ordered state was formed. The same result has been obtained by present authors, who have measured Hall coefficient of Cu_3Au at varying temperatures. The authors are now trying to verify Muto's prediction about other superlattice alloys by the experiment of the Hall coefficient, and in this paper the results on three Mg-Cd superlattice alloys are presented.

§ 2. Preparation of Specimen, and Experimental Procedure

Purity of magnesium used in the present investigation was 99.97% and that of cadmium was 99.95%. They were alloyed in an iron crucible, and casted into a small plate 20 of

mm $\times$ 10 mm $\times$ 2 mm. They were homogenized in argon gas about 70 hrs at 300°C, and then polished by sand paper until they were 0.15 mm $\sim$ 0.5 mm in thickness. After the copper leads of 0.2 mm in diameter were spotwelded to the specimens, they were again annealed in argon atmosphere about 10 hrs to remove residual strain. The specimens were enclosed in quartz tubes with argon gas, then they were placed between the pole pieces of an electromagnet.

It is less difficult to measure the Hall coefficient of quenched specimen at room temperature than at higher temperatures, because of smaller parasitic thermoelectric potential due to the inhomogeneous temperature distribution in the specimen. The relaxation time of these alloys, however, are so short that the quenching method can not be used. Moreover, as they, especially Cd₃Mg, are easily corroded in the air, we were afraid that there were some damage by corrosion during the repetition of heating and quenching process.

A stabilized A.C. 100 volt source was used for the electric furnace, and the heater current was controlled by hand. The magnetic field strength given by an electromagnet was about 6 kG.

The circuit for measurement are shown in Fig. 1. The resistors R_1 and R_2 are con-

nected to two pairs of the Hall leads, which were made of manganin wire, the resistance of which were about 3 Ω , and each wire had a copper contact which were able to slide on them. The thermoelectric potential and the residual voltage drop that was not cancelled by R_1 and R_2 , could be compensated by Yokogawa Low Potential Type Potentiometer P_1 , which had resistance of 10 Ω when measured from X terminals. The out-put was lead to galvanometer G_1 (Yokogawa G-3C type, voltage sensitivity is 3×10^{-7} V/mm), and its deflection was amplified by twin phototube P and electronic amplifier, and was read by an out-put meter M_1 . The voltage sensitivity of this galvanometer-amplifier system was 1.5×10^{-8} volts per one division of out-put meter⁵⁾.

The leads which are denoted as ρ_1 , ρ_2 in the figure, were for measurement of electrical resistivity, and the out-put potential from them and the potential of Alumel-Chromel thermocouple were read by potentiometer P_2 and galvanometer G_2 . The primary current 1 amp. was given by a storage battery.

The measurement at every temperature was made with following procedure. At first the specimen was heated above the transformation temperature, then heater current was decreased a little. After the equilibrium temperature of the specimen had been reached, Hall potential and voltage drop were measured. The magnetic field was turned on and then off, and the difference of the potentials which were read at Hall leads in both cases, gave the Hall potential at that temperature. After a measurement had been done, the heater current was decreased again, and the same procedure was repeated. The cooling rate is given in Tables I, II and III.

§ 3. Results

The results of the measurement are given in Table I, II and III and Figs. 2, 3 and 4.

As the measurements were made at high temperatures, the temperature distribution in the furnace was easily disturbed, which caused the drift or fluctuation of parasitic thermoelectric potential to increase. In such cases, the measurement was repeated twice or three times, the results of which are shown in the columns that are denoted 1, 2 and 3 in the tables. The cooling rate is given in these tables, but in those temperature ranges where cooling rate is not shown in the tables, the

nected to two pairs of the Hall leads, which are denoted as H_1 , H_2 and H_3 , H_4 respectively in the figure, by which it was possible to balance the voltage drop in the specimen due to the primary current. Both the coil L , which is coupled with electromagnet magnetically, and resistor R_3 were used to compensate the e.m.f. which were induced in the secondary circuit by changing the strength of magnetic field. R_1 , R_2 and R_3 were made of

ature is below the transformation temperature, and ordering formation sets in, then Hall coefficient increases abruptly. After the transformation finished perfectly, the Hall coefficient of Mg_3Cd increased still a little with descending temperature. On the other hand, the Hall coefficients of MgCd and MgCd_3 were nearly constant.

It also must be supplemented that there were considerable fluctuations in the absolute values of measured Hall coefficient of the specimens which had the same concentration, though their temperature-dependences, signs and transformation-temperature were not so different from one another.

§ 4. Discussions

As was described in the preceding section, there were some fluctuations in absolute values of the Hall coefficient, though its reason is not clear at present. The metals from which these specimens were made, the method of alloying of these metals to the specimen and their heat treatment were all the same, and yet such fluctuation appeared, so it may be thought that there might be some delicate and unknown factor which causes these fluctuations. Nevertheless, the sign and temperature dependence of the Hall coefficient were quite similar for all specimens, so that it may be reasonable to conclude that the Hall coefficients of the superlattice alloys of $\text{Mg}-\text{Cd}$ system did change rather abruptly their magnitude toward positive direction during the transformation from the disordered to the ordered state.

Fig. 5. The Brillouin zone of h.c.p. structure.

In the disordered state, these alloys have h.c.p. structure and their 1-st Brillouin zone is, as is shown by Fig. 5, surrounded by these surfaces such as $\{100\}$ (surface A), $\{002\}$ (surface B), and $\{101\}$ (surface P) surfaces. In this zone

$$2 - \frac{3}{4} \left(\frac{a}{c} \right)^2 \left\{ 1 - \frac{1}{4} \left(\frac{a}{c} \right)^2 \right\}$$

electrons per atom are contained. If we add prisms which are surrounded by the surfaces such as {101}, {100}, we obtain the complete zone which can contain 2 electrons per atom. As the number of valence electrons of magnesium and cadmium are 2 per atom, the complete zone is nearly filled in the disordered state, and then there are some overlapping electrons in the next zone, the equal number of holes appearing in the complete zone.

The positions where the mentioned overlaps take place, can not always be decided geometrically by the distance from the position to the origin of the wave number space, for it is naturally expected that, when the Fermi surface approaches the zone boundary, the electronic behaviours can not be approximated by the free electron model, and thus the form of the Fermi surface will depart from sphere. We shall tentatively assume that the holes are present at the corners of the zone according to Reitz and Smith⁶⁾. The positions where the overlaps take place are rather speculative at present, and we shall be contented with examining the effect of the superzone in the ordered state upon these speculative overlaps, such as *Q*-overlaps in the equatorial plane, *P*-overlaps on the slant faces, and the *B*-overlaps at the bottom.

The number of valence electrons per atom of Mg₃Cd and MgCd₃ and also two, so that it may be thought that, in the disordered state, the number of electrons in the higher zone are equal to that of holes in the lower zone. Therefore, the positive Hall coefficients of these alloys in the disordered state may be considered to indicate the predominance of hole-mobility over electron-one in this state.

The discontinuous change of the Hall coefficient during the order-disorder transformation, predicted by Muto and first observed for Cu₃Au superlattice alloy by Komar and Sidrov, was ascribed to the effect of the new reflection planes in the *k*-space, which appear in the ordered state and are responsible for the superzone, upon the behaviour of the electrons of the Fermi surface.

In order to understand quantitatively the reason why the change occurs towards the positive direction, however, it is necessary to know the details of the electronic structure

such as the energy gaps at the zone boundaries, the form of the Fermi surface and the state density etc.. For example, if we adopt the two-band model, the Hall coefficient *R* may be expressed as

$$R = \frac{1}{ec} \frac{n_1 \mu_1^2 - n_2 \mu_2^2}{(n_1 \mu_1 + n_2 \mu_2)^2}$$

where *n*₁ and *n*₂ are the numbers of electrons and holes, and *μ*₁ and *μ*₂ are mobilities of electrons and holes, respectively. Without the knowledge of the variation of *n* and *μ* with the order-disorder transformation, we can hardly understand the reason why the Hall coefficient changes in the positive direction when the ordered state is formed. In the ordered state, as was already pointed out, we may reasonably assume that *n*₁=*n*₂, whereas, in the ordered state, this can no more be true, and, furthermore, *μ*'s must be varied too, on account of the appearance of the superzone. In view of the above situation, it is difficult to derive a decisive conclusion about the theoretical basis of the measured changes of the Hall coefficient from the data at hand; at present we only know the observed data of the variation of the Hall coefficient and of the arrangement of atoms in the ordered and disordered state, determined by the x-ray analysis, from which the corresponding Brillouin zone (B.Z.) is constructed in an ordinary method.

In the following paragraphs, therefore, we will suggest a few situations, which may serve as interpretations of the above described change of the Hall coefficient due to the ordering formation, mainly referring to the change of *n*₁ and *n*₂.

(1) Mg₃Cd

The ordered structure of Mg₃Cd is also h.c.p., but as shown Table IV, the axial ratio becomes half times of that of the disordered states, and the unit cell contains 4 atoms. Therefore, new reflection planes, which are absent in the disordered states, appear in the *k* space in the ordered state. Among the resulting superzones, those which modify the Fermi surface greatly and may give an important effect on the Hall coefficient, are shown in Fig. 6. In that figure, *Q* tetrahedra which appear at the position near the *Q* overlap, and pentahedra *P* which appear on the slant face *P* may play an important role in this case.

Table IV.

***) H. Steeple: Acta Cryst. 5 (1952) 247.

Tetrahedra *Q* are surrounded by those surfaces as {211}, {222} and {200}, each contains

$$\frac{3}{4} \frac{1}{(c/a)} \left\{ \frac{1}{2} \frac{1}{(c/a)} - \frac{2}{3} \left(\frac{c}{a} \right) \right\}^3$$

electrons per atom. In the case of Mg₃Cd, there are 9.3×10^{-4} electrons per atom, and this values seems to be too small to give any effect upon the Hall coefficient.

Fig. 6. The Brillouin zone of ordered Mg₃Cd and MgCd₃

P-type pentahedra are surrounded by those planes as {111}, {200}, {221}, {002} and {201}, and can contain

$$\frac{1}{9} \left\{ 10 + \frac{15}{8} \frac{1}{(c/a)^2} - \frac{4}{3} \left(\frac{c}{a} \right)^2 \right\}$$

electrons per atom. Mg₃Cd has 1.2 electrons per atom in these pentahedra. If these are overlapping electrons at point *P* to the next zone, it is natural to think that they may be contained in the pentahedra. If this is true, the mean energy of the overlapping electrons must increase a little because the distance from the origin of the *k* space to the overlaps increase a little; it is probable that this can be cancelled by the depression of the energy levels by the newly appeared reflection planes. It is not unreasonable to consider that the contribution of these pentahedra is such that

Hall coefficient increase in the positive direction in the ordered state, changing the mobility of overlapping electrons at *P*, although it is natural to think that some electrons in the pentahedra still contribute to the conduction as negative charges in the ordered state too and it is not clear how *P*-overlaps behave in the ordered state.

(2) MgCd₃

The crystal structure of disordered MgCd₃ is similar with that of disordered Mg₃Cd, but as can be seen from Table IV, its axial ratio is larger than that of Mg₃Cd. So that, in the case of disordered MgCd₃, we have electron's overlap at the bottom (B) of the B.Z., while there are no *Q* overlaps. In the ordered state, *c/a* decreases and becomes nearly equal with that of Mg₃Cd. Therefore, it is possible that a part or all of those electrons which overlap to the next zone at *B* in the disordered state,

Fig. 7. Orthorhombic structure of MgCd (from Ref. (7))

can be contained in the first zone in the ordered state. This may be thought as a chief contribution to the increase of Hall coefficient in the ordered state though a little contribution from those holes in the tetrahedra

at point Q , which appears in the ordered state, can be expected.

(3) MgCd

The ordered structure of MgCd, which was determined by Steeple⁷⁾, is orthorhombic structure as in shown in Fig. 7. Its B.Z. which contains two electrons per atom is given by slightly distorting B.Z. of h.c.p. structure. In Fig. 8, the cross section of B.Z. of orthorhombic MgCd on the equatorial plane is shown

Fig. 8. Cross-section of the Brillouin zone of ordered (broken line) and disordered (real line) of MgCd.

by broken line, while that of disordered MgCd is given by full line. From the figure, it can be seen that the B.Z. of the ordered MgCd is given by slightly contracting the B.Z. of disordered MgCd in the k_x direction, and expanding it in the k_y direction. This suggests that the Q overlaps in the $[110]$ direction,

Fig. 9. The Brillouin zone of ordered MgCd.

which is denoted as Q' , may increase, while the other Q overlaps, Q'' , decrease; and H'' holes increase. Such situation will contribute to increase the absolute value of Hall coefficient in the ordered state.

As can be seen from Fig. 9, the Q tetra-

hedra in the ordered Mg_3Cd and $MgCd_3$ appear only at point Q' in the case of ordered MgCd. Q' tetrahedra are surrounded by those planes as $\{101\}$, $\{10\bar{1}\}$, $\{111\}$, $\{1\bar{1}1\}$, and have volume which can contain

$$\frac{1}{3} \left\{ 1 + \left(\frac{a_1}{a_3} \right)^2 \right\} \left(\frac{a_3}{a_2} - \frac{a_2}{a_3} \right)^2$$

electrons per atom, which is 4.7×10^{-3} electrons per atom in the case of MgCd. As in the case of Mg_3Cd and $MgCd_3$, this may be too small to affect the Hall coefficient.

It may be presumed that P overlaps are distorted in the complicated way as in the case of Mg_3Cd , while B overlaps are not affected appreciably by the order-disorder transformation.

It seems to be not so far from the truth to assume that the main cause of the increase in Hall coefficient in the ordered state of MgCd will come from the following facts that the number of overlapping electrons at point Q'' decrease while H'' holes increase, and, further, a part or all of the Q'' overlaps are contained in the Q' tetrahedra in the ordered state, may chiefly contribute to the increase of the Hall coefficient by ordering formation.

§ 5. Conclusion

1. The Hall coefficient of Mg-Cd system superlattice alloys increased towards positive direction by ordering formation. 2. At least, the change can be partly explained by band model, assuming the distortion of Fermi surface by the appearance of superzone in the ordered state.

It also seems to be an interesting problem that h.c.p. structure of disordered MgCd is distorted and becomes orthorhombic in the ordered state, which seems to be able to be explained by assuming a contribution of electronic energy to such distortion. It is also necessary to notice about the temperature dependence of these alloys in the disordered state.

In order to proceed further, the following experiment must be necessary; to control the number of electrons by adding to these alloys the third elements which are mono-, tri-, and quadri-valent, and have nearly equal atomic size with magnesium and cadmium; to measure the anisotropy of Hall coefficient by single crystal.

Surface Photoconductivity of Cadmium Sulphide modified with Magnetic Field

By Shōji TANAKA and Taizō MASUMI

*Department of Applied Physics, University of Tokyo,
Tokyo, Japan*

(Received April 13, 1957, Revised July 17, 1957)

An experiment on the changes of photocurrent in cadmium sulphide single crystals in magnetic field was performed. The results obtained are as follows; the changes of photocurrent by magnetic field are dependent on the strength of electric and magnetic fields which are parallel to the illuminated surface and are perpendicular to each other, and the changes are also dependent on the frequency of the alternating electric field, the wavelength of illuminating light and on the ambient atmosphere, while these changes are independent of the intensity of illuminating light. Some theoretical treatments based on the phenomenological theory of surface recombination are proposed with these experimental results, and they seem to give some informations about surface recombination of cadmium sulphide single crystals.

§ 1. Introduction

A large number of investigations on the surface recombination of electrons and holes in semiconductors have been reported already, especially in germanium, as related with some surface properties. Suhl effect, contact potential difference, surface conductance, noise, photoelectromagnetic effect, and field effect were studied in details. These phenomena suggest that the surface traps act as recombination centers of electrons and holes, and the effective carrier mobility in the space charge layer is slightly different from that of electrons in the volume.

The existence of surface photoconductivity in cadmium sulphide and zinc sulphide has been investigated by Bube¹⁾, and it is found that the presence of water vapour decreases

both the photosensitivity and time constant for exciting wavelength shorter than the absorption edge of CdS. On the assumption that the conductivity of surface region is less than that of the volume in the absence of water vapour, he explained these results presenting a model, where the presence of water vapour increases the conductivity of the surface, thereby increasing the recombination rate for electron-hole pairs generated at the surface. Liebson²⁾, and Tanaka and Aoki³⁾ emphasized also the influence of a change in barrier height on the photoconductivity and other properties. We have previously reported the change of surface-excited photocurrent of CdS in magnetic field⁴⁾. Though Moss and Pincherle⁵⁾, Aigrain and Bulliard⁶⁾ have investigated the photoelectromagnetic effects in

germanium and lead sulphide and studied recombinations of electrons and holes in these semiconductors and Sommers et al.⁷⁾ observed the similar effect in CdS, the observed phenomena in our experiment seem to be different from the other effects mentioned above, and it may be preferable that they are considered as the effects of the surface recombination decreased or increased by magnetic field. These effect also might be closely related to the observation of surface life time by Bube⁸⁾. We present here the general description and some physical considerations about the experiments of these phenomena.

§ 2. Experimental Method

The outline of the experimental arrangement is simple as shown in Fig. 1; a, b schematically. Samples used in this experiment are thin flakes of hexagonal cadmium sulphide single crystals produced by Frerichs' method,⁹⁾ which are about the size of $10\text{ mm} \times 3\text{ mm} \times 0.05\text{ mm}$. Nearly all the samples are of pure type prepared without doping and treated neither physically nor chemically. The distance between the evaporated metal electrodes is 0.2 mm . The specimens are set on a blackened glass sheet by metal spring. For the measurement in vacuum, this glass

Fig. 1. Schematic experimental arrangement.

Fig. 2. Glass tube enclosing the sample.

sheet was enclosed in a glass tube as shown in Fig. 2 through the window of which one surface of the sample is illuminated by the focalized monochromatic lights of $436\text{ m}\mu$ and $546\text{ m}\mu$ in wavelength, the former wavelength lies in the strong absorption region and the latter in the long wavelength tail of the absorption edge of CdS at room temperature. It seems to be important that the homogeneity of the intensity of illumination should be kept constant all over the surface of the

sample. As shown in the following section, absolute intensity of the illuminating light has little meaning, then, its measurement is replaced by that of the photocurrent under the constant electric field, and in this experiment the highest intensity corresponds to $70\text{ }\mu\text{A}$ in photocurrent at most in the electric field of about $8 \times 10^3\text{ volts/cm}$. The applied electric fields are static or alternative sinusoidal ones sufficiently stabilized, and their maximum magnitude is 10^4 volts/cm in static

field and 7.5×10^3 volts/cm in alternative field respectively, the frequency range of the latter extends from 25 cps to 5 kc/s. In the latter case, the alternating photocurrent are measured by reading the positive peak voltage across the connecting resistor. For the measurement of the changes of photocurrents in both cases, the low potential end of the sample is connected to ground through a low impedance resistor, the voltage across which was measured with a difference amplifier. The magnetic field used in the present experiment is static one, the strength of which varies from 0 to 8×10^3 gauss. The effective field area is sufficiently large to ensure the homogeneity of field around the specimen.

Thus, as shown already in Fig. 1, a sample is illuminated on one surface by light at room temperature and the applied electric and magnetic field are set to be parallel to this surface and perpendicular to each other where the direction of magnetic field is taken to be parallel to that of c-axis in hexagonal cadmium sulphide single crystals. When the magnetic field is applied, the photocurrent of CdS single crystal increases or decreases according to the directions of the fields.

§ 3. Experimental Results

The experimental results were mainly represented as the ratio of the changes of photocurrent in a magnetic field $(\Delta I)_H$ to the magnitude of photocurrent I , i.e., $(\Delta I)_H/I$, and we have observed some dependences of $(\Delta I)_H/I$ upon the several variables; strength of applied electric and magnetic fields, intensity of illuminating light or photocurrent corresponding to it, frequency of alternative electric field, wavelength of illuminating light, and ambient atmosphere.

The photocurrents of CdS single crystal decrease or increase according to the positive or negative sign of the product of applied electric and magnetic fields ($\mathbf{E} \times \mathbf{H}$) in the coordinate system chosen in Fig. 1. The positive sign of the product of electric and magnetic fields ($\mathbf{E} \times \mathbf{H}$) such that the flowing current carriers in the crystals are deflected towards the illuminated surface reduces the photocurrent, and the inversion of magnetic field shows a quite equivalent effect to that of electric field.

At first, in order to observe the dependence of $(\Delta I)_H/I$ upon electric field, the field-photo-current relation for static field was studied with constant illumination of blue light (436 m μ in wavelength) in air. Though the observed relations show slight differences with intensity

Fig. 3. The electric field-photocurrent relation for static field in air.

Fig. 4. Dependence of $(\Delta I)_H$ upon electric field (in air).

of illuminating light, they have, in general, considerably good linearities as shown in Fig. 3. The changes of photocurrent $(\Delta I)_H$ in a constant magnetic field ($H=7100$ gauss) under the same conditions have a parabolic dependence on the magnitude of electric field for the range from 0 to 10^4 volt/cm as presented in Fig. 4. Therefore, we obtain a linear relation between $(\Delta I)_H/I$ and applied electric field E as in Fig. 5. This is a fundamental relation throughout the present experimental results.

Fig. 5. Dependence of $(\Delta I)_H/I$ upon electric field (in air).

When the magnetic field strengths are varied under the same conditions with a fixed, the relative change of photocurrent $(\Delta I)_H/I$ increases or decreases proportional to the strength of the magnetic field H as shown in Fig. 6, where the electric field is about 10^4 volts/cm, and the photocurrent of $45.9 \mu A$. Furthermore, the observed result of similar dependence of $(\Delta I)_H/I$ on the intensity of illuminating light or on the equivalent photocurrent itself corresponding to the intensity are illustrated in Fig. 7 under the same conditions with a fixed electric and magnetic fields ($E=8 \times 10^3$ volts/cm, $H=70000$ gauss), and it is found that the changes of photo-

current are linear to I itself so $(\Delta I)_H/I$ are nearly independent on the intensity of illuminating light in the range of the present experiment in which the photocurrent is at most $71 \mu A$ with the electric field of about 8×10^3 volts/cm.

Fig. 6. Dependence of $(\Delta I)_H/I$ upon magnetic field (in air).

Therefore, putting together these results, the following expression may be probable for our observations

$$(\Delta I)_H/I = \mp CEH \tag{3.1}$$

where C is a constant dependent on some external and internal factors but independent of the intensity of illuminating light and its experimental value was observed to be 10^{-9} (cm/volt. gauss) in some samples. If the sample is illuminated by the green light ($546 \text{ m}\mu$ in wavelength) longer than the absorption edge, the values of $(\Delta I)_H/I$ are smaller by a factor of ten at least under the same conditions as illustrated in Fig. 6 as an example, though the general features of the results seem to be similar to the case of the blue light.

These amounts of $(\Delta I)_H/I$, however, have considerable fluctuations from sample to sample, and the fluctuations might be caused

by some sensitive properties included in the constant C in the equation (3.1). Similar experiments carried out in vacuum of $10^{-2\sim 3}$ mmHg for the blue light present a few informations relating to these considerations.

certain fixed frequency excepting that the electric field dependence of $(\Delta I)_H/I$ are slightly deviated at low field region (Fig. 9). To observe the relaxation effect, the dependence of $(\Delta I)_H/I$ on the frequency was studied

Fig. 7. Dependence of $(\Delta I)_H$ upon light intensity or photocurrent (in air).

As shown in Fig. 8, general tendencies of these phenomena are kept to be almost unchangeable from those of in air though the electric field dependence in Fig. 8 shows a slight deviation from the general relation in the high field region and the absolute value of C decreases to about three-fourth of the initial value in air. Besides, it is a very interesting fact that the photocurrents for the blue light differ between in air and in vacuum for the same conditions, and seems to suggest the existence of surface photoconductivity.

In the preceeding experiments, we used the static electric field, but the further experiment was performed under the application of sinusoidal alternating electric field and static magnetic field in order to indicate the relaxation effects, that are observed under relatively low frequencies. According to the measurement corresponding to the static case, the equation (3.1) are also maintained for a

Fig. 8. Comparison of electric field dependences between in air and in vacuum.

Fig. 9. Dependence of $(\Delta I)_H/I$ upon alternative electric field (in air) ($f = 30$ cps).

keeping the amplitudes of the alternating fields at a fixed value, for example 7.5×10^3 and 5×10^3 volts/cm respectively, over the frequency range from 25 cps to 5 Kc/sec. A typical example of the experimental results is illustrated in Fig. 10 and indicates that the relaxation effects for the alternating field of 7.5×10^3 volts/cm appear even below 300 cps,

and the effects of static magnetic fields are not observed in the frequency range above 2 kc/s, while the photocurrent is nearly independent of the frequency of the electric field in this region. For the smaller field strength of 5×10^3 volts/cm, the relaxation

effect seems to appear in the lower frequency range than for the higher field strength, but this behaviour still involves some experimental ambiguities. These results, however, will present some knowledge on the relaxation effect.

Fig. 10. Dependence of $(\Delta I)_H$ upon frequency of alternating electric field (in air).

In short, it may be concluded that the relative changes of photocurrent in a magnetic field $(\Delta I)_H/I$ generally depend on the electric and magnetic field strength proportionally and do not depend on the intensity of illuminating light under nearly all conditions. Then, in the range of our observation, the experimental expression of the equation (3.1) must be valid in nearly all cases, though the value of constant C varies with the frequency of electric field, the wavelength of illuminating light and the other external conditions such as humidity in air, etc. For example, the value of C is 1.25×10^{-9} (cm/volt. gauss) in static case for the blue light in air, and smaller by a factor of ten at least for the green light under the same condition. These complicated factors which have considerable fluctuations from sample to sample, may result from the some sensitive properties inherent to these phenomena.

§ 4. Discussions

It may be expected that there are several

possible interpretations about the experimental results in the preceding section. Then, we describe here some qualitative discussions and present a detailed treatment in the following section.

Fig. 11. Schematic figure of photoelectromagnetic effect.

In regard to these effects that rise from the behaviours of photoelectrons in a external magnetic field, the closely related phenomenon seems to be the photoelectromagnetic effect that are observed in germanium and lead sulphide. The photoelectromagnetic effect is understood as the phenomenon specified in Fig. 11 by Moss and Pincherle and others,^{(6), (7)} and the short-circuited current in

this effect is expressed as follows,

$$(I_s) = \frac{\eta Q e B}{l} \{ \mu_e (D_e \tau)^{1/2} + \mu_h (D_h \tau)^{1/2} \} \quad (4.1)$$

where Q is the number of photons absorbed at the surface of the sample (quanta/sec), η quantum efficiency, l dimension of the sample, B magnetic flux, e electronic charge, μ_e , μ_h ; D_e , D_h , mobilities and diffusion constants of electrons and holes, respectively, excited at the surface, τ life time. However, this short-circuited current may be produced when no external electric field is applied, and even if it were superposed on the photocurrent I , (I_s) would have the opposite signs to $(\Delta I)_H$ involved in the equation (3.1) for the same directions of magnetic field. These circumstances suggest that it is difficult to adopt the photoelectromagnetic effect for the explanation of the present experiment, although it was recently observed in insulating CdS crystal by Sommer et al.⁷⁾

In any case, however, it is considered that the relative changes of photocurrent expressed by the equation (3.1) are due to the changes in total number of photoelectrons N or the changes in mobility μ_e due to the surface scattering. The quadratic dependence of $(\Delta I)_H$ upon the electric field with a fixed magnetic field and light intensity (Fig. 4) also suggests it to be probable that only the

important factor in some cases. The experimental results expressed in section (3), however, show that the value of constant C in the equation (3.1) for the wavelength shorter than the fundamental absorption edge is much larger than that of the longer wavelength tail in absorption edge. Bube⁸⁾ also has shown an evidence that the free electron life time for surface excitation is smaller than the life time for volume excitation, because of a higher rate of recombination at the surface. These facts suggest a particular significance of surface recombination at the illuminated surface for the present experiment.

Surface recombination is primarily determined by the density of charge carriers at the surface, and then the change of this quantity seems to be exclusively responsible for the observed phenomena. If we take the coordinate system as shown in Fig. 12, x , the direction of electric field E ; y , the direction perpendicular to the illuminated surface, z , that of magnetic field, the concentration of distributed carriers $n(y)$ is independent on x and z under the present condition. When we apply magnetic field H , $n(y)$ varies according to the transverse effective electric field $\mu E H / c$ due to the deflection of moving carriers and also does the concentration at the illuminated surface $n(0)$. Therefore, the rate of surface recombination must be modified which results the change of N , and also photocurrents themselves, although the surface recombination velocity has a fixed value. This interpretation seems to be considerably plausible, and the more detailed phenomenological treatment of these phenomena based on it will be proposed in the following section with regard to the experimental results.

Fig. 12. Concentration of electrons near the surface.

changes of N must be responsible for the change of photocurrent. Such considerations lead us to a following interpretation, based on the surface recombination of photoelectrons and holes at the illuminated surface.

Recombination of electrons and holes generally occurs in the volume and surface, and as bulk recombination is not always negligible, the change of N due to it might be an im-

§ 5. Phenomenological Theory based on Surface Recombination

For the analytical consideration of the experimental results in the section (3), some equations must be introduced that are well-known as the "current" equation and others under a few assumptions. The definitions of the symbols used throughout this section are as follows;

- n ; concentration of photoelectrons (cm^{-3}),
 τ_n ; life time of excited electrons in bulk (sec),
 s ; surface recombination velocity (cm/sec),
 e ; positive charge of one hole, absolute value of electronic charge (coulomb),
 κ ; absorption coefficient of semiconductor (cm^{-1}),
 Q ; illumination intensity in quanta ($\text{cm}^{-2} \text{sec}^{-1}$),
 D_n ; diffusion constant of electron (cm^2/sec),
 μ_n ; mobility of electron ($\text{cm}^2/\text{volt sec}$),
 I_n ; charge current flow by electrons (ampere),
 E ; total electric field (volt/cm),
 E_s ; electric field due to the spatial distribution of charge carriers themselves (volt/cm),
 E_t ; transverse effective electric field produced by application of magnetic field (volt/cm),
 v_t ; transverse drift velocity of electron (cm/sec),
 H ; magnetic field (gauss),
 N ; total number of electrons per unit surface area (cm^{-2}),
 A ; concentration of electrons at the illuminated surface (cm^{-3}),
 α ; parameter representing the distribution of electrons (cm^{-1}),
 d ; depth of specimens.

If we take such definitions and adopt some assumptions with them, we can show a trial treatment for the experimental results. The assumptions involved in this consideration are as follows. (1) The concentration of carriers is sufficiently small that the "current" equation based on the diffusion theory is valid and the electric field is also small enough, so that it does not introduce any non-linear term of E into the current equation. (2) The photoelectrons excited by photons are completely free from electron-traps in the volume except direct recombination with trapped holes, while all the positive holes are almost immobile, that is, they have small diffusion length nearly equal to zero. (3) The distributions of photoelectron density may be considered to have the following form in all region,

$$n(y) = Ae^{-\alpha y} - \frac{Q}{D_n \kappa} e^{-\kappa y}$$

that approximate to

$$n(y) = Ae^{-\alpha y}$$

with κ of sufficiently large value,¹⁰⁾ and the similar expressions are valid even in the presence of magnetic field.* (4) Surface recombination velocity s assumed to be dependent upon only the concentration of trapped holes at the illuminated surface and their capture cross section for electrons accepts no modification by magnetic field, because all positive holes are immobile and the change in surface barrier height is not emphasized. Furthermore, the absolute value of s is sufficiently large that the condition $s \gg v_t$ is valid, i.e., the modification of surface recombination of carriers by magnetic field is also small. (5) The generation of carriers excited by illumination must keep a balance with the recombination in bulk and surface in steady state, then, the expression

$$Q = \frac{N}{\tau_n} + sA$$

holds. (6) Mobility of photoelectron shows no change by magnetic field, so the changes of total number of electrons N are exclusively responsible for those of photocurrents, and the difference between Hall and drift mobility is also neglected.

The current equation for photoelectrons assuming the small density of carriers (assumpt. (1)) is given by

$$I_{nz} = e\mu_n n E_x + eD_n \nabla n \quad (5.1)$$

In the configuration of electron distribution in stationary state shown in the Fig. 12, this equation is induced to the following forms

$$\begin{aligned} I_{nz} &= e\mu_n n E_x \\ I_{ny} &= e\mu_n n E_y + eD_n \frac{dn}{dy} \\ I_{nz} &= 0 \end{aligned} \quad (5.2)$$

where E_x is the externally applied field and E_y is

$$E_y = E_{sy} + E_{ty} \quad (5.3)$$

and

$$E_{ty} = \theta_n E_x = \frac{\mu_n E_x H_z}{c} \quad (5.4)$$

is the transverse effective electric field due to the magnetic field. But, here, we are

* Refining for more satisfactory form based on the diffusion theory of charge carriers will be discussed elsewhere.

particularly concerned with the y -component of them because of the importance of the changes of E_y and therefore the modification of $n(y)$ by magnetic field.

According to the assumption (3), $n(y)$ is expressed as follows

$$n(y) = Ae^{-\alpha y} \quad (5.5)$$

and α may be supposed to be enough large compared with $1/d$ so that the specimen depth d is equivalent to infinity for the specimen illuminated by the blue light.

(1) In the Absence of Magnetic Field (specified with suffix "0")

In the absence of magnetic field, the current equation and other expressions above, specified with suffix "0", are

$$I_{ny0} = e\mu_n n_0 E_{sy0} + eD_n \frac{dn_0}{dy} \quad (5.6)$$

$$n_0(y) = A_0 e^{-\alpha_0 y} \quad (5.7)$$

Supposing the fixed surface recombination velocity s at the illuminated surface even in the absence of magnetic field, we have

$$I_{ny0}(0) = esn_0(0) \quad (5.8)$$

as the boundary condition at the illuminated surface. These equations are equivalent to

$$\mu_n E_{sy0}(0) - D_n \alpha_0 = s \quad (5.9)$$

or

$$\alpha_0 = \frac{\mu_n E_{sy0}(0) - s}{D_n} \quad (5.10)$$

where D_n may be also written using the Einstein relation

$$\mu_n = \frac{e}{kT} D_n \quad (5.11)$$

Furthermore, total number of photoelectrons per unit area of surface in xz -plane may be given as follows

$$N_0 = \int_0^\infty n_0(y) dy = \frac{A_0}{\alpha_0} \quad (5.12)$$

by integrating the eq. (5.7) for the specimen illuminated by the blue light.

(2) In the Presence of Magnetic Field (specified with suffix "1")

The current equation of this case modified by the transverse electric field E_{ty} and other similar expressions with those in the case (1) are assumed to be valid even in the presence of magnetic field.

$$I_{ny1} = e\mu_n n_1 (E_{sy1} + E_{ty}) + eD_n \frac{dn_1}{dy} \quad (5.13)$$

$$n_1(y) = A_1 e^{-\alpha_1 y} \quad (5.14)$$

If we suppose the same surface recombination velocity s with that in the case (1) in the presence of magnetic field (assumpt. (4)), the boundary condition in this case gives

$$I_{ny1}(0) = esn_1(0) \quad (5.15)$$

hence

$$\mu_n \{E_{sy1}(0) + E_{ty}\} - D_n \alpha_1 = s \quad (5.16)$$

or

$$\alpha_1 = \frac{\mu_n \{E_{sy1}(0) + E_{ty}\} - s}{D_n} = \frac{\mu_n E_{sy1}(0) - v_t - s}{D_n} \quad (5.17)$$

where

$$v_t = -\mu_n E_{ty} = -\mu_n \theta_n E_x = -\frac{\mu_n^2 E_x H_x}{c} \quad (5.18)$$

is the transverse drift velocity of electron, and the total number of photoelectrons per unit surface area may be similarly given by

$$N_1 = \int_0^\infty n_1(y) dy = \frac{A_1}{\alpha_1} \quad (5.19)$$

for the same specimen.

Then, we should consider a balance between the generation and the recombination of electrons in a stationarily illuminated state. Hence,

$$Q = \frac{N}{\tau_n} + sA \quad (5.20)$$

holds according to the assumpt. (5). As the specimen is illuminated under a constant intensity of light, we have the following expressions with the same Q and s , τ_n corresponding to the both cases.

$$Q = \frac{N_0}{\tau_n} + sA_0 \quad (5.21)$$

$$Q = \frac{N_1}{\tau_n} + sA_1 \quad (5.22)$$

Thus, these equations result in

$$N_1 - N_0 = \frac{A_1}{\alpha_1} - \frac{A_0}{\alpha_0} = s\tau_n (A_0 - A_1) \quad (5.23)$$

or

$$\frac{A_1}{A_0} = \frac{1 + s\tau_n \alpha_0}{1 + s\tau_n \alpha_1} \cdot \left(\frac{\alpha_1}{\alpha_0} \right) \quad (5.24)$$

Suppose that there is no modification to the mobility μ_n of photoelectron by magnetic field (assumpt. (6)), the equation

$$\frac{(\Delta I_{nx})_H}{I_{nx}} = \frac{N_1 - N_0}{N_0} = \frac{\frac{A_1}{\alpha_1} - \frac{A_0}{\alpha_0}}{\frac{A_0}{\alpha_0}} - 1 \quad (5.25)$$

is valid for the change of photocurrent $(\Delta I_{nz})_H/I_{nz}$, and, whereas the quantities A_1/A_0 , α_1 , α_0 are easily given from the eq. (5.10), (5.17), (5.24) and $\mu_n\{E_{sy}(0) - E_{sy1}(0)\}$ may be considered to be much smaller than v_t , this leads to

$$\frac{(\Delta I_{nz})_H}{I_{nz}} = \frac{s\tau_n(\alpha_0 - \alpha_1)}{1 + s\tau_n\alpha_1} = \frac{s\tau_nv_t}{s\tau_n\{\mu_n E_{sy}(0) - v_t - s\} + D_n} \quad (5.26)$$

Furthermore, in the case to which we may impose some conditions based on the assumpt. (4) and neglect v_t and $D_n/s\tau_n$ in the denominator comparing with s , a more simplified form may be obtained

$$\frac{(\Delta I_{nz})_H}{I_{nz}} = \frac{v_t}{\mu_n E_{sy}(0) - s} = -\frac{\mu_n^2}{\mu_n E_{sy}(0) - s} \cdot E_x H_z \quad (5.27)$$

where c is the light velocity introduced in the eq. (5.18) for the absolute unit system of electric and magnetic fields while it takes the value of 10^8 for the practical unit system (volt/cm, gauss), and the sign of right side is determined from the combination E_x , H_z directions.

The eq. (5.27) is a suitable expression for a qualitative explanation of the present experiments, and the experiment conditions for the blue light ($\kappa \sim 10^6 \text{ cm}^{-1}$) with static electric field satisfy the adopted assumptions almost completely, while these are not the case for other cases. Then, finally, we can obtain the following relation comparing the eq. (5.27) with the eq. (3.1) in this case

$$s = \mu_n E_{sy}(0) - \frac{\mu_n^2}{Cc} \quad (5.28)$$

The experimental value of C for the blue light with static electric field given in the section (3) being the order of $1.25 \times 10^{-9} \text{ (cm/volt, gauss}^{-1})$ with one of samples, the value of s may be expressed as a function of μ_n

$$s = \mu_n E_{sy}(0) - 10\mu_n^2 \quad (5.29)$$

involving the parameter $E_{sy}(0)$ that must be properly chosen from other physical considerations. Hence, these results seem to suggest us that the value of s is the order of $10^4 \sim 10^5 \text{ (cm/sec)}$ provided that $\mu_n = 100 \sim 150 \text{ (cm}^2/\text{volt} \cdot \text{sec})^{11)}$ and $E_{sy}(0) = 1200 \sim 2000 \text{ (volt/cm)}$.

The obtained value of surface recombination velocity s is relatively larger than the ordinary observed value in some semiconductors.^{12), 13)}

The phenomenological treatment based on surface recombination in this section, however, is related to the so-called surface monolayer of illuminated surface, and compels us to consider that all the surface recombinations are due to this monolayer because of the importance of the boundary conditions in the treatment. The surface region effective to the recombination has a small but finite depth in fact and $n(y)$ is not always a satisfactory form. The treatment also involves some other assumptions, then, it is not improbable that s obtained from this treatment has such large values even if we properly select the arbitrariness in μ_n and $E_{sy}(0)$. For the green light, κ of which are much small, some of the assumptions become no longer valid and the treatment must be considerably modified.

The ambiguous points in this treatment lie in the following fact that we have neglected the changes in surface barrier height due to the surface states and the changes in effective carrier mobility by magnetic field. If we take account of the surface barrier height, the treatment will be slightly complicated. But, even in such case, the corresponding results would be scarcely modified from that of the present treatment, as the surface barrier due to the surface states would be lowered by the illumination of light⁹⁾. Though the second problem is also considerably important and some suggestions may be given by Schrieffer's theory¹⁴⁾, we have no detailed informations about this problem.

Finally, if we may regard these effects as the small ones of second order because of the small magnitude of the effective transverse electric field due to the magnetic field, it may be concluded that the changes of photocurrents are able to be explained in the terms of surface recombination modified with magnetic field. In addition, the dependence of $(\Delta I)_H/I$ upon the frequency of the alternating electric field would give some contributions to the kinematic properties of surface recombination. But, further detailed treatment based on the concepts of imperfection and surface state will be necessary for the more obvious interpretation of these phenomena.

§ 6. Summary and Conclusions

The observed phenomena in the present

experiment show many kinds of behaviours of photoelectrons and holes in cadmium sulphide single crystals, but, though these phenomena are complicated with other, we can express the summarized conclusions as follows.

(1) The relative changes of photocurrents of cadmium sulphide single crystals in a magnetic field are experimentally characterized by the equation (3.1).

$$(\Delta I)_H/I = \mp CEH$$

and, for instance, the value of constant C for the blue light ($\lambda=436\text{ m}\mu$) is the order of 10^{-9} (cm/volt. gauss $^{-1}$) for a sample and generally dependent on some sensitive properties of the illuminated surface.

Similar experiment for the alternative electric field presents some knowledges about the relaxation effect in these phenomena that rises in comparatively low frequency region.

(2) The phenomenological treatment of modified surface recombination in a magnetic field based on the diffusion theory of charge carriers seems to present a considerably plausible interpretation for the experimental results of surface-excited photoconductivity under several assumptions.

§ 7. Acknowledgments

The authors would like to express their sincere gratitudes to Professor Y. Suge and Professor T. Inui of Tokyo University for

their continual encouragements and to Professor Y. Uemura of Tokyo University and Dr. H. Miyazawa of Matsuda Research Laboratory of Tokyo-Shibaura Electric Company for their suggestive discussions. They are also indebted to Dr. S. Iijima of the Electrotechnical Laboratory for his co-operative works.

Electron Spin Resonance of M centers in Potassium Chloride

By Hazimu KAWAMURA and Keiko ISHIWATARI

Department of Applied Physics, Osaka City University, Osaka

(Received August 7, 1957)

An experiment on the electron spin resonance of colored KCl containing F and M centers was performed at 9500 Mc/sec. Subtracting the contribution from the F centers from the observed resonance curve, we could estimate the shape of the resonance line due to M centers alone, which was found to be Gaussian with the half-breadth of 48 oersteds and g value of 2,000. This result was discussed on the LCAO model.

§ 1. Introduction

The spin resonance absorption of F center in alkali halide has been measured by several authors^{1),2),3),7)}, and it is found that the absorption line is rather broad, being Gaussian in shape and independent of temperature. Kip *et al.*²⁾ have attributed this broadening to the hyperfine interaction between the F center electron and the nuclear magnetic moments of the neighboring ions. They could estimate the density of the electron cloud of F center at these nuclei from the observed line breadth. This interpretation was well confirmed when nineteen lines were separated for LiF and NaF by Lord³⁾.

The next common and well studied center in colored alkali halide is M center. Seitz has proposed the model of M center as composed of two negative ion vacancies and one positive ion vacancy, with an electron being attached as shown in Fig. 1. The optical absorption

Fig. 1. Schematic model of M center. Squares are the positive or negative ion vacancies. Numbers show the position of K ions, 5 being in the plane of paper, 1 and 3 above, and 2 and 4 below it.

peak for this center lies at 1.5 eV for KCl as shown in Fig. 3, while that of F center is found at 2.2 eV at room temperature. The electron cloud of M center may spread as that

of F center and will have a broad and structureless line for electron spin resonance just as F center at least for KCl. Moreover the M center is always accompanied by F center, and hence we shall have the two broad lines superposed.

We have carried out an experiment with additively colored crystals of potassium chloride. The M centers were produced by irradiating the quenched crystal with F light. The density of M centers was about 0.4 times that of F centers, which was the highest attainable relative value for the former. The shape of the resonance line was found by subtracting the contribution from the F center.

Although the definite conclusion cannot be drawn from this broad line, it will nevertheless afford some criterions about the electronic structure of M center.

§ 2. Experiment

The spin resonance measurements were performed by an equipment as shown in Fig. 2. The frequency at which these experiments were made was about 9500 Mc/sec and the corresponding field was 3500 oersteds. The microwave source was 2K25 reflex klystron having the output power of 40 mW. The microwave power was fed to a rectangular cavity operated at TE 101 mode through the coaxial cable. The transmitted power was detected by a 1N23 crystal. The magnetic field was modulated at 455 Kc/sec, where the crystal noise is much less than at the conventional frequencies of some fifty cycles. But since the alternating magnetic field of such a high frequency is unable to penetrate into the cavity, a coil of few turns was wound directly around the specimen and set on the end surface of the cavity. The absorption signal

detected by the crystal was fed to three stage resonant amplifier operated at 455 Kc/sec and then detected by a phase sensitive lock-in detector.

Fig. 2. Block diagram of electron spin resonance apparatus.

The specimens were the single crystals of potassium chloride which were additively colored at 580°C in potassium vapor. The small pieces of 8×4×2 mm. cut from these crystals were heated at 500°C for one minute and then quenched on a copper block. The optical absorption spectrum of this specimen

has a typical *F* absorption band as shown with curve 1 in Fig. 3. Assuming the oscillator strength to be 0.81, the density of the *F* centers is estimated to be $5.6 \times 10^{17} \text{ cm}^{-3}$. The

Fig. 3. Optical absorption spectra of colored KCl. Curve 1; quenched from 500°C. Curve 2; irradiated with sodium lamp for 5 minutes after quenching. Curve 3; irradiated for 30 minutes.

other specimens were then irradiated at room temperature with a sodium lamp whose line spectrum is at 2.1 eV and hence just within the *F* band. The *M* band grows as shown in curve 2 and 3 by this treatment. When the time of irradiation is as short as five minutes, we observe only *M* and *F* bands as shown by curve 2. If, however, the irradiation is continued half an hour, *R*₁ and *R*₂ bands come out between *F* and *M* bands as in curve 3. Since Okura* find the oscillator strength of *M*

Table I.

Specimen	ΔH in oersteds		<i>g</i>	N_M/N_F	
	peak to peak	half breadth		optical	spin resonance
1	49.5	58.5	1.994	0	0
2	46		1.996	0.31	0.36
3	45		1.997	0.41	0.46
<i>F</i>	49.5	58.5	1.994		
<i>M</i>	40.5	47.5	2.000		

center to be about 0.42 times that of *F* center, the density of *M* centers of these specimens can be estimated as in Table I.

The spin resonance measurements were performed with these three specimens which we shall call 1, 2 and 3 in accordance with the numbering of the absorption curves in Fig. 3. An example of the resonance curve recorded

on a chart is shown in Fig. 4. The sharp line

* H. Okura, to be published in this Journal. If the irradiation is not so heavy, the intensity of *M* band increases in proportion with the decreases of the *F* band. He estimates the ratio of the oscillator strength comparing the changes of the area of the absorption curves, assuming that the total density of *F* and *M* centers is constant.

superposed on the curve is the absorption due to diphenyl trinitrophenyl hydrazyl, an extremely small speck of which is attached on the modulating coil. The absolute values of g were determined referred to this line.

Fig. 4. Spin resonance absorption of specimen 2. Sharp line superposed is the absorption line due to diphenyl trinitrophenyl hydrazyl.

Fig. 5a. Spin resonance absorption of F centers. Solid curve is the theoretical Gaussian curve with half breadth of 58.5 oersteds. The arrow at $g=2.0036$ shows the position of the absorption line due to diphenyl trinitrophenyl hydrazyl.

Fig. 5b. Spin resonance absorption of F and M centers of specimen 2. Experimental curve is decomposed into curves due to F and M centers.

Fig. 5a, b and c are the absorption curves for many runs reproduced from the recording charts. In Fig. 5a we show the plots for specimen 1, with the theoretical Gaussian curve having the half-breadth of 58.5 oersteds and the g value of 1.994 which are to be compared with 54 oersteds and 1.995 obtained by

Fig. 5c. Spin resonance absorption of F and M centers of specimen 3. Experimental curve is decomposed into curves due to F and M centers.

Kip *et al.* The results for the specimens 2 and 3 are shown in Fig. 5b and 5c. Although the curve shapes are not so much different from that of specimen 1, the g values were 1.996 and 1.997 respectively which differ, beyond the experimental error, from that of pure F centers.

In the experiments shown in these figures, the magnetic field was applied along [100] direction. Almost the same curve with an identical g value was obtained for specimen 2, when the field was applied along [110] direction.

§ 3. Analysis of the Results

It may be expected that the curves in Fig. 5b and c are composed of the absorption curves due to F centers and M centers. Although R_2 centers have no effect upon spin resonance because of the pairing of the trapped electrons, R_1 centers in specimen 3 may give some contribution. But we shall neglect this effect in the following analysis, since its density is expected to be small enough. Since the shape and position of the curve for F centers is known from the above result, we can determine the absorption curve for M centers, adjusting so that the $\Delta H^2 \times D$ of these two curves have the appropriate ratio, where

ΔH is the peak to peak separation and D is the maximum deflection value of the derivative curve. $\Delta H^2 \times D$ is clearly proportional to the spin density of M or F centers. The ratio of these values which give the best fits of the curves are shown in the Table I. The fairly good coincidences with the optical data are seen. Thus we get the absorption curve for M centers alone as shown in these figures. The curve shape is Gaussian with the half-breadth of 48 oersteds and the g value 2,000.

In order to make the discussion to be concrete, we shall adopt the LCAO model^{(4),(5)}. According to Inui, Uemura and Toyozawa⁽⁴⁾ we shall consider only the five nearest atomic orbitals of potassium as shown in Fig. 1. The ions 1 and 3 are above the plane of the paper and 2 and 4 are below it, all being equivalent. According to Kip *et al.* we shall assume that the line broadening is resulting from the hyperfine coupling between each orbital electron and the nuclear magnetic moment of the corresponding potassium. Now let the amplitude of s function at the position 5 be α and 1 to 4 be β . Since the nuclear spin of potassium is $3/2$, it takes one of the four different values of magnetic moment along the direction of the magnetic field. If the magnetic moment of the nucleus at the position 5 takes one of these values, we may have the nearly Gaussian broadening due to the random orientation of the nuclear spin at four equivalent positions, the half-breadth* being $5.7 \beta A/g\mu$, where A is the hyperfine constant for free potassium and μ is the Bohr magneton. Now we shall allow for the nuclear moment at the position 5 to change from $+3/2$ to $-3/2$. Then we may have a curve composed of the four lines with this broadening, each of which is separated by $\alpha^2 A/g\mu$. If this separation is sufficiently small, the resultant curve is nearly Gaussian. The borderline for this situation is at about $\alpha^2 A/g\mu \sim 1.5 \beta^2 A/g\mu$. Since the larger value of α is favored from the theory, we shall assume tentatively that $\alpha^2 = 1.5 \beta^2$. Then

the half-breadth of the resultant curve becomes $7.1 \beta^2 A/g\mu$. Comparing this with the observed value of 48 oersteds and taking $A = 0.0077 \text{ cm}^{-1}$, we get $\beta^2 = 0.08$ and $\alpha^2 = 0.12$. The total of s part, therefore, amounts to 0.44. Among the residue the p function at the ion 5 may be largest since the polarizing field is fairly large. Moreover the considerable mixing of p functions are expected in the atomic orbitals around the ions 1 to 4.

Although the anisotropy of g value is expected because of the anisotropic configuration of the atomic p orbitals, the absolute value of Δg is as small as 0.002 which corresponds to 3~4 oersteds, and, accordingly, it will affect little the above analysis.

While we are preparing this manuscript, we were informed of the paper of Lord⁽⁹⁾ concerning the spin resonance of M centers in LiF. He found that the line of M centers are rather broad and structureless in accord with our result.

§ 4. Acknowledgement

We should like to express our deepest thanks to Dr. Y. Uemura of the Tokyo University for his stimulating discussion and to Dr. J. M. Baker of the Clarendon Laboratory to whom we owe the detailed technique of spin resonance with high frequency modulation. We are also indebted to Mr. H. Okura and Mr. E. Otsuka for many details of the experiments and discussions.

* We defined the half-breadth by $1.18 \Delta H$, ΔH being the peak to peak separation of the derivative curve. Since the absorption curve is not strictly Gaussian, $\Delta H/2$ is not equal to the square root of second-moment, and both are not strictly equal to the 2.35 times of true half-breadth.

Electrical Properties of $\text{FeTiO}_3\text{-Fe}_2\text{O}_3$ Solid Solution Series

By Yoshikazu ISHIKAWA

Institute of Science and Technology, University of Tokyo, Tokyo

(Received September 14, 1957)

D.C. electrical conductivity and Seebeck voltage of the synthesized solid solution $x\text{FeTiO}_3 \cdot (1-x)\text{Fe}_2\text{O}_3$ of ilmenite (FeTiO_3) and hematite (Fe_2O_3) were measured for a composition range of $1 \geq x \geq 0.33$. It was found that both conductivity and Seebeck voltage change continuously with the composition. At room temperature, the conduction is that of p type for $x > 0.73$ and n type for $x < 0.73$. Judging from these results, it was concluded that the valence state of Ti ions in the compound is tetravalent for the whole range of composition. Conductivity of all specimens obeys a simple Wilson's formula $\sigma = \sigma_0 \exp(-E/2kT)$ over a temperature range from 200°K to 970°K with two or three activation energies for each specimen. No anomalous change of conductivity could be observed at the ferrimagnetic or antiferromagnetic Curie point. It was, therefore, expected that the conduction electrons do not correlate with the magnetic spins in these compounds. Conductivity and Seebeck voltage of both ordered (ferrimagnetic) and disordered (antiferromagnetic) specimens with the same composition were compared. It was found that change of the ion arrangement does not affect electrical properties of these compounds.

§ 1. Introduction

It may safely be said that the conduction in the oxides of transition metals can be characterized by the extremely low mobility of its carriers. Owing to such a situation, the normal Hall voltage can not be observed for these compounds^{1,2)} and the conduction mechanism can not be explained by the ordinary Bloch type approximation.

The stoichiometric oxides of transition metals are, ordinarily, poor conductors. Their conductivity, however, is enhanced greatly by presence of ions of a given element in more than one valence states which are distributed randomly over crystallographically equivalent lattice points. In this conduction, the carriers are usually holes (p type conduction) when small amounts of cations in a higher valence state are distributed among those of the host and the carriers are electrons when small amounts of cations in a lower valence state are distributed. Detailed discussions of such a conduction mechanism in these compounds have been reported in the papers of Verwey and de Boer.^{3,4)}

In this paper, we shall report the electrical properties of the solid solution of FeTiO_3 and Fe_2O_3 . This investigation has been carried out mainly for the purpose of understanding

the peculiar magnetic properties of the solid solutions which have been reported in detail in the previous paper.^{5)*}

In order to understand their magnetic properties, it is very important to know the valence states of ions contained in the compounds. There are two possible valence states for ilmenite. One is $\text{Fe}^{2+}\text{Ti}^{4+}\text{O}_3$ and the other is $\text{Fe}^{3+}\text{Ti}^{3+}\text{O}_3$. Though we have showed in I that the magnetic properties can be interpreted well by assuming the former state, it is still possible to interpret the saturation value of magnetization and the general feature of thermomagnetic curves by assuming the latter state, because the magnetic interactions of Ti^{3+} ions between themselves and with other ions are expected to be fairly smaller than those of Fe^{3+} ions. Hence we can not decide conclusively from only the magnetic study which of these two states is realized in the compound.

The electrical conduction of these compounds, however, must be greatly different in these two cases. When we assume the former state for FeTiO_3 , Fe^{3+} ions in hematite are substituted by Fe^{2+} ions with increase of ilmenite content in the solid solution. Then

* This paper will be referred to as I hereafter in this paper.

there exist in the solid solutions a great number of pairs of Fe^{3+} and Fe^{2+} ions which increase the electrical conductivity of the solid solutions greatly. Furthermore, it is expected that the conduction is n type when the composition is near hematite and it changes into p type when the composition approaches to ilmenite.

On the other hand, when we assume another state, Fe ions in the solid solutions are always trivalent. Therefore, the compounds must be poor conductors when they are prepared stoichiometrically. The high conductivity of these compounds must be attributed, in this case, to the presence of pairs (Fe^{3+} , Fe^{2+}) and (Ti^{4+} , Ti^{3+}) which are produced by the deviation of the composition from the stoichiometrical value. Hence, in this case, the conduction is expected to be affected greatly by the atmosphere under which they are prepared and the continuous change of the electrical properties with their compositions can not be expected.

There are two other aims to investigate the electrical properties of these solid solutions. We have reported in I that the solid solution $x \text{FeTiO}_3 \cdot (1-x) \text{Fe}_2\text{O}_3$ becomes strong ferrimagnetics in the composition range of $0.95 \geq x \geq 0.5$. It is, therefore, necessary to investigate whether the conduction electron has any correlation with the magnetic spins as have been found in the conducting oxides such as magnetite and mixed lanthnum and strontium manganites.⁶⁾

Another aim is as follows. We have also reported in I and in another paper⁷⁾ that the magnetic properties of the solid solutions are affected greatly by heat treatments. For example, a specimen of $x=0.5$ can be changed from the antiferromagnetic state to the ferrimagnetic state by an appropriate heat treat-

ment. We have interpreted this experimental fact as a kind of order-disorder transformation phenomenon, where Ti and Fe ions are assumed to be distributed at random in the antiferromagnetic state, while in order in the ferrimagnetic state.

If the ordered ions are responsible for the electrical conduction, such a change of the arrangement of ions would cause a great change in the conductivity. Hence we may obtain some knowledge on the ordered state by comparing the electrical conductivity and the Seebeck voltage of the ferrimagnetic specimen with those of the antiferromagnetic specimen.

§ 2. Preparation of Specimens

The methods for preparing specimens have been reported in detail in I and in another paper.⁸⁾ For the present purpose, a mixture of FeTiO_3 and Fe_2O_3 in a desired proportion was pressed into a parallelepiped of $4 \text{ mm} \times 4 \text{ mm} \times 20 \text{ mm}$ dimension, by using a pressure of 5 ton per square centimeter, which was sealed into an evacuated quartz tube. Then, after sintering at 1200°C for more than 12 hours, it was quenched down to room temperature. The composition was determined by the X-ray and the chemical analysis as was reported in I.

In this method for preparation, the oxygen atmosphere under which the specimen is prepared is controlled properly by the specimen itself which absorbs or ejects out the oxygen in the quartz tube. Accordingly, the specimens thus obtained have very different porosities with each other and the specimen of $x < 0.33$ can not be sintered at all by this method. Hence we must restrict our measurement in a composition range of $x \geq 0.33$. In Table I,

Table I. The porosity and magnetic property of the specimen

No.	FeTiO_3 mol %	Porosity (%)	Curie point	Magnetic property
1	100		55 ($^\circ\text{K}$)	antiferromagnetic
2	95	12.0	63	ferrimagnetic
3	80	16.5	224	ferrimagnetic
4	67	8.0	394	ferrimagnetic
5	51	10.8	483	antiferromagnetic
5'	(51)	10.8	530	ferrimagnetic
6	47	21.0	529	antiferromagnetic
7	33	33.1	632	antiferromagnetic

we showed the porosity of the specimens used in the experiment which is defined as $P = \rho_b - \rho_x / \rho_x$ where ρ_b and ρ_x mean the bulk and X-ray density of the specimen.

In this table, the magnetic properties of the specimens are also presented. As we see in the table, all specimens have fairly high porosities. Hence the absolute value of the conductivity seems to have no meaning in this experiment.

§ 3. Experimental Results

The electrical conductivity was measured in air by a usual potential probe method over a temperature range from $800 \sim 700^\circ\text{K}$ to 100°K . These specimens are not stable either in air or in high vacuum at temperatures higher than 800°K except a specimen No. 2 for which the measurement was carried out up to 1100°K .

Fig. 1. D.C. resistivity vs. the reciprocal of temperature. Arrows indicate the Curie points of the specimens.

In Fig. 1, we showed the resistivity vs. the reciprocal of temperature curves of several specimens, all of which were found to obey a formula $\rho = \rho_0 \exp(E/2kT)$ having one or two breaks above 200°K . Arrows in the figure indicate the Curie temperatures of the specimens. We can find from the figure that even a slight break does not occur on $\log \rho$ vs. $1/T$ curves at the ferrimagnetic Curie point as well as the antiferromagnetic Curie point. The

temperature at which the break occurs seems to depend rather on the degree of sintering, because the specimens with the same composition have different break points when they are prepared at different times. Other specimens which were omitted in this figure have similar temperature dependence.

In Fig. 2 the value of the resistivity at

Fig. 2. D.C. resistivity at room temperature vs. the composition.

●.....ferrimagnetic specimens.
○.....antiferromagnetic specimens.

Fig. 3. Activation energies above 200°K obtained from Fig. 1 vs. the composition.

room temperature of these specimens are plotted against their compositions. As the resistivity is greatly affected by the porosity of the specimen, these values can not be plotted on a smooth line. It may, however, be concluded from this figure that the resistance decreases continuously with increase of the concentration of hematite in the solid solution. In Fig. 3 the activation energies obtained from Fig. 1 are plotted against the composition.

This quantity is also found to be strongly dependent on the porosity of the specimen. Nevertheless, it must be noticed that all specimens have nearly same activation energies.

The Seebeck voltage was measured with respect to a PtRh wire by the same method as was described in the previous paper.⁸⁾ The measurement was carried out in air over a temperature range from room temperature to 400°C and results are shown in Fig. 4.

Fig. 4. Seebeck voltage vs. temperature.

Fig. 5. Seebeck voltage vs. the composition.
○.....the value at room temperature.
△.....the value at 400 °C.

We can find in the figure that the Seebeck voltages of all specimens change linearly with temperature over this temperature range, and their slopes change continuously with the composition. In Fig. 5, the values of the Seebeck voltage at room temperature and at 400°C are plotted against the composition. Contrary to the case of the conductivity, these values are expressed by smooth lines. This fact is expected naturally. Because, as the measurement of the Seebeck voltage does not involve the current flow, its value is expected to be independent on the porosity of the intergranular barrier. We can see from the figure that the Seebeck voltage changes continuously with composition, and their signs are those of *p* type for $x > 0.73$, and *n* type for $x < 0.73$.

Effect of the heat treatment.

As we stated in the introduction, the specimen of $x=0.5$ can be changed from antiferromagnetic to ferrimagnetic by the appropriate heat treatment. In order to see how the heat treatment or the change of arrangement of ions affect the conductivity and the Seebeck voltage, we carried out the following experiment.

Fig. 6. D.C. resistivity of a specimen No. 5 vs. temperature.
○.....before the heat treatment (antiferromagnetic).
●.....after the heat treatment (ferrimagnetic).

We measured at first the conductivity and the Seebeck voltage of an antiferromagnetic specimen with $x=0.51$. This specimen was sealed again into evacuated quartz tube and was cooled very slowly from 800°C to room temperature, which was recently found the best way to establish the perfect ordering

between Fe and Ti ions.⁹⁾ After this heat treatment this specimen becomes strong ferromagnetics.

In Figs. 6 and 7 the resistivity and the

Fig. 7. Seebeck voltage of a specimen No. 5. vs. temperature.

○.....before the heat treatment

(antiferromagnetic).

●.....after the heat treatment (ferrimagnetic).

Seebeck voltage measured for the specimen before and after the heat treatment are plotted against temperature. We found from these results that the Seebeck voltage does not change at all by the heat treatment. Though the resistivity increased a little after the heat treatment, the difference may be due to other effects such as the slight change of the composition on the grain boundary by the heat treatment. Hence it may safely be said that the conductivity as well as the Seebeck voltage are not affected by the heat treatment.

§ 4. Discussion

As was stated in the previous section, the specimens used for the measurement are very porous. Then the effect of the porosity or the intergranular barrier on the conductivity must be considered first in discussion.

According to Henish¹⁰⁾, when the specimen contains the intergrain boundaries, the observed activation energy obtained from a $\log \rho$ vs. $1/T$ curve is not real one of this substance. He showed that the average activation energy obtained between temperature T_1 and T_2 can be expressed by

$$E_{0b} = E + 2\bar{\phi} + S^2/2kT_1 + S^2/2kT_2, \quad (1)$$

where E is the true activation energy of the substance and $\bar{\phi}$ and S are the mean of the height of the intergranular barriers and the standard deviation from it respectively. He

showed further that a standard deviation of as much as 10 per cent in the value of ϕ would not normally result in any detectable departure from the exponential form of the temperature dependence so long as the temperature range is not so wide.

His theory seems to be applicable to our case. We can see this by comparing the activation energy obtained from the measurement of the conductivity with that obtained from the Seebeck voltage.

For example, for the specimen No. 2, the carriers are expected to be only the holes. So the Seebeck voltage Q can be expressed by the following equation

$$QT = E_f = E/2, \quad (2)$$

where E_f means the Fermi level measured from the filled valence band. The kinetic energy term in the Seebeck voltage was neglected following Morin's suggestion.¹¹⁾ Then, the activation energy obtained from the Seebeck voltage turns to be the order of 0.12 ev at room temperature which is fairly smaller than the value 0.42 ev obtained from the conductivity. This difference must be attributed to the intergranular barriers as the equation shows.

Though we can not, thus, obtain the true activation energy from the experimental results, it may be concluded from Fig. 3. that the true activation energy also does not change greatly with the composition in this solid solution.

Next we consider the result of the Seebeck voltage. The Seebeck voltage Q of the specimen is expressed as following when two types of the carriers are contained in it.

$$QT = (Q_+ \mu_+ n_+ + Q_- \mu_- n_-) T / n_+ \mu_+ + n_- \mu_-, \quad (3)$$

where Q_+ , μ_+ and n_+ mean the Seebeck voltage, the mobility and the concentration of holes and Q_- , μ_- and n_- are those of electrons.

When we assume that Ti ions are tetravalent in the solid solution, the concentration n_+ and n_- in the solid solution $x\text{FeTiO}_3 \cdot (1-x)\text{Fe}_2\text{O}_3$ may be proportional to x and $2(1-x)$ respectively. Then, if we assume, as the first approximation, $Q_+ = Q_-$ and $\mu_+ = \mu_-$, the Seebeck voltage disappears at the concentration of $x=2/3$, and at this point its sign changes from that of n type to p type with increase of FeTiO_3 in the solid solution. Such a situation is nearly realized as we can see in Fig. 5.

On the other hand, when we assume that Ti ions in the solid solution are trivalent, their conduction must be attributed to the production of pairs (Ti^{3+} , Ti^{4+}) and (Fe^{2+} , Fe^{3+}) in the solid solution as was stated in the above paragraph. In this case, n_+ and n_- indicate the numbers of pairs (Ti^{3+} , Ti^{4+}) and (Fe^{2+} , Fe^{3+}) respectively, which do not depend on the concentration of ilmenite in the solid solution. Hence the change of the Seebeck voltage or the numbers of carriers with the composition can not be expected in this case. Furthermore, as we found from the experimental result that in the specimens for $x > 0.73$ the conduction is p type, (Ti^{3+} , Ti^{4+}) conduction is expected to predominate over (Fe^{2+} , Fe^{3+}) conduction in these specimens, while in the specimens for $x < 0.73$, the latter must be predominant. Accordingly, the activation energy of the specimen for $x > 0.73$ must be different from that of the specimen for $x < 0.73$, because (Ti^{3+} , Ti^{4+}) conduction is expected to have the different activation energy from that of (Fe^{2+} , Fe^{3+}) conduction.

Such situations are, however, not observed in the solid solution. Hence we can conclude, from these considerations, that nearly all of Ti ions in the solid solution are tetravalent and do not play any role on the magnetic coupling.

Of course, we can not decide completely from these experimental results whether a small amount of trivalent ions exist in the compound or not. It may, however, be said that the amount of trivalent Ti ions is, if existed, too small to affect the magnetic properties as well as the electrical properties.

The answer to the second problem is very evident. As we could not observe any anomalous change of the conductivity at the Curie point, the conduction electrons have little correlation with the magnetic spins.

In § 3, we found that the change of arrangement of ions does not affect the conductivity as well as the Seebeck voltage. This result suggests that Fe^{2+} and Fe^{3+} ions in the hexagonal layer are distributed at random even in the ordered specimen. Because if Fe^{3+} and Fe^{2+} ions are arranged in some ordered pattern, the electron transfer from Fe^{2+} to a

neighbouring Fe^{3+} must need higher activation energy than in the case when they are distributed randomly. The simple consideration on the electrostatic energy of the several states of ion arrangements also supports this situation as was stated in I.

If (Ti^{3+} , Ti^{4+}) conduction plays important role in these compounds, it is expected that the ferromagnetic specimen in which Ti ions arrange in the ordered pattern must have higher resistance than the antiferromagnetic one. Hence, the result on the effect of the heat treatment also supports the conclusion which we have made above.

In view of the grain structure of these ceramic specimens, there seems to be nonsense in computing the mobility of the carriers from the experimental results apart from the difficulty that this is a case of mixed electron and hole conductions. Hence, the problem relating to the d -electron conduction in general was not treated in this paper.

Acknowledgement

The author wishes to express his hearty thanks to Prof. Shozo Sawada for his kind encouragement. His thanks are also due to Dr. Akimoto for his X-ray analysis and kind criticism, to Dr. Katsura for his chemical analysis and to Drs. Iida, Kurosawa and Kondho for their discussions.

Absorption Coefficients of Fine Structures of X-ray Absorption Spectra at Various Absorber Thickness

By Kenjiro TSUSTUMI,* Masayoshi OBASHI,** and Masao SAWADA*

* *Department of Physics, Faculty of Science, Osaka University*

** *North College, Osaka University*

(Received June 15, 1957)

By using the North American Philips Diffraction Unit and Wide Range Goniometer modified to a tube spectrometer described by Coster and De Lang, the fine structures of X-ray K absorption spectra of copper in metallic copper, $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and cobalt in $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ at various thickness were measured. The structures near the absorption edges are affected by the absorber thickness. The mass absorption coefficients of maximum absorption jumps become large with decreasing absorber thickness, and the small maximum and minimum near the absorption edges also become indistinct with increasing absorber thickness. The wavelengths of these structures are slightly affected. This is due to the finite resolving power of the spectrometer and the tail of the spectral window as mentioned by Parratt. In the high energy regions from the absorption edges the absorption coefficients are not affected by the absorber thickness.

§ 1. Introduction

On the short wavelength side of the X-ray absorption edges, typical for a certain element, the absorption coefficient does not show a monotonic variation but fluctuates over a distance of several hundred volts from the main edge. In the case of crystalline solids or polyatomic molecules in which the absorption element forms a constituent. This phenomenon, the so-called "fine structures of X-ray absorption edges", finds its explanation¹⁾ in the scattering of a K photoelectron in the crystalline solid or in the polyatomic molecule that contains the absorbing atom. To date many investigations of these fine structures have been carried out but measurements have been confined almost exclusively to wavelengths of the fine structures. Moreover, there is only a few investigations²⁾ on the relation of the absorption coefficients of fine structures with the absorber thickness.

This is due to the fact that it is very difficult to measure the non-absorbed intensities at least when the photographic recording is being used in such a simple way as has mostly been done. Sandström³⁾ remarked at the Madison Conference on the applications of X-ray spectroscopy to solid state problems in October 1950 that under certain conditions non-real details could be introduced into the absorption spectra, and in many ways a spec-

trum giving the variations with wavelength of the transmitted intensity was deficient as the details would depend on the thickness of the absorber. Recently Parratt⁴⁾ and others investigated the thickness effect in absorption spectra near absorption edges of chlorine in KCl , and found that the details of an observed absorption spectrum depended upon the thickness of the absorber, and they concluded that this was due to the role of the effective spectral window of the spectrometer.

Authors also found the same effect when we investigated the fine structures of X-ray K absorption spectra of various compounds⁵⁾ by using the North American Philips Diffraction Unit and Wide Range Goniometer modified to a tube spectrometer with the Geiger-Müller counter. Thus we investigate the relation of the absorption coefficients of the fine structures of X-ray K absorption spectra with the thickness of the absorber. As absorbers we choose metallic copper and $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ ⁶⁾ and $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ ⁷⁾ which are considered as a metallic and homopolar and ionic compounds respectively, and $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ which contains the different absorbing element.

§ 2. Experiments

Preparation of Specimens. The copper foil was prepared by the electrolysis. The alkali electrolyte containing CuCN , NaCN , and

Na_2CO_3 . The P_H of this electrolyte was 11.5. The electrolytic current densities were 0.1–0.2 amp./dm². When the stainless steel cathode was used, the electrodepositions were easily stripped from the cathode. Several foils were prepared and we chose the foil which had the proper thickness and had no hole. The thickness was determined by weights and areas of the foils. The weight of foil which was used was 1.47 mg/cm². As $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ were very well solved into water, we solved these compounds into water and infiltrated in the filter papers which had been measured their weights and areas. Then after these papers were dried in the vacuum desiccator, the total weights and areas were measured. Thus, the weights of compounds were determined. The weights of $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ were 2.30, 3.55 and 3.03 mg/cm² respectively.

Absorption Spectra. X-ray Diffraction Unit and Wide Range Goniometer of North American Philips Company Inc. (Norelco)⁸⁾ were used. This unit is mechanically so arranged as to maintain a 1:2 ratio of the rotational speed between the crystal holder of the centre of the spectrometer and the Geiger-Müller counter as required for Bragg reflections. We used this unit as a tube spectrometer described by Coster and De Lang.⁹⁾ The techniques of our modified method have been described in previous publications.¹⁰⁾ As we can directly measure the primary X-ray intensity and the transmission X-ray intensity in this case, this method is easily changed so as to enable the measurement of the absorption coefficient. The divergency of the slit system of this instrument was about 0.0004 radians. The first order reflections of the LiF was used. The X-ray tube with a Mo target was loaded with 10–20 mA. at 14 kV. for the copper edges and 12 kV. for the cobalt edge which were too low to excite the second order. The fine structures of absorption spectra of copper in Cu, $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ and $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, and of cobalt in $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ at various thickness were recorded automatically on the strip-charts. Considering the time constants of the rate-meter and the recorder, the scanning speed of the Geiger-Müller tube 1/8°/min was used in all cases. Several runs were recorded at various time constants 2–8 sec. Then the intensities of the large maximum and minimum

points were also measured manually by fixed counting method.⁸⁾ As the absorbers we used the sheet of onefold to fourfold or fivefold of above mentioned specimens. The primary intensities were measured through only the same filter paper in the cases of compounds.

§ 3. Results and Discussions

Photos 1, 2, 3 and 4 are the reproductions of the curves of the fine structures of the X-ray *K* absorption spectra of copper in metallic copper, $\text{CuCl}_2 \cdot 2\text{H}_2\text{O}$ and $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, and cobalt in $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ respectively. Tables I, II, III and IV show the wavelength values of

A become larger with decreasing absorber thickness, and the small minimum *α* and small maximum *B* become indistinct with increasing absorber thickness. In general in the regions of 40 eV from the main edges the mass absorption coefficients of maxima become large with decreasing absorber thickness. In the case of metallic copper the initial absorption *Q* is also greatly affected by the absorber thickness, and this initial absorption become indistinct with increasing absorber thickness, so that the percentage of the maximum absorption jump *A* accounted for by the initial absorption *Q* is only true when the absorber thickness becomes infinitesimally thin.

The wavelength values of these structures in this region are slightly affected. These thickness effects are more apparent when the main absorption jump are large. In the high energy region from the main edge the fine structures are not affected by the absorber thickness. As the suitable thickness of the absorber for the absorption spectra we must choose the thinner absorber when the absorp-

tion spectra near the absorption edge are investigated and the relatively thicker absorber when the extended fine structures are investigated. It is evident that the thickness effect is not due to the bonding type of the substances in which absorbing element forms a constitute or the sort of the absorbing element. Perhaps it is true that the thickness effect is due to the spectral window of the spectrometer as pointed out by Parratt.⁴⁴⁾ In our spectrometer the resolving power is not so high due to the slit divergency and the penetration of the X-rays in the reflecting crystal, and moreover the X-ray focal spot used as a slit is not strictly a rectangular shape and it has a very weak tail due to the scattering of bombarding electrons and fluorescent excitations. In the case of the single crystal spectrometer there is no definition of the spectral window shape but in our tube spectrometer it is similar to that of the double spectrometer. The thickness effect is due to the finite resolving power of the spectrometer and the enormous asymmetry of the shape of absorption edge. This quite agrees with the conclusion mentioned by Parratt⁴⁾ and we will support their conclusion in our present experimental results.

Studies on the Radial Distribution Analysis in Diffraction Methods

II. Effect of Non-nuclear Scattering and Analysis of the Radial Distribution Curve* **

By Kinya KATADA

The Institute of Polytechnics, Osaka City University, Osaka

(Received August 20, 1957)

An improved procedure is described for determining the molecular structures from electron diffraction data of gases by the radial distribution method. By this procedure the structural data can be straightforwardly obtained from the radial distribution function derived from the observed intensity data without any assumption on the structure and disregard of the effect of non-nuclear scattering.

The radial distribution function derived here is the sum of the nuclear distribution function and the additional terms which have the same forms as the former. A method of the analysis of the radial distribution curve is developed by use of the moments of the distribution function.

In addition, Karle and Karle's procedure is discussed and errors involved there are estimated.

§ 1. Introduction

In the studies on the structures of gaseous molecules by electron diffraction the radial distribution method, which gives us directly much information on the structure, became more powerful in consequence of the advances of experimental techniques and procedures of analysis. The ingenious procedure proposed by Debye²⁾ in 1941 and realized by Karle and Karle³⁾ in 1949 made clear the structures of various molecules. It was shown that the sine transformation of

structure sensitive intensity = (observed total intensity/estimated background intensity) - 1

(1)

gave the radial *nuclear* distribution approximately. In their procedure, of course, it is necessary to assume a structure model of the molecule in question, from which the intensity in the range of small scattering angle is calculated since the observed intensity data can not be used in that region. The validity of the approximation involved in their procedure, that is the disregard of the differences among the unitary scattering factors of constituent atoms in the range of moderate and large angles, has not been examined closely. It is, however, clear

that a more rigorous treatment is now necessary for discussing details of the structure from the consideration of recent experimental accuracy. Recently Bartell, Brockway and Schwendeman⁴⁾ developed a refined procedure for analysis. They converted successively the experimental intensity to an intensity without non-nuclear scattering, which was then used in computing the radial nuclear distribution function.

In this paper the author will present another improved procedure, by which the structural data can be straightforwardly obtained from the sine transformation of the experimental intensity function without any assumption on the structure and disregard of the effect of non-nuclear scattering. In § 2 a radial distribution function which is convenient for the practical use is derived by considering the modifying effect of the atomic scattering factor. In § 3 a method of the analysis of the radial distribution curve is described.

In addition, errors involved in the Karle and Karle's procedure are discussed in § 4.

§ 2. A Radial Distribution Function

The radial distribution function*** $rD(r)$ is

*** In this paper, $rD(r)$ is called the "radial distribution function" for convenience and is mainly treated rather than $r^2D(r)$ or $D(r)$, because $r(D)r$ possesses more advantageous mathematical properties than $r^2D(r)$ or $D(r)$. See reference 5 or 6.

* This paper was read at the Annual Meeting of the Physical Society of Japan, Tokyo, October 1955.

** The first paper in the series was presented by T. Ino in this Journal. See reference 1.

given by Fourier sine transformation of the structure sensitive intensity function $I(s)$; that is

$$sI(s) = \int_0^\infty 4\pi r D(r) \cdot \sin sr \, dr \quad (2)$$

and

$$4\pi r D(r) = \langle 2/\pi \rangle \int_0^\infty sI(s) \cdot \sin sr \, ds,$$

where $s = (4\pi/\lambda) \cdot \sin(\theta/2)$, λ = wave-length of electrons, θ = scattering angle and r = distance occurring in the aggregation of atoms. $rD(r)$ may directly give us information on the structure, whose physical meanings are different according to the type of $I(s)$ used.

In this paper the same type of the structure sensitive intensity function as shown in Eq. (1) is adopted. If all atoms in the molecule are considered to be undergoing simple harmonic vibrations, the structure sensitive intensity function $I^\phi(s)$, which is directly derived from the observed data, may have the form⁷⁾:

$$sI^\phi(s) = \sum_{(ij)} si_{(ij)}^\phi(s) = \sum_{(ij)} \frac{2Z_i Z_j \phi_i(s) \phi_j(s) \exp(-l_{ij}^2 s^2) \sin sr_{ij}}{r_{ij} \sum_i Z_i^2 \phi_i^2(s)}, \quad (3)$$

where $\phi_i(s) = (Z_i - F_i(s))/Z_i$ = unitary atomic scattering factor of i -th atom for electrons, Z_i = atomic number of i -th atom, $F_i(s)$ = atomic scattering factor of i -th atom for X-rays, r_{ij} = equilibrium internuclear distance between i -th and j -th atoms, $2l_{ij}^2$ = average of the square of the deviation of distance from its equilibrium value r_{ij} , and $\sum_i$ = summation taken over all atomic pairs in the molecule. In Eq. (3), the term of the inelastic scattering is omitted, since this part may not be essential to the discussion.* Let us define another structure sensitive intensity function $I^s(s)$ as follows:

$$sI^s(s) = \sum_{(ij)} si_{(ij)}^s(s) = \sum_{(ij)} \frac{2Z_i Z_j \exp(-l_{ij}^2 s^2) \sin sr_{ij}}{r_{ij} \sum_i Z_i^2}. \quad (4)$$

This function may present the intensity without non-nuclear scattering. These two intensity functions $I^\phi(s)$ and $I^s(s)$ respectively produce two kinds of the radial distribution functions:

$$rD^\phi(r) = \sum_{(ij)} r d_{(ij)}^\phi(r) = (1/2\pi^2) \sum_{(ij)} \int_0^\infty si_{(ij)}^\phi(s) \cdot \sin sr \, ds \quad (5)$$

and

$$rD^s(r) = \sum_{(ij)} r d_{(ij)}^s(r) = (1/2\pi^2) \sum_{(ij)} \int_0^\infty si_{(ij)}^s(s) \cdot \sin sr \, ds. \quad (6)$$

It is not $rD^\phi(r)$ but $rD^s(r)$ that gives us directly the "radial nuclear distribution".

When the radial distribution function is computed by the transformation of experimental intensity function, the artificial temperature factor, $\exp(-a^2 s^2)$, is often used in order to diminish the effect of terminating the intensity function. Thus, $rD^\phi(r)$ is defined as

$$rD^\phi(r) = (1/2\pi^2) \int_0^\infty \exp(-a^2 s^2) \cdot sI^\phi(s) \sin sr \, ds. \quad (7)$$

The following expression of $rD^\phi(r)$ may be suitable for further calculations:

$$rD^\phi(r) = \sum_{(ij)} r d_{(ij)}^\phi(r) = (1/2\pi^2) \sum_{(ij)} \int_0^\infty \{m_0(s) + m_{ij}(s)\} \cdot si_{(ij)}^\phi(s) \sin sr \, ds, \quad (8)$$

where

$$m_0(s) = \exp(-a^2 s^2)$$

and

$$m_{ij}(s) = \left[\frac{i_{(ij)}^\phi(s)}{i_{(ij)}^s(s)} - 1 \right] \cdot \exp(-a^2 s^2) = \left[\frac{\phi_i(s) \phi_j(s) \sum_i Z_i^2}{\sum_i Z_i^2 \phi_i^2(s)} - 1 \right] \cdot \exp(-a^2 s^2). \quad (9)$$

$m_0(s)$ and $m_{ij}(s)$ are called the "modification functions"⁸⁾. The former does not depend on the kind of atomic pair**, but the latter is characteristic of atoms i and j and modifies the peak shape of the radial nuclear distribution curve in the different manner for each atomic pair.

As $m_{ij}(s)$ does not depend on the configuration of atoms, it may be possible to express it approximately in terms of an appropriate function in advance. For example, if $m_{ij}(s)$

** The modifying effect of $m_0(s)$ on the radial distribution function has been already studied by several investigators. For example, see reference 3 or 5.

* See the footnote * in p. 53.

is approximated as follows:

$$m_{(ij),s} = \sum_{k=1} A_{ij,k} \exp(-a_{ij,k}^2 s^2), \tag{10}$$

as done by Bartell *et al.*,⁴⁾ then, it follows from Eqs. (8), (10) and (4) that

$$rD^\phi(r) = \sum_{(ij)} r d_{(ij)}^\phi(r) = (8\pi^{3/2} \sum_i Z_i^2)^{-1} \sum_{(ij)} [(2Z_i Z_j / r_{ij}) \cdot \sum_{k=0} A_{ij,k} (a_{ij,k}^2 + l_{ij}^2)^{-1/2} \cdot \{\exp[-(r-r_{ij})^2 / 4(a_{ij,k}^2 + l_{ij}^2)] - \exp[-(r+r_{ij})^2 / 4(a_{ij,k}^2 + l_{ij}^2)]\}], \tag{11}$$

where $A_{ij,0} \equiv 1$ and $a_{ij,0}^2 \equiv a^2$ (the coefficient in the artificial temperature factor). The component $k=0$ is the radial nuclear distribution function $rD^s(r)$ modified by the artificial temperature factor and the sum of components $k \neq 0$ is the additional term arising from the consideration of non-nuclear scattering. The area $\sigma_{(ij)}^\phi$ under the peak of $r^2 d_{(ij)}^\phi(r)$ for each atomic pair is given as

$$\sigma_{(ij)}^\phi = (4\pi \sum_i Z_i^2)^{-1} \cdot (2Z_i Z_j) \cdot \sum_{k=0} A_{ij,k}, \tag{12}$$

being equal to $\sum_{k=0} A_{ij,k}$ times $\sigma_{(ij)}^s$, the area under the peak of $r^2 d_{(ij)}^s(r)$.

An example is presented below for carbon tetrachloride. $m_{CCl}(s)$ and $m_{ClCl}(s)$ are obtained from values of the atomic scattering factors $F_C(s)$ and $F_{Cl}(s)$ tabulated by Viervoll and Ögrim⁸⁾ and $a^2 = (0.070/\pi^2)\text{\AA}^2$, as shown

Fig. 1. Curves of the modification function $m_{ij}(s)$ for carbon tetrachloride.

in Fig. 1. By curve fittings the values of the coefficients in Eq. (10) are determined as follows* **:

$$\left. \begin{aligned} A_{CCl,1} &= 0.30, & A_{ClCl,1} &= -0.020, \\ A_{CCl,2} &= 0.23, & A_{ClCl,2} &= -0.015, \\ A_{CCl,3} &= 0.14, & A_{ClCl,3} &= -0.014, \\ a_{CCl,1}^2 &= a_{ClCl,1}^2 = (0.17/\pi^2)\text{\AA}^2, \\ a_{CCl,2}^2 &= a_{ClCl,2}^2 = (0.42/\pi^2)\text{\AA}^2, \\ a_{CCl,3}^2 &= a_{ClCl,3}^2 = (3.5/\pi^2)\text{\AA}^2. \end{aligned} \right\} \tag{13}$$

* The values of $A_{ij,k}$ and $a_{ij,k}^2$ vary slightly when the inelastic scattering is taken into account.
** It is the author's experience that $m_{ij}(s)$ can be satisfactorily expressed by two or, at most, three terms of Gaussian functions.

In Fig. 2 components of Eq. (11) are illustrated which are calculated by using $r_{CCl} = 1.77\text{\AA}$, $r_{ClCl} = 2.88\text{\AA}$ (regular-tetrahedral structure), $l_{CCl}^2 = l_{ClCl}^2 = (0.030/\pi^2)\text{\AA}^2$ and the values of $A_{ij,k}$ and $a_{ij,k}^2$ given above. It is shown that the contributions from the additional term

Fig. 2. $r d_{(ij)}^\phi(r)$ and their components (dashed line) for carbon tetrachloride: (a) $4 \cdot r d_{CCl}^\phi(r)$ and (b) $6 \cdot r d_{ClCl}^\phi(r)$.

(sum of the components $k=1, 2$ and 3) are considerably large for C-Cl pair but small and negative for Cl-Cl pair. These behaviours are characteristic of the constitution of the compound.

The radial distribution curve computed numerically from the experimental intensity data by Eq. (7) is expressed in terms of unknown parameters r_{ij} , l_{ij}^2 and $Z_i Z_j$ by Eq. (11). Therefore, it is possible to determine these parameters by analysing the curve. The method of "trial and error" for the analysis usually used is applicable in this case, but the author will show another method in the next section.

§ 3. A Method of the Analysis of the Radial Distribution Curve

It is always necessary in the radial distribution method to analyse the obtained distribution curve. Some hunches of the radial distribution curve are composed of peaks for several distances, when the molecule possesses nearly equal equilibrium distances or the effective artificial temperature factor is used in order to diminish what is called the "diffraction effect". The direct method of resolution without any assumption on the structure is desirable. Investigators, however, de-

composed the composite peaks with some introductory knowledge about the structure*. A procedure for the determination of unknown parameters r_{ij} , l_{ij}^2 etc., or the decomposition of composite peaks into the components without any assumption on their approximate values is briefly described below.

The n -th "moment" of the radial distribution function $rD(r)$, defined by

$$\mu_n = \int_{-\infty}^{\infty} r^n \cdot rD(r) dr, \quad (n=0, 1, 2, \dots), \quad (14)$$

may be useful when the distribution function has the Gaussian form, because integral in Eq. (14) can be performed and an algebraic function is derived.

As $rD(r)$ is the odd function and the moments of even order vanish certainly, it is advantageous to omit the second term of $rD(r)$, the term $\exp[-(r+r_{ij})^2/4(a_{ij,k}^2+l_{ij}^2)]$. Then, for such a radial distribution function as shown in Eq. (11), moments are obtained as follows:

The moments of the lower order can be easily calculated by the usual numerical integration from the radial distribution function obtained experimentally. Thus, the unknown parameters may be determined by solving the above simultaneous equations.

$$\left. \begin{aligned} \mu_0 &= (4\pi \sum_i Z_i^2)^{-1} \sum_{(ij)} [(2Z_i Z_j \sum_{k=0} A_{ij,k})/r_{ij}], \\ \mu_1 &= (4\pi \sum_i Z_i^2)^{-1} \sum_{(ij)} [2Z_i Z_j \sum_{k=0} A_{ij,k}], \\ \mu_2 &= (4\pi \sum_i Z_i^2)^{-1} \sum_{(ij)} [(2Z_i Z_j \sum_{k=0} A_{ij,k})r_{ij} + 4Z_i Z_j \sum_{k=0} A_{ij,k}(a_{ij,k}^2 + l_{ij}^2)/r_{ij}], \\ \mu_3 &= (4\pi \sum_i Z_i^2)^{-1} \sum_{(ij)} [(2Z_i Z_j \sum_{k=0} A_{ij,k})r_{ij}^2 + 12Z_i Z_j \sum_{k=0} A_{ij,k}(a_{ij,k}^2 + l_{ij}^2)], \\ &\dots\dots\dots \end{aligned} \right\} \quad (15)$$

In order to examine the usefulness of this method an arbitrary model is set up as follows: $r_{AB}=1.50\text{\AA}$, $l_{AB}^2=0.0010\text{\AA}^2$, $Z_A Z_B=150$, $r_{CD}=1.70\text{\AA}$, $l_{CD}^2=0.0030\text{\AA}^2$ and $Z_C Z_D=300$. Fig. 3 shows the $rD^\phi(r)$ curve obtained from this model with the values of $A_{ij,k}$ and $a_{ij,k}^2$ given in the previous section. Now, the four moments μ_0 , μ_2 , μ_3 and μ_4 are calculated from this $rD^\phi(r)$ and the simultaneous equations are set up, regarding r_{AB} , l_{AB}^2 , r_{CD} and l_{CD}^2 as unknown. The approximate values of them are obtained by solving the

equations and the correct values of them are finally determined by the method of least squares in such a way that the best fit is obtained between the curve in Fig. 3 and that calculated by Eq. (11) with the obtained values. The final results are $r_{AB}=1.50\text{\AA}$, $l_{AB}^2=0.0010\text{\AA}^2$, $r_{CD}=1.70\text{\AA}$ and $l_{CD}^2=0.0030\text{\AA}^2$.

Another test is also carried out for the case where a peak in the radial distribution curve is not known to be single or composite. $rD^\phi(r)$ curve is drawn by the use of one kind of atomic pair ($r_{AB}=1.50\text{\AA}$, $l_{AB}^2=0.0010\text{\AA}^2$ and $Z_A Z_B=150$). Even if this peak of

* For example, see reference 9.

$rD^\phi(r)$ is assumed to be a composite peak of two kinds of atomic pairs, (r_1, l_1^2) and $(ZZ)_1$ and (r_2, l_2^2) and $(ZZ)_2$, the procedure mentioned above leads to such results as $r_1=r_2=r_{AB}$, $l_1^2=l_2^2=l_{AB}^2$ and $(ZZ)_1+(ZZ)_2=Z_A Z_B$.

Fig. 3. The radial distribution curve $rD^\phi(r)$ obtained from an arbitrary model. Dashed line shows the individual peaks for each distance.

It may be worthwhile to note here that the procedure of solving the simultaneous equations when $rD^\phi(r)$ is taken as the radial distribution function in Eq. (14) is no more troublesome than that when $rD^z(r)$ is taken, because values of $A_{ij,k}$ and $a_{ij,k}^2$ are known.

§ 4. Errors due to the Partial Disregard of the Differences among the Unitary Scattering Factors of the Constituent Atoms

Since Karle and Karle's work³⁾, many investigators have analysed the molecular structures, assuming that $\phi_i(s) \approx \phi_j(s)$ in the range of moderate and large scattering angles ($s \geq s_0$) and hence such a radial distribution function as

$$rD^c(r) = (1/2\pi^2) \left[\int_0^{s_0} sI^z(s) \cdot \sin sr \, ds + \int_{s_0}^{\infty} sI^\phi(s) \cdot \sin sr \, ds \right] \quad (16)$$

is approximately equal to $rD^z(r)$. In this section the deviation of $rD^c(r)$ from $rD^z(r)$ will be estimated.

Let us consider carbon tetrachloride again, which has the same structure as shown in § 2. From this model the intensity functions $I^\phi(s)$ and $I^z(s)$ are calculated and then

three radial distribution functions $rD^\phi(r)$, $rD^c(r)$ and $rD^z(r)$ are obtained by means of the punched-card method¹⁰⁾ with $a^2 = (0.070/\pi^2)$ Å². These are shown in Fig. 4 together with the differences among them. In the computation of $rD^c(r)$, $sI^\phi(s)$ is connected to $sI^z(s)$ at the point $s_0 = \pi \text{Å}^{-1}$. Fig. 4 shows that

Fig. 4. Computed radial distribution curves and differences among them for carbon tetrachloride in the same longitudinal scale. Curve (A) is $rD^\phi(r)$, (B) $rD^c(r)$, (C) $rD^z(r)$, (D) $\Delta rD^\phi(r) = rD^\phi(r) - rD^z(r)$ and (E) $\Delta rD^c(r) = rD^c(r) - rD^z(r)$. The lowest curve is $\Delta rD^c(r)$ calculated from eq. (19).

both $rD^\phi(r)$ and $rD^c(r)$ deviate appreciably from $rD^z(r)$ and the areas under the peaks of $rD^\phi(r)$ and $rD^c(r)$, especially for C-Cl pair, are not equal to those of $rD^z(r)$ **, but the positions of the maxima of the peaks agree satisfactorily with each other. Moreover, it is to be noted here that $rD^c(r)$ has ripple along the base line.

Now, the deviation $\Delta rD^c(r) = rD^c(r) - rD^z(r)$

* The manner of the connection in the vicinity of s_0 has little influence on the resultant $rD^c(r)$.

** From (13) the factors $\sum_{k=0} A_{ij,k}$ in (12) are 1.57 and 0.95 for C-Cl and Cl-Cl pairs, respectively.

is considered from such a standpoint as described in § 2. It followed that

$$\begin{aligned} \Delta r D^o(r) &= \sum_{(ij)} \Delta r d_{(ij)}^o(r) \\ &= (1/2\pi^2) \sum_{(ij)} \int_{s_0}^{\infty} m_{ij}(s) \cdot s i_{(ij)}^z(s) \cdot \sin sr \, ds. \end{aligned} \quad (17)$$

Therefore, $\Delta r d_{(ij)}^o(r)$ depends on the value of $m_{ij}(s)$ in the range $s \geq s_0$. If $m_{ij}(s)$ in $s \geq s_0$ is roughly fitted as

$$m_{ij}(s) = B_{ij} \exp(-b_{ij}s), \quad (18)$$

then $\Delta r D^o(r)$ is approximately obtained as follows:

$$\begin{aligned} \Delta r D^o(r) &= \sum_{(ij)} \Delta r d_{(ij)}^o(r) \\ &= (4\pi^2 \sum_i Z_i^2)^{-1} \sum_{(ij)} \left[(2Z_i Z_j / r_{ij}) \cdot B_{ij} \exp(-b_{ij}s_0) \right. \\ &\quad \cdot \left. \left\{ \frac{b_{ij} \cos s_0(r - r_{ij}) - (r - r_{ij}) \cdot \sin s_0(r - r_{ij})}{b_{ij}^2 + (r - r_{ij})^2} \right\} \right]. \end{aligned} \quad (19)$$

Maximum of the deviation $\Delta r d_{(ij)}^o(r)$ appears at the equilibrium distance r_{ij} and its value $\Delta r_{ij} d_{(ij)}^o(r_{ij})$ varies inverse-exponentially with s_0 .

In practice, the ratio of $\Delta n_{ij} r_{ij} d_{(ij)}^o(r_{ij})$ or $\Delta r_{ij} D^o(r_{ij})$ to $n_{ij} r_{ij} d_{(ij)}^z(r_{ij})$ may be suitable for the estimation of error in the peak of atomic pair (ij) , where n_{ij} is the number of atomic pairs having an equal equilibrium distance. It follows approximately that

$$\begin{aligned} \Delta r_{ij} d_{(ij)}^o(r_{ij}) / r_{ij} d_{(ij)}^z(r_{ij}) \\ = (2\pi^{-1/2}) \cdot (a B_{ij} / b_{ij}) \cdot \exp(-b_{ij}s_0), \end{aligned} \quad (20)$$

and such a relation as

$$\begin{aligned} \Delta r_{ij} D^o(r_{ij}) \leq (4\pi^2 \sum_i Z_i^2)^{-1} \sum_{(ij')} (2Z_i Z_{j'} / r_{ij'}) \\ \cdot |B_{ij'}| \exp(-b_{ij'}s_0) \frac{b_{ij'} + |r_{ij} - r_{ij'}|}{b_{ij'}^2 + (r_{ij} - r_{ij'})^2} \end{aligned} \quad (21)$$

is useful for the approximate calculation of $\Delta r_{ij} D^o(r_{ij}) / n_{ij} r_{ij} d_{(ij)}^z(r_{ij})$, because rough estimation of unknown $r_{ij'}$ may be permissible. Of these two ratios, the latter is related to the case where the effect of neighbouring peaks is considered and must be adopted when some neighbouring peaks have the large deviations of $m_{ij}(s)$ from zero and the large scattering powers. These estimations of errors seem to be useful in choosing the value of s_0 for the compound in question in the case where $r D^o(r)$ is adopted in place of $r D^z(r)$.

For carbon tetrachloride, $B_{\text{CCl}} = 0.86$, B_{ClCl}

$= -0.065$ and $b_{\text{CCl}} = b_{\text{ClCl}} = (0.85/\pi) \text{\AA}$ and some results obtained from Eqs. (20) and (21) are listed in Table I. In the calculation of $\Delta r_{ij} D^o(r_{ij}) / n_{ij} r_{ij} d_{(ij)}^z(r_{ij})$, values of $r_{ij'}$ are roughly estimated as follows: $r_{\text{CCl}} = 1.8 \text{\AA}$ and $r = 2.9_{\text{ClCl}} \text{\AA}$. The lowest curve in Fig. 4 is the one obtained from Eq. (19) and agrees satisfactorily with the curve (E).

Table I. Some results obtained from Eqs. (20) and (21) for carbon tetrachloride.

s_0	$\frac{\Delta r_{ij} d_{(ij)}^o(r_{ij})}{r_{ij} d_{(ij)}^z(r_{ij})}$		$\frac{\Delta r_{ij} D^o(r_{ij})}{n_{ij} r_{ij} d_{(ij)}^z(r_{ij})}$

§ 5. Discussion

There are many cases where the radial distribution function $r D^o(r)$ used by many investigators has the appreciable deviation from the correct nuclear distribution function $r D^z(r)$ as described in § 4. For example, the peak height for C-Cl pair of carbon tetrachloride varies by 15 ~ 10% of it when the calculated intensity function $I^z(s)$ is connected to the experimental one $I^o(s)$ at $s = 3 \sim 5 \text{\AA}^{-1}$. In the "correlation" method the experimental intensity is usually compared with the calculated intensities with constant coefficients Z_i in place of $(Z_i - F_i(s))$. These procedures in which the differences among $\phi_i(s)$ of the constituent atoms are partially disregarded make uncertain the measurements of the mean square amplitude of vibration and the distances for atomic pairs with the weaker scattering powers. Therefore, the reliability of the results obtained in the past should be examined closely.

If the structural data obtained from such $r D^o(r)$ are correct or closely approximate, it may happen that some errors in the observed total intensity or in the estimated background intensity compensate for the deviation of $r D^o(r)$ from $r D^z(r)$. In the latter case it seems that an incorrect background intensity is intentionally determined in order to obtain such a structure sensitive intensity that gives $r D^z(r)$. If so, the consequent background line

should fluctuate, at least, in the case of carbon tetrachloride. Moreover, it is doubtful whether such conversion of $rD^e(r)$ into $rD^z(r)$ can be performed uniquely only by the criterion for the estimation of the background intensity given by Karle and Karle¹¹⁾, because it is only a necessary condition that the nuclear distribution function must be non-negative everywhere.

Recently Bartell *et al.*⁴⁾ discussed on the uncertainty of the results due to neglect of the variability of $m_{ij}(s)$ with s and developed a refined procedure which compensated for the interference arising from non-nuclear scattering. They converted successively $I^\phi(s)$ into $I^z(s)$, starting with values of r_{ij} and l_{ij}^2 obtained from $rD^e(r)$. Their procedure may be easy of access, but there remains the necessity of assuming a structure model and there may be some questions about the convergency of the successive approximation.

The Norwegian school¹²⁾ took into account the effect of non-nuclear scattering as it is. Consequently the radial distribution curve is intricate and its analysis becomes troublesome.

In the procedure described in this paper the interference effects arising from non-nuclear scattering are partially compensated by deviding the total scattered intensity by the background intensity as done by the American school, and the residual effects are taken into account with the consideration of the differences among the unitary scattering factors of the constituent atoms. Therefore, the comparably small additional terms are only supplemented to the radial nuclear distribution function. Furthermore, the additional term has the Gaussian form which is similar to the radial nuclear distribution function modified by the artificial temperature factor and hence the analysis of the distribution curve becomes little complicated.

Another advantage of the procedure is the fact that the observed intensity data can be used up to the range of smaller scattering angle. Therefore, no structure model need be assumed from which the intensity is calculated in that region. The assumption of the model is difficult in the case where the material has the complicated structure. The author prefers to abolish the presumption on the structure in the radial distribution method.

In the neighborhood of the diffraction center, however, it is difficult not only to measure the diffracted intensity but also to estimate the background intensity. The extrapolation method which will be presented in the following paper may be easily adopted to make up the absence of the structure sensitive intensity in the range of very small angle.

The modification function $m_{ij}(s)$ can be obtained from the chemical constitution of the compound and the values of the atomic scattering factors without any knowledge about the atomic configuration. However, in the range of very small angle there remains some uncertainty in the values of the elastic and inelastic scattering factors and hence it may be difficult to obtain $m_{ij}(s)$ correctly in that region. However, the behaviour of $m_{ij}(s)$ in the inner-most region of s gives only very small and flat contribution over the wide range of r on the radial distribution function. Therefore, such an approximation as shown in (13) may be practical and the values of σ_{ij}^ϕ obtained with values of $A_{ij,k}$ in (13) agree satisfactorily with those of areas under the peaks of $r^2D^\phi(r)$ derived from $rD^\phi(r)$ in Fig. 4.

The advantage of the method of the analysis of the radial distribution curve described in §3 is the fact that the structure data can be obtained by this method without any introductory knowledge about the structure. Therefore, the method is very powerful when the kind or number of atomic pairs coming in a composite peak is unknown. As the method is especially easily applicable to the decomposition of the peak composed of small number of components, it is desirable to divide the whole radial distribution curve into some parts mutually isolated if possible and apply it to each part. When the numerical integration is performed for lower order moments ($n \lesssim 4$), it is permissible to cut the integral range at the arbitrary points on the both feet of the peak.

At the end it is noteworthy that such a treatment as described here is able to be extended by some proper considerations to the cases of liquid and amorphous solid in which halo patterns are obtained by the diffraction of X-rays or electrons.

It is the author's pleasure to express his

sincere thanks to Prof. J. Kakinoki and Mr. T. Ino for their valuable criticisms. The author also wishes to thank the Osaka Municipal Office for making available to him a set of electrical accounting machines of the I.B.M. Corporation.

Uniaxial Anisotropy in Iron-Cobalt Ferrites

By Shūichi IIDA, Hisashi SEKIZAWA, and
Yoshimichi AIYAMA

Department of Physics, Faculty of Science, Tokyo University, Tokyo

(Received April 13, 1957)

The uniaxial anisotropy induced by the magnetic annealing in both single and poly-crystals of iron-cobalt ferrites has been studied experimentally. It is shown that the magnitudes of the uniaxial anisotropy depend essentially on the degree of oxidation of the specimens and become almost zero after deoxidizing heat treatments. Contrary to the conclusion by Bozorth *et al.*, the dependence of the magnitude of the uniaxial anisotropy on the direction of the annealing magnetic field is observed for a cobalt rich single crystal, showing a maximum along $\langle 100 \rangle$ and a minimum along $\langle 110 \rangle$ in (001) plane. Relaxation behaviour of the uniaxial anisotropy is studied by measuring directly the change of torque at high temperatures ($240^\circ\text{C} \sim 350^\circ\text{C}$) with a polycrystalline cobalt ferrite. It has been found that the results can be described by a simple empirical formula, supporting that the magnetic annealing effect has no critical temperature. The variation of electrical conductivity with temperature has also no anomaly at the effective temperature range.

Considering all the experimental results obtained, we have reached the conclusion that the uniaxial anisotropy in these ferrites is due to the presence of directional short range order among various cations and cation vacancies in the spinel matrix. The nearest neighbour pair of a cobalt ion and a vacancy seems to play a principal role in this mechanism.

§ 1. Introduction

It is well known that certain ferromagnetic materials respond to heat treatment in a magnetic field. When they have been annealed in a magnetic field in a certain temperature range, they get a uniaxial anisotropy with

a stable direction parallel to the annealing field. Iron-nickel alloys,¹⁾ alnico V,²⁾ copper-cobalt alloys,³⁾ and magnetite⁴⁾ are typical examples. In the case of iron-nickel alloys the magnetic annealing effect is well accounted for by the mechanism of the directional short

range order and in the case of alnico V by the formation of oriented precipitates.

The magnetic annealing effect in the iron-cobalt ferrites was first found by Kato and Takei in 1933⁶⁾. Since then, Kawai⁸⁾, Nakamura⁷⁾, Sugiura⁸⁾, Guillaud⁹⁾, Bozorth *et al.*¹⁰⁾ and H. J. Williams *et al.*¹¹⁾ have made many interesting studies from various points of view. Especially Bozorth *et al.* have performed the study on single crystals of these ferrites and clarified various characteristics of this effect. But the conclusive theoretical interpretation does not seem to be given by them.

Since 1951, we have also been engaged in experimental studies of this problem and reached the conclusion that the uniaxial anisotropy originates in the directional local order among cobalt ions and cation vacancies in the ferrite crystal¹²⁾. The present paper reports the principal parts of the studies concerning the uniaxial anisotropy of the iron-cobalt ferrites. The experimental study of the phase diagram of iron-cobalt-oxygen system was published already¹³⁾.

In § 2, the ways of the preparation of various specimens used are described. In § 3, the results of the experimental study for the uniaxial anisotropy constants of the polycrystalline specimens are described. It is shown that the magnitude of the constants depends strongly on the degree of oxidation of the specimens. Magnetostriction curves of these specimens at each degree of the oxidation are also shown. In § 4, the details of the magnetic study carried out on single crystals are presented. In § 5, the results of the study on the relaxation of the induced uniaxial anisotropy of cobalt ferrite are shown. In § 6, the experimental results on the variation of the electrical conductivity of the iron-cobalt ferrites with temperature are presented. In § 7, a possible mechanism of the uniaxial anisotropy in iron-cobalt ferrites is presented. Lastly in § 8, several of other mechanisms proposed for the uniaxial anisotropy of these ferrites are discussed together with the possibility of the presence of similar effects in other ferrites.

§ 2. Preparation of the Specimens

Both polycrystalline and single crystal specimens were used.

The polycrystalline specimens were prepared

by the usual ceramic techniques: calcination, milling, pressing and firing. The starting oxides were prepared by "nitric acid method", i.e., dissolving the mixture of constituent metals in the desired proportion in conc. HNO_3 , drying the solution with an infra-red ray lamp and heating at about 800°C in air to remove the nitrogen. The proposed compositions of metals were $r=0.000, 0.083, 0.167, 0.250, 0.333$, and 0.417 , where r stands for the atomic ratio $\text{Co}/(\text{Fe}+\text{Co})$.

The firings, i.e., the heat treatments after the pressing, were made according to the phase diagram established by one of the authors¹³⁾. The heat treatments were made in an air tight alumina tube. The phase diagram is reproduced in Fig. 1. In the figure, the region

Fig. 1. Phase boundaries of Iron-Cobalt oxides with various metallic compositions. Each solid line indicates the boundary corresponding to each metallic composition, by which spinel phase field (lower) is separated from two phase field with hematite and spinel (upper).

Broken line indicates the partial pressure of CoO vapour decomposing from the spinel matrix. Below this critical pressure, active decomposition of CoO vapour from the spinel matrix occurs.

in which spinel phase is stable in common to all the compositions now studied is hatched. We prepared several sets of specimens with the various compositions mentioned and the firing was made to each set of specimens simultaneously. It was an annealing for thirty minutes at 1400°C in oxygen of about 50 mm Hg and the following slow cooling in the hatched region (during cooling the pressure

of oxygen was controlled). The firing by this program is referred as heat treatment "S", for convenience in the present report.

It is remarked that below 800°C the oxygen pressure required in this heat treatment becomes lower than the lowest limit obtainable with our apparatus. However, as concluded before and is confirmed again by various measurements in this report, a simple extrapolation of the phase diagram shown in Fig. 1 is considered to be still valid below 800°C. Actually the electric and magnetic properties of the specimens were found to be affected to some extent by a slight change in conditions of vacuum below 800°C.

Polycrystalline specimens used in torque measurements were discs of 14 mm in diameter and of 1 mm in thickness, and those used in electrical conductivity measurements were square rods of 4 mm × 4 mm × 25 mm in size.

Single crystals used were grown from the melt in a platinum crucible in air. Measurements were made on two cobalt rich single crystals one of which had a mixing composition of $r=0.253$ and cut in a sphere of 2.75 mm in diameter and the other had a composition of $r=0.283$ according to chemical analysis and cut in a (001) disc of 6.00 mm in diameter and of 0.70 mm in thickness.

Preceding the measurements, heat treatments were also applied to these specimens according to the phase diagram.

§ 3. Uniaxial Anisotropy and Magnetostriction in Polycrystals

The magnitudes of the uniaxial anisotropy induced by the magnetic annealing were measured for the disc-shaped polycrystalline specimens by a torque-meter.

It was found by preliminary measurements that the uniaxial anisotropy constants induced by the magnetic annealing depend strongly upon the degree of oxidation of the specimens. Fig. 2 shows the results. Curves from (1) to (7) illustrate the variation of the uniaxial anisotropy constants of a set of specimens caused by applying various heat treatments in a vacuum successively. The magnetic field applied was about 4000 Oe and it was applied in each time perpendicular to the direction of the magnetic field applied in the preceding heat treatment so as to eliminate the influence

of the preceding magnetic annealing.

The results show that the uniaxial anisotropy in these ferrites which is induced by the magnetic annealing decreases considerably by repeating heat treatments in a high vacuum and is almost zero in the most deoxidized state. It seems certain that the dependence of the magnitude of the uniaxial anisotropy on the rate of the cooling is not so distinctive.

Fig. 2. Change of uniaxial anisotropy of an iron-cobalt ferrite series caused by applying various heat treatments in a vacuum successively. The heat treatments are as follows.

(1): The specimens after heat treatment "S" were heated up to 750°C in a vacuum and quenched from this temperature in a vacuum with an applied magnetic field.

(2): again heated up to 750°C in a vacuum, cooled slowly with an applied magnetic field.

(3), (4): heated up to 750°C in a vacuum, cooled to 260°C in (3), and from 750°C in (4).

(5): heated up to 250°C in a vacuum, and cooled with a magnetic field.

(6), (7): heated up to 750°C in a vacuum, kept 24 hours in (6), and 56 hours in (7), and cooled in a magnetic field.

It should be mentioned that the change in weight of the specimens after these heat treatments could not be detected (probably less than 0.5%) and x-ray study confirmed spinel structure of the specimens even in the most deoxidized state.

Then, starting from specimens in the most deoxidized state, the recovering process of the uniaxial anisotropy was observed. Another set

of specimens with a series of composition r , identical to the former, were annealed for five hours at 1000°C in a high vacuum and then cooled slowly with an applied magnetic field. The anisotropy constants measured after this treatment are shown by curve (0) in Fig. 3 (a). Then, seven oxidizing heat treatments were performed in succession on these specimens. The first six treatments were the annealings at 400°C for four hours in oxygen of various

Fig. 3(a) Change of the uniaxial anisotropy of an iron-cobalt ferrite series caused by applying the heat treatments in various oxidizing conditions. The heat treatments, applied successively, are in turn as follows.

(0): Specimens were annealed for five hours at 1000°C in a vacuum and cooled with an applied magnetic field.

(1), (2), ... (6): annealed for four hours at 400°C in oxygen at the pressure indicated in the figure, and cooled in a magnetic field.

(7): annealed at 500°C in oxygen at 763 mm Hg.

pressures. The results were shown in Fig. 3 (a) by curves (1) to (6). The pressures of the oxygen gas in the successive heat treatments are 0.7, 1.7, 6.4, 28, 160, and 765 mm Hg, respectively. The last heat treatment, corresponding to curve (7), was an annealing at 500°C in oxygen at 763 mm Hg. In these cases also, the directions of the applied magnetic field were always chosen to be perpendicular to that in the foregoing heat treatment. The

results are replotted in Fig. 3 (b) against the pressure of oxygen atmosphere during the heat treatments.

From these measurements it is confirmed that the uniaxial anisotropy in these ferrites are essentially influenced by the degree of oxidation of the specimens and it increases almost monotonously as the degree of oxidation increases.

According to Fig. 1, the final equilibrium state of these specimens in every condition of the above heat treatments is undoubtedly a mixture of hematite and cobalt rich spinel (probably nearly stoichiometric cobalt ferrite). However, it should be pointed out that the oxidization of the ferrite containing divalent iron ions progresses at low temperatures frequently with little precipitation of α hematite but the increase of cation vacancies in the spinel matrix. Therefore, it is also certain that the oxidization in the above heat treatments progresses to some extent in the spinel matrix itself with the associated increase of the cation vacancies. The detailed discussion will be given in § 7.

Together with these measurements of the anisotropy constants, measurements of the magnetostriction of these specimens were carried out at each stage of oxidization by an optical lever method. The measurements were performed on both longitudinal and transverse magnetostriction in both settings at which the applied magnetic field is parallel and perpendicular to the direction of the annealing magnetic field. The results at typical four stages for each specimen are shown in Fig. 3 (c). The abscissa in Fig. 3 (c) does not indicate the effective field but the applied external magnetic field.

Here, the magnetizing characters of these specimens are discussed shortly. According to the measurements performed on single crystals by several authors, the variation of the three major constants K_1 , λ_{100} , and λ_{111} with the composition in iron-cobalt ferrites are as follows: K_1 is about -1×10^6 in magnetite⁽⁴⁾⁽¹⁰⁾, changes sign with slight addition of cobalt ferrite (below one percent)⁽¹⁴⁾, and increases steeply to about 4×10^6 in cobalt ferrite; λ_{100} is about -2×10^{-5} in magnetite, increases its absolute value steeply to -6×10^{-4} in cobalt ferrite; and λ_{111} is about 8×10^{-5} in magnetite, increases slowly to about 1×10^{-4} in cobalt

Fig. 3(b). Change of the uniaxial anisotropy of an iron-cobalt ferrite series with the pressure of oxygen at which specimens were annealed for four hours at 400°C successively. The points on the rightest side indicate the values after annealing at 500°C with the pressure of oxygen at 763 mm Hg.

Fig. 3(c). Change of magnetostriction curve of iron-cobalt ferrites caused by applying various heat treatments successively to the specimens. The notations ||L and ||T or ⊥L and ⊥T mean longitudinal and transverse magnetostrictions in each setting at which the applied magnetic field is parallel or perpendicular to the direction of annealing magnetic field. The pressure of oxygen in the preceding annealing at 400°C is indicated in each unit figure.

errite. All curves in Fig. 8 are explained well by these variations of the constants. The large change of the magnetostriction curves from $r=0$ to $r=0.083$ corresponds clearly to the change of the sign in K_1 . All longitudinal magnetostriction curves of the specimens containing cobalt have positive slopes in high field range. It indicates the presence of the positive magnetostriction constant λ_{111} . It should be pointed out that in spite of the fact that large uniaxial anisotropy is present, the direction of the magnetization of each domain seems to be aligned not so much parallel to the direction of the annealing magnetic field. This conclusion can be deduced from the fact that the magnetostriction does not become so small in the setting at which the applied magnetic field is parallel to the annealing magnetic field. From this view point, it should be also pointed out that the cubic anisotropy predominates especially in $r=0.333$, i. e., stoichiometric cobalt ferrite specimen.

Fig. 4. Torque curves in (100), (110), and (001) planes of a spherical single crystal ($\text{Co}/(\text{Co}+\text{Fe})=0.253$) after cooling in a magnetic field along [001].

4. Uniaxial Anisotropy in Single Crystals of Cobalt Ferrite

A spherical single crystal specimen with the proposed composition $r=0.253$ was heated up to 1000°C in oxygen of about 1~2 mm Hg and cooled with a magnetic field of about 6000 Oe applied along [001] direction. The torque curves of this single crystal in (100), (110) and (001) planes are shown in Fig. 4. It shows

clearly the presence of the uniaxial anisotropy with the easy direction along [001] superposed on the usual cubic crystal anisotropy.

Next the dependence of the magnitudes of the uniaxial anisotropy on the direction of the annealing magnetic field was studied by using another single crystal of (001) disc, having a composition $r=0.283$. After the preparation, it was annealed for two days in air at about 750°C in order to get a sufficiently oxidized state. Then it was heated up to 400°C in air and cooled slowly with an applied magnetic field. The treatment was applied repeatedly with the annealing magnetic field along various crystal directions in the (001) plane. The torque curve for the specimen with the annealing magnetic field applied along [100] is shown in Fig. 5, together with the

Fig. 5. Torque curves for a (001) disc of cobalt ferrite after cooling with and without a magnetic field along [100].

one without the annealing magnetic field. The torque curves with the annealing magnetic field applied along other directions than [100] were very complicated. The magnetic field of 17000 Oe applied at the torque measurements was not sufficient to obtain a saturated magnetization.

The influence of the higher order harmonics can be reduced in the magnetic energy curves which can be obtained from torque curves by integration. Several of these curves are shown in Fig. 6. The uniaxial anisotropy constants were calculated from these curves by using certain approximation techniques. The procedures are given in Appendix.

From these analysis it can be concluded that

an expression of the magnetocrystalline energy in (001) plane of the type:

$$E = K_1 \sin^2 \theta \cos^2 \theta + K_u \sin^2 (\theta - \theta_T) \quad (1)$$

is also applicable in this case, where θ is the angle of the direction of the magnetization from [100], and θ_T is the angle of the direction of the uniaxial anisotropy from [100]. It was found in every case that the direction of the uniaxial anisotropy coincided with that of the annealing magnetic field within several degrees.

The expression given above is the same as that proposed for cobalt-zinc ferrite by Bozorth *et al.*¹⁰⁾. However, being different from their

Fig. 6. Effect of magnetic anneal in various directions in (001) plane taken for a (001) disc of cobalt ferrite. Energy curves are illustrated and the direction of annealing magnetic fields is indicated by an arrow.

Fig. 7. Uniaxial anisotropy constant of cobalt ferrite plotted against the direction of annealing magnetic field in (001) plane.

results, our value of K_u was dependent on the direction of the annealing magnetic field. (The value of K_1 was about 2×10^6 ergs/gr.*). The results are shown in Fig. 7. It is shown that $\langle 100 \rangle$ is the most effective direction for the magnetic annealing, while $\langle 110 \rangle$ the least effective in (001) plane. This variation of the magnitudes of the uniaxial anisotropy with the direction of the annealing magnetic field is smaller than that which is predicted by Néel's theory but larger than that which is calculated by Taniguchi. There are some

Fig. 8(a), (b). Uniaxial anisotropy of a cobalt ferrite at liquid air temperature as compared with that at room temperature. (a) shows the torque curve in the (001) plane, and (b) shows the variation of maximum torque with the strength of applied magnetic field in the measurements.

ambiguities about the measurements along the directions near [110] in Fig. 7. The annealing magnetic field of about 7000 Oe is not sufficiently large to saturate the magnetization completely along these directions.

The uniaxial anisotropy constant increases steeply as the temperature is lowered. Figs. 8(a) and (b) show the results. Fig. 8(a) shows the torque curves at 25°C and -183°C of the

* K_2 of about -1.5×10^6 ergs/gr was observed for a (111) disc specimen with $r=0.333$ made by flux method.

001) disc specimen after annealed with a magnetic field applied along [010]. Fig. 8 (b) shows the variation of the maximum value of the torque with the intensity of the applied magnetic field in these measurements. As can be seen, at -183°C , saturation of the magnetization has not been attained by the magnetic field applied.

Lastly, the specimen was annealed at 750°C for one day in a high vacuum and cooled with and without applied magnetic field along [100]. The results are shown in Fig. 9. In accordance with the result for the polycrystalline specimens, the magnitude of the uniaxial anisotropy reduced to almost zero by this vacuum treatment.

Fig. 9. Torque curves of a cobalt ferrite single crystal after annealing in a vacuum, showing a remarkable decrease of the magnetic annealing effect.

§ 5. Relaxation Character of the Uniaxial Anisotropy

It is well known that the magnetic annealing effect shows magnetic relaxation phenomenon in its effective temperature range¹⁵⁾. Our experiments were performed on a disc-shaped polycrystalline cobalt ferrite by a torque-meter at high temperatures. The specimen was heated up in a furnace to 600°C in air, kept 30 minutes, and cooled down with an applied magnetic field of about 4000 Oe to a desired temperature. After maintaining for about 30 minutes at this temperature, the specimen was abruptly rotated by 45 degrees with its normal axis as the rotation axis. In this case a torque L_u must be exerted to the

specimen in order to maintain the orientation of the specimen unchanged. This torque L_u was considered to be proportional to the uniaxial anisotropy $K_u(t)$ which should have been formed in the specimen during the preceding heat treatment along the direction of the applied magnetic field and should be decaying after the rotation. In these conditions, a new uniaxial anisotropy K_u' would grow along the new direction of the applied magnetic field, but it should have no effect on the torque.

(a)

(b)

Fig. 10 (a), (b). Decaying of the torque of a cobalt ferrite disc with time of annealing in a magnetic field. The torque is due to the presence of the uniaxial anisotropy induced by the preceding cooling and annealing with an applied magnetic field along the direction different by 45 degrees from the direction of the magnetic field during measurements. Characters are illustrated by different scales in (a) and (b).

Fig. 10(a) and (b) show the obtained results.

It has been found that these curves can be expressed accurately (within the experimental errors) by an empirical formula:

$$K_u(t) = K_0 \exp \{ -t/(\tau + \alpha t^{1/2}) \} \quad (2)$$

with suitable values of K_0 , τ , and α . The values of K_0 , τ , and α are shown in Fig. 11.

Fig. 11. Uniaxial anisotropy constant K_0 , half time $t_{1/2}$, and two constants τ and α are plotted against the reciprocal of temperature. Activation energy determined from the half time curve is 1.6 eV.

In the figure, the annealing time $t_{1/2}$ at which the torque becomes one half of the initial value is also shown. We can see from these curves, in accordance with the conclusion in § 2, that there is no critical temperature for the phenomenon. The activation energy calculated from the inclination of the $\log t_{1/2} - 1/T$ curve is 37000 cal/mole = 1.6 eV.

Similar studies of the relaxation were also carried out by Sakamoto¹⁸⁾ (variation of the residual magnetization of a polycrystalline cobalt ferrite) and Bozorth *et al.*¹⁰⁾ (variation of the ratio of the first minimum torque to the first maximum torque of a cobalt-zinc ferrite single crystal). Both reported also that there was no critical temperature, giving the activation energies of 37500 cal/mole, and 21400 cal/mole, respectively.

§ 6. Electrical Conductivity in Polycrystals

In order to observe the variation of the electrical conductivity as a function of temperature, two sets of polycrystalline specimens with the identical series of compositions x were prepared. One set of specimens were those by the standard method, i.e., prepared by heat treatment "S". Another set of specimens were those which were considered to be in the most deoxidized state, i.e., heat-treated according to the program of heat treatment "S" and then annealed at 900°C for four hours in a high vacuum.

Fig. 12. The conductivity of iron-cobalt ferrites in a somewhat oxidized state as a function of temperature. The composition of each ferrite is indicated in the figure.

The measurements were made from about 700°C to liquid air temperature in a high vacuum. The results for the former set of specimens are shown in Fig. 12 and that for the latter in Figs. 13(a) and (b).

As shown, no anomaly is observed at about

300°C for all the curves. This supports also that there is no phase change in this temperature range. The curves in Fig. 12 for the specimens with compositions $r=0.000$, 0.083, 0.167, and 0.250 have slight angles at about 300°C. The angles, however, are so slight that they will not indicate the presence of any structural change. The fact that the angle is present also in magnetite ($r=0$) suggests that it might be related to the rapid change of diffusion rates of cations in the ferrite matrix¹³.

In Fig. 13 (b), the well-known low temperature transition of magnetite is seen at -160°C. Comparing with Verwey's data, it shows that this specimen is nearly stoichiometric¹⁷. The specimen of magnetite of the former set did not show any anomaly in this low temperature range.

§ 7. A Possible Mechanism of the Uniaxial Anisotropy

Various mechanisms were already proposed in order to explain the uniaxial anisotropy in iron-cobalt ferrites. Considering all the experi-

Fig. 13 (a), (b). The conductivity of iron-cobalt ferrites in a deoxidized state (probably near stoichiometric composition) as a function of temperature. At high temperatures in (a), and at low temperatures in (b).

mental results mentioned, however, we reached to another mechanism.

Our propositions are as follows.

I. Below the Curie temperature, a certain degree of directional local ordering between the magnetic ions and cation vacancies is formed along the direction of the spontaneous magnetization in these ferrites.

II. Iron-cobalt ferrites have no phase changes in the temperature range from 400°C to room temperature. For the time duration of the order of our experiments, however, the diffusion rate of cations seems to decrease

remarkably below about 300°C and the cation configuration realized at that temperature is fixed fairly completely by the ordinary cooling.

Proposition I is deduced mainly from the magnetic data which show strong dependence of the magnitude of the uniaxial anisotropy on the degree of oxidation, and the relaxation experiments which show that the direction of the uniaxial anisotropy is reversibly changeable at high temperatures, regardless of the duration of the preceding annealing, i.e., there is no "over-aging effect".

On this model it is reasonable to assume that cation vacancies in these ferrites distort the crystalline fields at the neighbouring sites severely. Since it is known that a cobalt ion in these ionic crystals has a strongly anisotropic wave function coupled to its spin direction through spin-orbit coupling, the electronic energy of the Co^{++} ion neighbouring a vacancy may depend considerably on its spin direction referred to the direction of the pair of the Co^{++} ion and the vacancy. (It is well known that the lowest orbital energy level of a Co^{++} ion in a cubic crystalline field is a triplet, whereas that of a Fe^{+++} ion is a singlet¹⁸.) Then, it follows that the pair energies of magnetic ions, especially of cobalt ion and a vacancy, are affected by the change in their spin direction, resulting in non uniform distribution of the number of the pairs referred to the spin direction (Fig. 14).

Fig. 14. Illustration of the directional order present between a cobalt ion, iron ions, and a cation vacancy. The smallest unit of cation arrangement on 16d sites in spinel is shown. Dotted arrows indicate the direction of the anisotropic crystalline field induced by the presence of a vacancy.

Accordingly, below the Curie temperature, where the magnetic moments in 16d sites are aligned parallel mutually, the directional short range ordering is expected to be formed along the direction of the magnetization. The directional order should increase as the temperature is lowered, as expected from Fig. 11, and would be fixed in the temperature range from

300°C to 200°C owing to the rapid decrease of the diffusion rate of cations. The uniaxial anisotropy at room temperature is thus formed by the presence of this directional ordering.

Even if the specimen is annealed without a magnetic field, each magnetic domain of the specimen has a uniaxial anisotropy along its spontaneous magnetization but the total uniaxial anisotropy of the specimen is canceled out.

§ 8. Discussions on Other Mechanisms

Many mechanisms have been already presented for the origin of the uniaxial anisotropy in iron-cobalt ferrites. Bozorth *et al.* discussed these mechanisms in detail¹⁰, pointing out certain difficulties involved in each of the mechanisms. Here, difficulties will be pointed out again from the stand point based on our experimental results.

The first mechanism¹⁹, suggested by Néel, is the one which ascribes the uniaxial anisotropy to the directional order between cobalt ion and iron ion. It is a straightforward extension of the mechanism successful in explaining the magnetic annealing effect in metallic solid solutions. However, it has difficulties in explaining the observed strong dependence of the uniaxial anisotropy on the degree of oxidation. An assumption seems to be possible that the dependence is caused by the change of the diffusion rate of cations due to the change of the concentration of cation vacancies. But as can be seen from our various relaxation experiments (in § 3, and § 5), it is almost certain that we are dealing with the almost saturated value of the uniaxial anisotropy.

The second mechanism is the one which assumes the preferential growth of micro-precipitates of the second phase²⁰. In this case two different mechanisms are considered: The one is based on the anisotropy induced by the change of magnetostatic energy with the direction of magnetization, and the other on the anisotropic surface energy due to the spin-orbit coupling of the magnetic ions as proposed by Néel¹⁹. The magnetostatic energy in this case, however, is estimated roughly by

$$E_u = \frac{1}{2} \Delta N \cdot (\Delta M_s)^2 \cdot v(1-v) \lesssim 10^6 \text{ ergs/cc} \quad (3)$$

where v is the total volume fraction of the precipitates. It is much smaller than that

observed experimentally ($\sim 10^6$ ergs/cc). It can not explain also the steep increase of the anisotropy at low temperatures. Therefore, the former mechanism by magnetostatic energy will not be applicable in this case. H. J. Williams *et al.*¹¹⁾ stated recently that they had proved experimentally the existence of the second phase with spinel structure. However, their electron diffraction patterns of the second phase obtained for cobalt-zinc ferrites seem to involve some ambiguous points and they have not determined the composition of the second phase. The phenomenon of the torque reversal in single crystals of these ferrites, which they considered an evidence for the existence of the precipitates, should be regarded as a general property of single crystals which respond to magnetic annealing, as pointed out by Chikazumi and others²¹⁾.

According to the phase diagram in Fig. 1, it is probable that the relevant second phase is α hematite²²⁾. However, there are many experimental facts against the mechanism by precipitation of α hematite. Those are:

(1) Cobalt rich specimens ($r=0.333$ and 0.417) have also the uniaxial anisotropy of the same order of magnitude. It may be difficult to suppose the precipitates of α hematite existing in these specimens in the same order of amount as in the cobalt poor specimens.

(2) X-ray study has shown that the iron-cobalt ferrites are oxidized easily (and with appreciable decreases in lattice constants) without changing the crystal structure.

(3) The observation of the relaxation of the uniaxial anisotropy shows that the decaying down or growing up of the uniaxial anisotropy takes place fairly rapidly and the phenomenon has no critical temperature. At about 350°C , the change is finished almost within a minute. It will be difficult to assume that the shape of precipitates of α hematite is altered so rapidly at these temperatures. Relating to this consideration it should be also mentioned that in the experiments in §3, the magnetic annealing effect does not decay down after the prolonged annealing.

The plastic deformation theory seems too poor to bear quantitative discussions. One more mechanism might be considered that some linear or planar imperfections such as dislocation lines or dislocated layers (analogous to the stacking fault in the extended

dislocation) combine with the cobalt ions and make directional configurations. It should, however, be noticed that the density of such imperfections large enough to be effective for the uniaxial anisotropy must be much larger than that probably existing in the usual oxides.

Our mechanisms can account for all the experimental results well. Above-mentioned fact (1) is explained by considering that the Co^{++} ions can be oxidized to Co^{+++} ions and accordingly vacancies must be also present in the cobalt rich specimens. The fact (2) is a convincing evidence for the existence of a considerable amount of cation vacancies. The fact (3) is quite natural in our mechanism, for the local order will easily change its directionality through several elementary processes of ionic migration.

It is added here that a suitable explanation can be given to the fact in Fig. 5 that the anisotropy is rather small for pure cobalt ferrite. Namely, the composition might be especially favourable to make a certain short range order of iron and cobalt ions in the 16d sites in the meaning of the usual non-directional superstructure²³⁾ and this tendency suppresses the growth of the directional local order between vacancies and cobalt ions; an analogous situation is seen in the case of Ni_3Fe .

Quite recently Oguchi²⁴⁾ has performed a theoretical calculation of the uniaxial anisotropy in the case of our model. Assuming that the crystalline field on the 16d sites neighbouring a cation vacancy is orthorhombic, he has concluded that the energy of the cobalt ion at A position in Fig. 14 can be lower than that at B position by about 30 cm^{-1} . He gives a maximum of anisotropy along $\langle 100 \rangle$ direction and zero along $\langle 110 \rangle$ and $\langle 111 \rangle$. His result agrees in tendency with our experimental result shown in Fig. 12. The discrepancy should be mainly due to several simplified assumptions made by him.

Lastly, we will mention about the uniaxial anisotropy of other ferrites. According to our mechanism, every kind of other ferrites are expected to show the magnetic annealing effect to some extent after appropriate oxidation heat treatment, although the magnitude of the induced uniaxial anisotropy is to depend on both the manner of splitting of the orbital energy levels under the influence of the cry-

stalline field and the strength of the spin-orbit coupling of the metal ions concerned. We found that the iron-nickel ferrites show magnetic annealing effect which is also dependent on the degree of oxidation of the specimens²⁶⁾. This effect certainly exists also in iron-manganese ferrites, as inferred from permeability measurements²⁶⁾. It can also be possible that Néel's mechanism, i.e., directional order without vacancy, is dominant in the case where the concentration of vacancies is very small.

Acknowledgments

We wish to express our hearty thanks to Prof. Seiji Kaya for his advice and constant encouragements. We also thank to Mr. Hiroshi Nakamura of the Mitsubishi Electric Mfg. Company for his kind communications of his data, to Mr. Takehiko Oguchi for permission to mention his unpublished results, and to Mr. Motoo Hori for his cooperation in the early stage of our study.

This research was financially supported by the Scientific Research Expenditure of the Ministry of Education.

Appendix Analysis of the Torque Curves

It is first assumed that the magnetic free energy of the (001) disc specimen in torque measurements is expressed as

$$E = K_1 \sin^2 \varphi \cos^2 \varphi + K_u(\theta_T) \sin^2(\varphi - \theta_T) - HM \cos(\varphi - \theta) \quad (1)$$

Here, φ , θ_T , θ are the angles of the directions of the magnetization M , of the annealing magnetic field and of the applied magnetic field H from [100] axis.

φ should be determined from the equation:

$$\frac{\partial E}{\partial \varphi} = 0. \quad (2)$$

The condition is rewritten as

$$\begin{aligned} & \frac{K_u}{HM} \left[\sin 2(\theta - \theta_T) \cos 2\varepsilon + 2(\theta - \theta_T) \sin 2\varepsilon \right] \\ & + \frac{K_1}{2HM} \left[\sin 4\theta \cdot \cos 4\varepsilon + \cos 4\theta \cdot \sin 4\varepsilon \right] \\ & + \sin \varepsilon = 0 \end{aligned} \quad (3)$$

where

$$\varepsilon = \varphi - \theta. \quad (4)$$

In our measurements, $K_u \approx 1.5 \times 10^6$ ergs/cc, $K_1 = 2 \times 10^6$ ergs/cc and $HM \approx 7 \times 10^6$ ergs/cc. So that

$$\frac{K_u}{HM} \approx 0.21 < 1, \quad \frac{K_1}{2HM} \approx 0.14 < 1, \quad (5)$$

Therefore, by expanding $\sin \varepsilon$ in the powers of $K_u/H \cdot M$ and $K_1/2 \cdot H \cdot M$, we can obtain $\sin \varepsilon$ from Eq. (3) with successive approximation. Using this expression, the magnetic energy of the specimen is expressed as a function of θ .

$$\begin{aligned} E(\theta_T, \theta) = & - \int L d\theta = \frac{1}{2} K_u(\theta_T) + \frac{K_1}{8} \\ & - \frac{K_u}{2} \cos 2(\theta - \theta_T) - \frac{K_1}{8} \cos 4\theta \\ & - \frac{K_u}{2} \cdot \frac{K_1}{2HM} \cos 2(\theta + \theta_T) \\ & + \frac{K_u}{2} \cdot \frac{K_u}{HM} \cos 4(\theta - \theta_T) \\ & + \frac{K_u}{2} \cdot \frac{K_1}{2HM} \cos(6\theta - 2\theta_T) \\ & + \frac{K_1}{8} \cdot \frac{K_1}{2HM} \cos 8\theta + \dots \end{aligned} \quad (6)$$

Fig. 15. Comparison of the experimental curves (full lines) and the calculated curves (dotted lines).

The expression can be simplified by taking the difference of the two curves in which the directions of the two annealing magnetic fields make a right angle. Namely,

$$\begin{aligned} & E(\theta_T, \theta) - E\left(\theta_T + \frac{\pi}{2}, \theta\right) \\ & = F(\theta_T, \theta) = -K_u \cos 2(\theta - \theta_T) \\ & \quad - 2K_u \cdot \frac{K_1}{2HM} \cdot 4 \sin 4\theta \cdot \sin 2(\theta - \theta_T). \end{aligned} \quad (7)$$

Therefore,

$$F\left(\theta_T, \theta_T + \frac{\pi}{2}\right) - F(\theta_T, \theta_T) = 2K_u. \quad (8)$$

Basing upon these arguments, we performed

14 pairs of heat treatments in which every pair consists of two heat treatments with the applied magnetic fields at a right angle with each other. Some typical curves of $F(\theta_T, \theta)$ are shown in Fig. 15. The two dotted curves were drawn by calculating the right-hand side of Eq. (7), using the values of parameters K_u , and $K_1/2HM$ determined from the experimental curves. They fit fairly well with the experimental curves, showing the appropriateness of the procedure.

Narrowing Effect in Nuclear Magnetic Double Resonance in Solids

By Yushiro SAITO

Department of Physics, Kobe University

(Received September 9, 1957)

Experiments on nuclear magnetic double resonance were performed in several ionic crystals of type AB where the resonance behavior of the A-spin was investigated under the irradiation of strong rf field resonating to the B-spin. At the strongest rf field experimented, narrowing of the line width was observed and this fact showed evidently that the local field at the position of A-spin originating from B-spin was averaged out to zero. By using this principle the origin of the anomalously broad line width in TlBr crystal was pursued. The experimental results supported our suggestion that the broad line width would be attributable to the indirect nuclear spin-spin coupling. The second moment of the line width in double resonance calculated by the use of rotating coordinate system was in agreement with the experimental value.

§ 1. Introduction

Recently the technique of the double resonance has been applied to various problems, especially the precise measurement of the h.f. coupling constant,¹⁾ the determination of the molecular structures,²⁾ the analysis of the relaxation time,³⁾ the nuclear polarization,^{3),4)} the Maser⁵⁾ and so on.⁶⁾ But there have been few⁷⁾ of the n.m. double resonance experiments in *Solids*. In this paper we reported the experimental results of the n.m. double resonance in solids, discussed the condition for narrowing of the line width in a double resonance experiment, and analysed the origin of the anomalously broad line width in TlBr crystal.

In some of the thallium halide crystals, the observed line widths are much larger than the theoretical ones calculated by the direct dipolar couplings between nuclear magnetic moments. For example, the observed second moments of the Tl²⁰⁵ and the Br^{79,81} resonances in TlBr crystal are both about ten times larger than the calculated ones. Yosida and Moriya⁸⁾ estimated the line width due to the indirect *I-I* coupling caused by the partially covalent bonding in ionic crystals. To get the coupling constant appropriate to the experimental line width, the theory needed a great degree of covalency between the thallium and the bromine atoms which was inconsistent with the chemical shift data of n.m. resonance⁹⁾ of the Br spin. Therefore, it was

desired to analyse the contribution of each constituent magnetic isotope to the line width. The narrowing effect observed in our double resonance experiments is well fitted for this purpose as will be stated below.

Hereafter we will call it the "AB-experiment" where the former, "A" denotes the nucleus whose resonance behavior is under investigation with the weak rf field and the latter, "B", the nucleus irradiated by the strong rf field.

§ 2. Experiments and Results

The AB-experiment was performed by the use of permanent magnet of field strength either of 6200 gauss or of 3900 gauss. Keeping the frequency f_B constant, n.m. resonance of the A-spin was observed by sweeping the frequency f_A by a slow rotation of the axis of the variable condenser of the autodyne detector. Experimental diagram is shown schematically in Fig. 1. As the rf voltage applied to the coil B amounted to as much as 800 volts (effective value) we had to prevent the coil from heating up by blowing the air cooled by the freezing mixture (dry ice and ethyl alcohol system). For the measurements of the net effect of strong rf field resonating to the B-spin, the line width and the intensity of A-resonance in the just-resonant case, $f_B = f_B^0$, were compared with those in the completely off-resonant case, $f_B \gg f_B^0$ or $f_B \ll f_B^0$, alternately, in order to cancel the spurious effects

caused by the strong irradiating field.

In the case of $f_B = f_B^0$ and in some kinds of crystals having rather long relaxation time, as we increased the rf voltage of f_B , the intensity of A-resonance gradually decreased and finally disappeared from observation. We call this phenomenon "collapsing". As the field strength was further increased, the resonance line appeared again, but in this time with a narrowed line width. This narrowing effect was observed in *all* the crystals experimented and so, these two phenomena, collapsing and narrowing, are considered to be of different origins. Since the collapsing is not yet thoroughly interpreted, we here report only about the narrowing effect.

Consider the $Tl^{205}F^{19}$ -experiment. While the rf field $2H_2 \cos \omega_2 t$ was irradiated to the F^{19}

Fig. 1. Block diagram of the experimental apparatus.

spin, the resonance line of the Tl^{205} spin was observed. The variation of the maximum slope separation $(\Delta H)_{ms}$ of Tl^{205} resonance with the strength of the rf field H_2 is shown in Fig. 2 and Photo. 1. In Fig. 2 the dotted line corresponds to the region where the collapsing was observed and hence the width could not be measured exactly. The intensity

Fig. 2. Variation of the maximum slope separation $(\Delta H)_{ms}$ of Tl^{205} resonance with the strength of rf field H_2 irradiating to F^{19} spin in $Tl^{205}F^{19}$ -experiment.

a) off-resonant case, $f_F - f_F^0 \approx 100$ kc/sec ($f_F^0 = 16.0$ Mc/sec.), which is the same as the case of single resonance.

b) just-resonant case, $f_F = f_F^0$, which shows the narrowed width compared to the case a).

(maximum deflection of the derivative curve) of the most narrowed resonance was unexpectedly approximately the same as that of the original broad resonance. But the intensity problem in the $\text{Tl}^{205}\text{F}^{19}$ -experiment cannot be further discussed because of the simultaneous occurrence of the collapsing effect.

In Table I are listed the calculated second moments¹⁾ contributed from each constituent isotope under the assumption of the direct dipolar coupling alone, and also the observed second moments in single and double resonances in TlF and TlBr crystals. The condition for narrowing will be discussed in Sec.

3 in terms of the relation of the strength of rf field to the line width. The line shape in single resonance in these crystals was nearly Gaussian. In the double resonance experiments, we had to use as small an amount of powder sample as possible in order to produce the large strength of rf field. Accordingly the resonance was inevitably of low S-N ratio, so that the second moment in double resonance experiment was forced to be estimated from the peak-to-peak separation of a derivative curve under the assumption of Gaussian shape. In the case of $\text{Tl}^{205}\text{F}^{19}$ -experiment (the 3rd column in Table I), the narrowed width

Table I. Calculated second moments from constituent isotopes and experimental values in single and double resonances in TlF and TlBr crystals.

crystal	TlF		TlBr	
observed nuclei	F^{19}	Tl^{205}	$\text{Br}^{81,79}$	Tl^{205}
dipolar contribution from halogen nuclei	1.31 gauss ²	2.13 gauss ²	0.17 gauss ² 0.16 ²⁾	0.25 gauss ²
dipolar contribution from Tl^{205} nucleus	0.51	0.31	0.18	0.16
dipolar contribution from Tl^{203} nucleus	0.21	0.06	0.07	0.03
total $\langle \Delta H^2 \rangle_{\text{cal}}$	2.03	2.50	0.42 0.41 ²⁾	0.44
$\langle \Delta H^2 \rangle_{\text{exp}}$ in single resonance	2.6	3.1	10.2	20.4
$\langle \Delta H^2 \rangle_{\text{exp}}$ in double resonance ¹⁾	1.7 ($\text{F}^{19}\text{Tl}^{205}$ —exp)	0.3 ($\text{Tl}^{205}\text{F}^{19}$ —exp)	3.7 ($\text{Br}^{81,79}\text{Tl}^{205}$ —exp) 7.4 ($\text{Br}^{81,79}\text{Tl}^{203}$ —exp)	

1) estimated from Gaussian-shape assumption.

of 0.3 gauss² is almost in agreement with the difference between the calculated total width of 2.5 gauss² and the width of 2.1 gauss² from the F^{19} spin, or with the width of 0.4 gauss² from only Tl^{203} and Tl^{205} spins. This fact shows evidently that the field, existing at the location of the Tl spin and originating from the F spin, is averaged out to zero, and that the remaining local field is due to only Tl^{203} and Tl^{205} spins. And further referring to the 6th and 7th rows of this Table, we see that the second moments of Tl and Br resonances in TlBr crystal calculated from the above-mentioned dipolar assumption account for only

a few per cent of the experimental values. The peak-to-peak separation reduced to about 60 per cent of original one in $\text{Br}^{79,81}\text{Tl}^{205}$ -experiment and to about 85 per cent in $\text{Br}^{79,81}\text{Tl}^{203}$ -experiment. The contribution of the Tl^{205} spin to the second moment of $\text{Br}^{79,81}$ resonance was proved, by our double resonance experiments, to be 64 per cent, and that of the Tl^{203} spin to be 28 per cent of total ones. Taking into account the magnetic moment ratios and abundances of these two isotopes, the experimental results confirmed that the broadening originated from the interaction between nuclear spins themselves and not from, say, pa-

ramagnetic impurities and so on.

§ 3. Discussion

Consider a crystal which includes three spin species A ($S, g, j=1, 2, \dots N$), B' ($S', g', j'=1, 2, \dots N'$) and C'' ($S'', g'', j''=1, 2, \dots N''$) and a case when a strong rf field is impressed to B' -spin and a weak rf field for observation to A -spin. The total Hamiltonian of the system in Van Vleck's notation¹²⁾ is the sum of

$$\mathcal{H} = \mathcal{H}_z + \mathcal{H}_{\text{dip.}+\text{ex.}} + \mathcal{H}_{\text{strong rf}} \quad (1)$$

and

$$\mathcal{H}_{\text{det. rf}}$$

where

$$\mathcal{H}_z = g\beta H_0 \sum_j S_{zj} + g'\beta H_0 \sum_{k'} S'_{zk'} + g''\beta H_0 \sum_{l''} S''_{zl''} \quad (2)$$

$$\mathcal{H}_{\text{dip.}+\text{ex.}} = \sum_{j \neq k} \mathcal{H}_{jk} + \sum_{j' \neq k'} \mathcal{H}_{j'k'} + \sum_{j'' \neq k''} \mathcal{H}_{j''k''} + \sum_{jk'} \mathcal{H}_{jk'} + \sum_{jl''} \mathcal{H}_{jl''} + \sum_{jk''} \mathcal{H}_{jk''} \quad (3)$$

$$\mathcal{H}_{jk} = \frac{1}{2} (A_{lk} \mathbf{S}_j \cdot \mathbf{S}_k + B_{jk} S_{zj} S_{zk}) \quad (4)$$

etc. (between like spins)

$$\mathcal{H}_{jk'} = C_{jk'} S_{zj} S'_{zk'}$$

etc. (between unlike spins) (5)

$$\mathcal{H}_{\text{strong rf}} = g'\beta \sum_{k'} S'_{zk'} 2H_2 \cos \omega_2 t \quad (6)$$

$$\mathcal{H}_{\text{det. rf}} = g\beta \sum_j S_{zj} 2H_1 \cos \omega_1 t. \quad (7)$$

In the above Hamiltonian, A_{jk} and $C_{jk'}$ correspond to the expressions (6) and (26) of Van Vleck's paper, respectively, that is, contain dipolar and exchange couplings.

Transform this Hamiltonian by the operator

$$R_{z\omega_2 t} = \exp [-i\omega_2 t \sum_j S_{zj}] \cdot \exp [-i\omega_2 t \sum_{k'} S'_{zk'}] \times \exp [-i\omega_2 t \sum_{l''} S''_{zl''}] \quad (8)$$

to the r -system¹³⁾ (rotated around the z -axis by an angle $\omega_2 t$) and then transform the B' spin-coordinate alone by the operator

$$R_{y\theta} = \exp [-i\theta \sum_{k'} S'_{yk'}] \quad (9)$$

to the ρ -system (rotated around the y -axis by an angle $\theta = \tan^{-1}[\gamma H_2/(\omega_2 - \omega_0')]$, which is the angle between the z -axis and the direction of the effective field for the B' spin, ω_0' being resonance frequency of the B' -spin). And we get:

$$\mathcal{H}^\rho = \mathcal{H}_z^\rho + \sum_{j \neq k} \mathcal{H}_{jk} + \sum_{j' \neq k'} \mathcal{H}_{j'k'}^\rho + \sum_{j'' \neq k''} \mathcal{H}_{j''k''} + \sum_{jk'} \mathcal{H}_{jk'}^\rho + \sum_{k'l''} \mathcal{H}_{k'l''} + \sum_{jl''} \mathcal{H}_{jl''} \quad (10)$$

and

$$\mathcal{H}_{\text{det. rf}}^\rho = g\beta H_1 [\sum_j S_{zj} \cos(\omega_1 - \omega_2)t - \sum_j S_{yj} \sin(\omega_1 - \omega_2)t] \quad (11)$$

where

$$\mathcal{H}_z^\rho = g\beta(H_0 - \omega_2/\gamma) \sum_j S_{zj} + g'\beta[(H_0 - \omega_2/\gamma')^2 + H_2^2]^{1/2} \sum_{k'} S'_{zk'} + g''\beta(H_0 - \omega_2/\gamma'') \sum_{l''} S''_{zl''} \quad (12)$$

$$\mathcal{H}_{j'k'}^\rho = \frac{1}{2} \left[A_{j'k'} S'_{j'} \cdot S'_{k'} + B_{j'k'} \cos^2 \theta S'_{zj'} S'_{zk'} + \frac{1}{4} B_{j'k'} \sin^2 \theta (S'_{j'}^+ S'_{k'}^+ + S'_{j'}^- S'_{k'}^- + S'_{j'}^+ S'_{k'}^- + S'_{j'}^- S'_{k'}^+) + \frac{1}{2} B_{j'k'} \sin \theta \cos \theta \{ S'_{zj'} (S'_{k'}^+ + S'_{k'}^-) + S'_{zk'} (S'_{j'}^+ + S'_{j'}^-) \} \right] \quad (13)$$

$$\mathcal{H}_{jk'}^\rho = C_{jk'} S_{zj} \left[S'_{zk'} \cos \theta + \frac{1}{2} (S'_{k'}^+ + S'_{k'}^-) \sin \theta \right] \quad (14)$$

$$\mathcal{H}_{k'l''}^\rho = C_{k'l''} S''_{zl''} \left[S'_{zk'} \cos \theta + \frac{1}{2} (S'_{k'}^+ + S'_{k'}^-) \sin \theta \right]. \quad (15)$$

Applying the Van Vleck's method to ρ -system, it follows that

$$h^2 \langle \nu_\rho^2 \rangle_{\text{Av}} = - \frac{T_r [U^\rho]^2}{T_r [\mathcal{H}_{\text{det. rf}}^\rho]^2}$$

and

$$h^4 \langle \nu_\rho^4 \rangle_{\text{Av}} = \frac{T_r [\mathcal{H}^\rho U^\rho - U^\rho \mathcal{H}^\rho]^2}{T_r [\mathcal{H}_{\text{det. rf}}^\rho]^2}, \quad \left. \vphantom{\frac{T_r [\mathcal{H}^\rho U^\rho - U^\rho \mathcal{H}^\rho]^2}{T_r [\mathcal{H}_{\text{det. rf}}^\rho]^2}} \right\}$$

where

$$U^\rho = \mathcal{H}^\rho \mathcal{H}_{\text{det. rf}}^\rho - \mathcal{H}_{\text{det. rf}}^\rho \mathcal{H}^\rho. \quad (17)$$

(16) In the above expression $\langle \nu_\rho^2 \rangle_{\text{Av}}$ means the

mean square deviation of the frequency of A-resonance spectrum from the frequency of irradiating field $\omega_2/2\pi$.

Under the condition

$$g'\beta H_2 \gg g\beta H_{\text{loc}} = \sum (A_{jk}, B_{jk}, C_{jk'}, C_{jk'')}, \quad (18)$$

where $2H_{\text{loc}}$ means the peak-to-peak separation of A-resonance, the side bands resulted from the terms including $S'_{k'}^{\pm}$ do not overlap the central one. Then by the use of the "truncated" Hamiltonian missing such terms as $S_{zj} \cdot S'_{k'}^{\pm}$, the second moment in the ρ -system is obtained as follows:

$$\begin{aligned} h^2 \langle \Delta\nu^2 \rangle_{\text{Av}} = & \frac{1}{3} S(S+1) \sum_k B_{jk}^2 \\ & + \frac{1}{3} S'(S'+1) \sum_{k'} C_{jk'}^2 \cos^2 \theta \\ & + \frac{1}{3} S''(S''+1) \sum_{k''} C_{jk''}^2. \end{aligned} \quad (19)$$

In the case of just-resonance, $f_B = f_B^0$, and of

strong rf field $H_2 \gg (g/g')H_{\text{loc}}$, we may put $\cos \theta = 0$ and then both dipolar and exchange couplings with B'-spin cease to contribute to the second and the fourth moments of A-resonance, whereas the contribution from A and C'' spins leaves unchanged. In the $\text{Tl}^{205}\text{F}^{19}$ - and $\text{F}^{19}\text{Tl}^{205}$ -experiments, the above results were confirmed quantitatively (Fig. 2, and Table I).

In our experiments, the necessary condition for narrowing, that is, the expression (18) was satisfactorily fulfilled as shown in Table II and the complete narrowing was experimentally ascertained.

Finally, consider the origin of the anomalously broad resonance width in TlBr -crystal. As seen from Table I, the total second moment of the Br single resonance and the narrowed moment of the BrTl^{205} -experiment are 10.2 gauss² and 3.7 gauss², respectively, and

Table II. The relation between the strength of irradiating field $2H_2 \cos \omega_2 t$ and the line width of observed spin.

H_2	7	15	10	10	

1) $2H_{\text{loc}}$ means the maximum slope separation of the observed resonance.

2) The unprimed γ is the gyromagnetic ratio of the observed spin and the primed γ' is of the irradiated spin.

we may expect that the difference between them corresponds to the contribution from the Tl^{205} spin. We see from this Table that this difference, 6.5 gauss², is nearly equal to the moment in the BrTl^{205} -experiment, 7.4 gauss², which includes the contributions from Tl^{205} and Br nuclei. These experimental results show that the contributions to Br resonance width from Br spins or nuclear electric quadrupole coupling are negligibly small. Possible quantitative explanation of broad line widths will be given below.

When two atoms A and B are covalently bonded in a crystal through their s or p electrons, the exchange or dipolar coupling between electron and nucleus will produce an indirect spin-spin coupling between A and B

nucleus. Generally, this coupling is expressed as a sum of the exchange type and the dipolar type;

$$\begin{aligned} \mathcal{H}_{\text{AB}} = & a\gamma_A\gamma_B\hbar^2 \mathbf{I}_A \cdot \mathbf{I}_B \\ & + b\gamma_A\gamma_B\hbar^2 \{ \mathbf{I}_A \cdot \mathbf{I}_B - 3(\mathbf{R} \cdot \mathbf{I}_A)(\mathbf{R} \cdot \mathbf{I}_B) \} \end{aligned} \quad (20)$$

where $\mathbf{R}$ is a unit vector connecting A and B nucleus. Expressions of a and b are listed in Table III for s and p electronic wave functions belonging to A or B atom. Using $4p$ -orbital of Br atom and $7s$ -orbital of Tl atom, $\langle 1/r^3 \rangle_p$ given by Barnes and Smith¹⁴⁾, h.f.s.-constant¹⁵⁾, and corrected excitation energy⁶⁾, we get the degree of covalency per bond of 33 per cent to interpret the experimental line width. The change of $7s$ of Tl to $6p$ orbital will give too weak a coupling to inter-

prete the width (Table IV). On the other hand, the chemical shift of Br-resonance is explained by the covalency per bond of 4.4 per cent⁹⁾ and that of Tl resonance by the covalency of 9.4 per cent.¹⁶⁾

Table III. The coefficients a and b of the indirect exchange and the pseudo-pipolar couplings in the Expression (20).

electronic orbital		a	b
A	B		
s	s	$\frac{\beta^2}{\Delta E} \frac{128\pi^2}{9} \psi_A(0) ^2 \psi_B(0) ^2$	0
s	p	0	$\frac{\beta^2}{\Delta E} \frac{32\pi}{15} \psi_A(0) ^2 \langle \frac{3}{r^3} \rangle_B$
s	p	$\frac{\beta^2}{\Delta E} \frac{16}{25} \langle \frac{1}{r^3} \rangle_A \langle \frac{1}{r^3} \rangle_B$	$\frac{\beta^2}{\Delta E} \frac{8}{25} \langle \frac{1}{r^3} \rangle_A \langle \frac{1}{r^3} \rangle_B$

Table IV. Numerical values of a and b .

electronic orbital		calc. (10^{23} cm^{-3})	exp. (10^{23} cm^{-3})	covalency (%)
Tl	Br			
$7s$	$4p$	$b=4.5$	$b=1.5$	33
$6p$	$4p$	$a=0.32$ $b=0.16$	$a=1.34$ $b=0.67$	420

The discrepancy between the covalency obtained from the chemical shift and that obtained from the line width of the Br-resonance may be partly due to (i) some amounts of s - p hybridization, because an s -part is ineffective to the chemical shift and a p -part to the line width, and (ii) the difference of $|\psi_{\text{Tl}}(0)|^2$ in solid state from that in atomic state. And moreover, from the analysis of the chemical shift of the Tl resonance we get much larger degree of covalency than that from the Br resonance, as mentioned above. This is interpreted by the presence of covalent bonding between Tl atoms which is consistent with the following conclusion resulted from the line width analysis: using the coupling constant between Tl and Br spins, the second moment of Tl resonance is calculated to be contributed from the Br spins by 50 per cent of its total value and by the remainder 50 per cent presumably from remote Tl spins. On this problem the TlBr-experiment would give us the

decisive evidence, but it was not performed because (i) much stronger rf field was required for the TlBr-experiment than for the BrTl-experiment to satisfy the necessary condition for narrowing (18), and (ii) only the transition $+\frac{1}{2} \leftrightarrow -\frac{1}{2}$ might be observed owing to the quadrupole coupling and so the Br nucleus in other spin states than $\pm\frac{1}{2}$ would not be effected by the rf field.

§ 4. Concluding Remarks

Here we reported only the case of just resonance $f_B = f_B^0$. When f_B was slightly deviated from the center of the resonance line, the line shape of A-resonance displayed a remarkable asymmetry. Interpretation is not yet done and we will postpone the discussion to a future time.

The author wishes to express his gratitude to Professor T. Kanda under whose direction this work was performed. He is grateful also to Assistant Professor Y. Masuda for his kind cooperation throughout this experiment and to Mr. A. Tsunekawa for his technical assistance. This work has been supported in part by the Scientific Research Expenditure of Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 1, JANUARY, 1958

Theory of Dilute Polymer Solutions (I)[†] Chain Configuration and Light Scattering

By Hiromi YAMAKAWA* and Michio KURATA**

*Department of Textile Chemistry and **Department of Industrial
 Chemistry, Kyoto University, Kyoto, Japan

(Received October 2, 1957)

Statistical properties of a single polymer-chain in a continuous medium are studied on the basis of the pearl-necklace model. Proper account is taken of the spatial interference between segments and of the effect of a heat of interaction between solvent and polymer. The $2m$ -th moment of the distribution function of the distance between k -th and l -th segments $\langle R_{kl}^{2m} \rangle$, the mean square distance between k -th segment and the molecular center of mass $\langle S_k^2 \rangle$, and the mean square radius of gyration $\langle S^2 \rangle$ are calculated by using Ursell-Mayer-Tera-moto's method of expanding the chain phase integral. The results obtained are of non-Markoffian character at any temperature but the Flory point, and are qualitatively in consistency with the experimental data of lattice chain obtained by direct counting of its configurations. The angular distribution of scattered light is also calculated and a method is proposed to evaluate $\langle S^2 \rangle$ by the dissymmetry method.

§ 1. Introduction

Whether the introduction of the long-range excluded volume effect into the polymer chain statistics changes the Markoffian character of the chain or not, proposes an interesting problem in both mathematical and statistical-mechanical senses, and has close relation to the various properties of the solution. According to Flory,¹⁾ the mean square end-to-end distance $\langle R^2 \rangle$ is given by

$$\langle R^2 \rangle \propto M^{1+\epsilon} \quad (0 < \epsilon < 0.2),$$

where M is the molecular weight, and the polymer chain can never be regarded as the

Markoffian. This is inevitably of importance for theoretical interpretation of the intrinsic viscosity^{1), 2)} and other physical properties.

A number of ways of approach, accordingly, has been presented by many researchers to the excluded volume effect. In 1951, Teramoto³⁾ has developed the statistical theory of a chain polymer based on the Ursell-Mayer method of imperfect gas theory and justified the conclusion of Flory. Thereafter, Zimm and others⁴⁾⁻⁷⁾ have reached the similar conclusion. On the other hand, Teramoto, Kurata and their coworkers⁸⁾ have made clear by direct counting of the possible configurations of lattice chains that the excluded volume effect gives the distribution function of the

[†] For the preliminary reports of this work see ref. 14.

end-to-end distance considerably different from a Gaussian type, and that the ratio of $\langle R^2 \rangle$ to the mean square radius of gyration $\langle S^2 \rangle$ exceeds the value 6 for Gaussian chain.

However, in most previous theories except the Flory's, the effect of a heat of interaction between solvent and polymer has not explicitly been taken into consideration and thereby some difficulties in the experimental verification have been raised. Accordingly, it would be interesting to discuss from a unified standpoint the various physical properties connected with the excluded volume effect taking account of the segment size as well as the dispersion energy (or heat of interaction) between segments.

In the present paper, the excluded volume effect is discussed for a single polymer chain present in dilute solution. We follow the outline of Teramoto's method,³⁾ and then calculate the $2m$ -th moment of the distribution function of the distance between k -th and l -th segments $\langle R_{kl}^{2m} \rangle$, that of the end-to-end distance $\langle R^{2m} \rangle$, and the mean square radius of gyration $\langle S^2 \rangle$, etc. Our results qualitatively account for the experimental data for lattice chains obtained by Teramoto-Kurata.³⁾ The introduction of the effect of dispersion energy between segments makes it possible to discuss the Flory point in poor solvents and the influences of temperature and of solvents on the chain configurations. The present paper will be closed by the discussions on the excluded volume effect on the dissymmetry ratio in the light scattering.

§ 2. Model and Formulation

Suppose the polymer chain, in which $N+1$ spherical segments (with diameter b) are connected one after the other with a constant bond length a and are attached numbers $0, 1, 2, \dots, N$ from one end to the other (pearl-necklace model). Their coordinates, according to Mc-Millan-Mayer's symbolisms,⁹⁾ are represented by $(0), (1), (2), \dots, (N)$, and the coordinate set and the number set of n segments are denoted by $\{n\} = (1), (2), \dots, (n)$ and $[n] = 1, 2, \dots, n$, respectively.

For the sake of simplicity, the chain is assumed to be completely flexible; the short range interferences, for example, the hindrance to the free rotation about the single bonds, are neglected. However we take into

consideration the short range forces like the van der Waals's forces between solvent molecules, between segments, and between solvent molecules and segments. Now if we adopt a continuous medium approximation, the potential $\phi(r_{ij})$ of mean force between segments may be assumed to be additive, where r_{ij} is the distance between segments i and j , being $r_{ij} = |(j) - (i)|$. Accordingly the potential energy of this system Φ may be written in the form,

$$\Phi\{N+1\} = \sum_{\substack{0 \leq i < j \leq N \\ j-i \neq 1}} \phi(r_{ij}) \equiv \sum \phi_{ij} \quad (1)$$

Here the summation extends over all segment pairs except $j-i=1$ (chemical bond).

For this system the problem is formally the same as that of imperfect gases, namely the evaluation of the partition function

$$\begin{aligned} \Omega(R_{kl}, N, T) &= \int \cdots \int_{|(i+1)-(i)|=a} \exp[-\sum \phi_{ij}/kT] d\{N-1\} \quad (2) \\ &= \int \cdots \int_{|(i+1)-(i)|=a} [1 + \sum_{\substack{0 \leq i < j \leq N \\ j-i \neq 1}} f_{ij} \\ &\quad + \sum \sum f_{ij} f_{mn} + \cdots] d\{N-1\} \quad (2') \end{aligned}$$

with

$$f_{ij} = \exp(-\phi_{ij}/kT) - 1, \quad (3)$$

where the integration extends over all the possible configurations under the conditions of constant bond length a and of fixing segment k to origin and segment l to a point at distance R_{kl} from the origin; i.e. $R_{kl} \equiv r_{kl} = |(l) - (k)|$. The partition function Ω is a function of R_{kl} , N , temperature T , and segment numbers k and l , but abbreviated to $\Omega(R_{kl})$ hereafter.

Teramoto³⁾ has shown that, fixing both ends with the distance R ($\equiv R_{0N}$), the partition function $\Omega(R)$ can be expanded in ascending order μ of interaction between segments. His method can be easily extended to apply to $\Omega(R_{kl})$, and we obtain

$$\Omega(R_{kl}) = \sum_{\mu=0}^N B_{\mu}(R_{kl}) \quad (4)$$

with

$$\begin{aligned} B_0(R_{kl}) &= \int \cdots \int_{|(i+1)-(i)|=a} d\{N-1\} \quad (5) \\ &= \int \int \Omega_0(r_{0k}, k) \Omega_0(r_{kl}, l-k) \\ &\quad \times \Omega_0(r_{lN}, N-l) d(0) d(N), \quad (5') \end{aligned}$$

$$B_{\mu}(R_{kl}) = \sum_{\kappa=\mu+1}^{2\mu} \mathcal{F}_{\mu}^{\kappa}(R_{kl}) \quad (\mu \geq 1), \quad (6)$$

$$\mathcal{F}_{\mu}^{\kappa}(R_{kl}) = \sum_{\text{conf.}} \sum_{\substack{\kappa_1 + \kappa_2 + \kappa_3 = \kappa \\ (\kappa_1, \kappa_2, \kappa_3 = \text{const})}} F_{\mu}(R_{kl}, [\kappa]), \quad (7)$$

$$F_{\mu}(R_{kl}, [\kappa]) = \iint \cdots \int \sum_{\substack{ij \in [\kappa] \\ \text{cluster} \\ \text{number} = \kappa - \mu}} \Pi f_{ij} \Omega_{\kappa_1}(r_{0k}, k, \{\kappa_1\}) \\ \times \Omega_{\kappa_2}(r_{kl}, l-k, \{\kappa_2\}) \\ \times \Omega_{\kappa_3}(r_{lN}, N-l, \{\kappa_3\}) d\{\kappa+2\}, \quad (8)$$

$$\Omega_{\kappa}(r, n, \{\kappa\}) = \iint \cdots \int_{|(\bar{i}+1) - (\bar{i})| = \alpha} d\{n-1-\kappa\} \quad (9)$$

$$= \prod_{(i < j) \in [\kappa]} \Omega_0(r_{ij}, j-i), \quad (9')$$

$$\Omega_0(r, n) = \iint \cdots \int_{|(\bar{i}+1) - (\bar{i})| = \alpha} d\{n-1\}, \quad (10)$$

where $\Omega_0(r, n)$ is the partition function of an ideal random flight chain composed of $n+1$ segments, fixing both ends with the distance r . $\Omega_{\kappa}(r, n, \{\kappa\})$ is the *partial* phase integral of this chain, and the integrations in Eq. (9) extend over the coordinates of all segments except some κ and both end ones. The integrations in Eq. (8) are performed over the coordinates of both end segments and of κ ones in the state of interaction (κ_1 , κ_2 and κ_3 of them belong to the subchains $-1(0 \sim k)$, $-2(k \sim l)$ and $-3(l \sim N)$ respectively). The summation in Eq. (8) is carried out over all configurations in which these κ segments compose $\kappa - \mu$ clusters. The first summation sign in Eq. (7) denotes summation over all the ways, in which κ_1 , κ_2 and κ_3 segments are selected from the subchains -1 , -2 and -3 respectively, and the second, summation over κ_1 , κ_2 and κ_3 under the condition $\kappa_1 + \kappa_2 + \kappa_3 = \kappa$.

§ 3. Functional Forms of $\phi(r)$ and $\Omega_0(r, n)$

The potential $\phi(r)$, for convenience, is assumed to have the form*

$$\phi(r) = \begin{cases} \infty & ; \quad r \leq b \\ -\varepsilon_0 \exp\left(-\frac{3}{2\lambda^2} r^2\right) & ; \quad r > b \end{cases} \quad (11)$$

where λ is a parameter which is assumed to

* If we denote the depth of $\phi(r)$ at $r=b$ by ε , it may be rewritten as

$$\phi(r) = -\varepsilon \exp\left(-\frac{3b^2}{2\lambda^2}\right) \exp\left(-\frac{3}{2\lambda^2} r^2\right) \text{ for } r \geq b. \quad (11')$$

be of the same order as a . $\phi(r)$ is shown in Fig. 1. In the case of $\varepsilon_0 > 0$, the force between segments becomes attractive in the range of $r > b$, and the segments have the tendency to condense. Therefore this corresponds to a poor solvent system. On the

Fig. 1. Potential $\phi(r)$.

other hand, ε_0 is negative in a good solvent system. Substituting Eq. (11) into Eq. (3), the function $f(r)$ becomes

$$f(r) = \begin{cases} -1 & ; \quad r \leq b \\ \frac{\varepsilon_0}{kT} \exp\left(-\frac{3}{2\lambda^2} r^2\right) & ; \quad r > b \end{cases} \quad (12)$$

where all terms higher than the second of ε_0/kT were neglected. This neglect is justified by the experimental result that the heat of mixing is usually small in polymer solutions.

Next, if the chain, in which there exists no interaction, is approximated by a Gaussian chain, $\Omega_0(r, n)$ is given by

$$\Omega_0(r, n) = \frac{(4\pi a^2)^n}{(2\pi n a^2/3)^{3/2}} \exp\left(-\frac{3}{2na^2} r^2\right) \quad (n \geq 2), \quad (13)$$

Here $(4\pi a^2)^n$ is the partition function of this chain which is allowed to have all the configurations without fixing both ends. We shall use Eqs. (12) and (13) in the further calculations.

§ 4. End-to-End Distance and Radius of Gyration

In this section, our primary aim is to calculate the mean square end-to-end distance $\langle R^2 \rangle$ and the mean square radius of gyration $\langle S^2 \rangle$, which characterize the statistical properties of a single polymer chain present in dilute solution. Before proceeding to this, it would be useful to derive the general expression for $\langle R_{kl}^{2m} \rangle$ from the partition function $\Omega(R_{kl})$, be-

cause this would not only give the expressions for $\langle R^2 \rangle$ and $\langle S^2 \rangle$, but also serve to calculate the angular distribution in the light scattering.

Considering the terms up to the order of interaction $\mu=1$,* the partition function $\mathcal{Q}(R_{ki})$ simplifies to

$$\Omega(R_{kl}) = B_0(R_{kl}) + B_1(R_{kl}) \quad (14)$$

$B_0(R_{kl})$ can be easily obtained by Eqs. (5') and (13), that is,

$$B_0(R_{kl}) = \frac{(4\pi a^2)^N}{\{2\pi(l-k)a^2/3\}^{3/2}} \exp\left\{-\frac{3R_{kl}^2}{2(l-k)a^2}\right\}. \quad (15)$$

Using Eqs. (6) to (10) $B_1(R_{kl})$ may be written down as

$$B_1(R_{kl}) = \sum_{(1)} F_1(R_{kl}, [200]) + \sum_{(2)} F_1(R_{kl}, [020]) + \sum_{(3)} F_1(R_{kl}, [002]) \\ + \sum_{(4)} F_1(R_{kl}, [110]) + \sum_{(5)} F_1(R_{kl}, [011]) + \sum_{(6)} F_1(R_{kl}, [101]) \quad (16)$$

with

$$\left. \begin{aligned} F_1(R_{kl}, [200]) &= \iiint f_{ij} \Omega_0(r_{0i}, i) \Omega_0(r_{ij}, j-i) \Omega_0(r_{jk}, k-j) \\ &\quad \times \Omega_0(r_{kl}, l-k) \Omega_0(r_{lN}, N-l) d(i) d(j) d(0) d(N), \\ F_1(R_{kl}, [020]) &= \iiint f_{ij} \Omega_0(r_{0k}, k) \Omega_0(r_{ki}, i-k) \Omega_0(r_{ij}, j-i) \\ &\quad \times \Omega_0(r_{jl}, l-j) \Omega_0(r_{lN}, N-l) d(i) d(j) d(0) d(N), \\ &\vdots \end{aligned} \right\} \quad (17)$$

The other integrals also can be easily presented. Each summation in Eq. (16) extends to the configurations corresponding to each clus-

ter diagram illustrated in Fig. 2.

On performing the integrations in Eq. (17), the following approximation is introduced,

$$b \ll \lambda \leq a. \quad (18)$$

This is a necessary condition in order that the imperfect gas-like expansion could be applied: the first condition, $b \ll a$, indicates that the volume effect is sufficiently small, and the second condition, $\lambda \leq a$, means the mean force of segmental interaction to be short-ranged, as supposed from Eq. (11).

All the integrals in Eq. (17) can be evaluated by the Fourier and its inverse transformations.^{3),11)} An example is taken of $F_1(R_{kl}, [020])$ below. Integrating over (0) and (N), we obtain

Fig. 2. Cluster Diagrams.

$$F_1(R_{kl}, [020]) = (4\pi a^2)^{N+k-l} \iint f_{ij} \mathcal{O}_0(\mathbf{r}_{kl}, i-k) \mathcal{O}_0(\mathbf{r}_{ij}, j-i) \mathcal{O}_0(\mathbf{r}_{jl}, l-j) d(i) d(j). \quad (19)$$

If the Fourier transform of this integral is denoted by $H_1(\mathbf{q}, [020])$, the inverse transform F_1 is

$$F_1(R_{kl}, [020]) = \frac{(4\pi a^2)^{N+k-l}}{8\pi^3} \int \exp(-i\mathbf{q} \cdot \mathbf{R}_{kl}) H_1(\mathbf{q}, [020]) d\mathbf{q} \quad (20)$$

with

* This corresponds to the single contact approximation of Zimm.^{4), 10)}

$$\left. \begin{aligned}
 H_1(\mathbf{q}, [020]) &= \alpha(\mathbf{q}, i-k) \beta(\mathbf{q}, j-i) \alpha(\mathbf{q}, l-j), \\
 \alpha(\mathbf{q}, i-k) &= \int \Omega_0(\mathbf{r}_{ki}, i-k) \exp(i\mathbf{q} \cdot \mathbf{r}_{ki}) d\mathbf{r}_{ki}, \\
 \beta(\mathbf{q}, j-i) &= \int f(\mathbf{r}_{ij}) \Omega_0(\mathbf{r}_{ij}, j-i) \exp(i\mathbf{q} \cdot \mathbf{r}_{ij}) d\mathbf{r}_{ij}, \\
 \alpha(\mathbf{q}, l-j) &= \int \Omega_0(\mathbf{r}_{jl}, l-j) \exp(i\mathbf{q} \cdot \mathbf{r}_{jl}) d\mathbf{r}_{jl}.
 \end{aligned} \right\} \quad (21)$$

After laborious calculations, $F_1(R_{kl}, [020])$ becomes

$$\begin{aligned}
 &F_1(R_{kl}, [020]) \\
 &= -\frac{(4\pi a^2)^N}{(2\pi a^2/3)^{3/2}} \left(\frac{6}{\pi}\right)^{1/2} \frac{1}{(j-i)^{3/2}(l-k-j+i)^{3/2}} \left(\frac{b}{a}\right)^3 \left[\exp\left\{-\frac{3R_{kl}^2}{2(l-k-j+i)a^2}\right\} - \left(\frac{\varepsilon_0}{kT}\right) \right. \\
 &\quad \times \left\{ \left(\frac{\pi}{6}\right)^{1/2} \left[\frac{(j-i)(l-k-j+i)}{(j-i)(l-k-j+i) + (\lambda/a)^2(l-k)} \right]^{3/2} \left(\frac{\lambda}{b}\right)^3 \exp\left[-\frac{3\{j-i + (\lambda/a)^2\}R_{kl}^2}{2\{(j-i)(l-k-j+i) + (\lambda/a)^2(l-k)\}a^2}\right] \right. \\
 &\quad \left. \left. - \exp\left[-\frac{3R_{kl}^2}{2(l-k-j+i)a^2}\right] \right\} \right] \quad (22)
 \end{aligned}$$

up to the terms of order $(b/a)^3$, the approximation (18) being taken into account. If we further neglect $(\lambda/a)^2$ compared to $j-i$ by the approximation (18), F_1 is simplified to

$$\begin{aligned}
 &F_1(R_{kl}, [020]) \\
 &= -\frac{(4\pi a^2)^N}{(2\pi a^2/3)^{3/2}} \left(\frac{6}{\pi}\right)^{1/2} \frac{1}{(j-i)^{3/2}(l-k-j+i)^{3/2}} \left(\frac{b}{a}\right)^3 \left(1 - \frac{\Theta}{T}\right) \exp\left\{-\frac{3R_{kl}^2}{2(l-k-j+i)a^2}\right\} \quad (23)
 \end{aligned}$$

with

$$\Theta = \left\{ \left(\frac{\pi}{6}\right)^{1/2} \left(\frac{\lambda}{b}\right)^3 - 1 \right\} \left(\frac{\varepsilon_0}{k}\right). \quad (24)$$

Θ/T corresponds to the integral over the range $b \leq r_{ij} \leq \infty$ in $\beta(\mathbf{q}, j-i)$, namely the energetical part. This integral is split into two parts, 0 to ∞ and b to 0, which correspond to the first and second terms in Eq. (24) respectively. Θ has the dimension of temperature and it is expected from Eq. (18) to have the same sign as ε_0 . If we would consider higher terms than the second of ε_0/kT in Eq. (12), $(1-\Theta/T)$ would be replaced by a power series of Θ/T in general.

If we would calculate the remaining F_1 's in Eq. (16) by using the similar procedure as mentioned above and sum up them, $\Omega(R_{kl})$ could be evaluated. However, without deriving the explicit form of $\Omega(R_{kl})$,* we turn immediately to the derivation of $\langle R_{kl}^{2m} \rangle$. That is

$$\langle R_{kl}^{2m} \rangle = \frac{\int_0^\infty R_{kl}^{2m+2} \Omega(R_{kl}) dR_{kl}}{\int_0^\infty R_{kl}^2 \Omega(R_{kl}) dR_{kl}} \quad (25)$$

$$= \frac{(2m+1)!}{6^m m!} (l-k)^m a^{2m} \left[1 + \left(\frac{6}{\pi}\right)^{1/2} \left(\frac{b}{a}\right)^3 \left(1 - \frac{\Theta}{T}\right) D_m(N, k, l) \right] \quad (26)$$

where

$$\begin{aligned}
 D_m(N, k, l) &= \sum_{(2)} \left[1 - \left(1 - \frac{j-i}{l-k}\right)^m \right] (j-i)^{-3/2} + \sum_{(4)} \left[1 - \left\{ 1 - \frac{(j-k)^2}{(l-k)(j-i)} \right\}^m \right] (j-i)^{-3/2} \\
 &\quad + \sum_{(6)} \left[1 - \left\{ 1 - \frac{(l-i)^2}{(l-k)(j-i)} \right\}^m \right] (j-i)^{-3/2} + \sum_{(6)} \left[1 - \left(1 - \frac{l-k}{j-i}\right)^m \right] (j-i)^{-3/2}. \quad (27)
 \end{aligned}$$

* The implicit form of $\Omega(R_{kl})$ will be used to calculate the osmotic 2nd virial coefficient in the next paper.

Each summation in Eq. (27) denotes summation over i and j under the conditions specified in Fig. 2, and the configurations $-(1)$ and $-(3)$ are easily seen to make no contribution to $\langle R_{kl}^{2m} \rangle$. When the terms like $\binom{m}{p}$ in Eq. (27) are expanded, and summations over i and j are replaced by integrations, D_m becomes

$$D_m(N, k, l) = 4 \sum_{p=1}^m \frac{(-1)^{p+1} p}{(p^2 - \frac{1}{4})(p + \frac{1}{2})} \binom{m}{p} (l-k)^{1/2} + \sum_{p=1}^m \frac{(-1)^{p+1} \binom{m}{p}}{p + \frac{1}{2}} \sum_{q=0}^{2p} \frac{(-1)^{q+1} \binom{2p}{q}}{p-q + \frac{1}{2}} \\ \times (l-k)^{-p} [k^q (l^{p-q+1/2} - k^{p-q+1/2}) + (N-l)^q \{(N-k)^{p-q+1/2} - (N-l)^{p-q+1/2}\}] \\ + \sum_{p=1}^m \frac{(-1)^{p+1}}{p^2 - \frac{1}{4}} \binom{m}{p} (l-k)^p \{N^{-p+1/2} - l^{-p+1/2} - (N-k)^{-p+1/2}\} \quad (27')$$

up to the terms of order $N^{1/2}$.

When $m=1$, $\langle R_{kl}^{2m} \rangle$ reduces to

$$\left. \begin{aligned} \langle R_{kl}^2 \rangle &= (l-k) a^2 \left[1 + \left(\frac{6}{\pi} \right)^{1/2} \left(\frac{b}{a} \right)^3 \left(1 - \frac{\Theta}{T} \right) D_1(N, k, l) \right], \\ D_1(N, k, l) &= \frac{4}{3} \left[\frac{8}{3} (l-k)^{1/2} - 4(N-k)^{1/2} - 4l^{1/2} + \frac{l-k}{N^{1/2}} \right. \\ &\quad \left. - \frac{8}{3(l-k)} \{ (N-l)^{3/2} - (N-k)^{3/2} - l^{3/2} + k^{3/2} \} \right]. \end{aligned} \right\} \quad (28)$$

In the case of $k=0$ and $l=N$, we obtain for the $2m$ -th moment of the distribution function of the end-to-end distance

$$\langle R^{2m} \rangle = \frac{(2m+1)!}{6^m m!} N^m a^{2m} \left[1 + \left\{ \sum_{p=1}^m \frac{(-1)^{p+1} \binom{m}{p}}{p^2 - \frac{1}{4}} \right\} \xi \right], \quad (29)$$

where

$$\xi = \left(\frac{6}{\pi} \right)^{1/2} \left(\frac{b}{a} \right)^3 \left(1 - \frac{\Theta}{T} \right) N^{1/2}. \quad (30)$$

Eq. (29), when $m=1$, gives the mean square end-to-end distance,

$$\langle R^2 \rangle = N a^2 \left(1 + \frac{4}{3} \xi \right). \quad (31)$$

We are now in a position to calculate the mean square radius of gyration $\langle S^2 \rangle$. If we denote the distance between the molecular center of mass and segment k by S_k , $\langle S^2 \rangle$ is given by

$$\langle S^2 \rangle = \frac{1}{N} \sum_k \langle S_k^2 \rangle = \frac{1}{N^2} \sum_{k < l} \langle R_{kl}^2 \rangle. \quad (32)$$

Substituting from Eq. (28), and replacing summation by integration, we see that Eq. (32) becomes

$$\langle S^2 \rangle = \frac{N a^2}{6} \left(1 + \frac{134}{105} \xi \right). \quad (33)$$

In addition, $\langle S_k^2 \rangle$ can be easily shown to have the expression,

$$\langle S_k^2 \rangle = \frac{1}{N} \sum_{l=0}^{k-2} \langle R_{lk}^2 \rangle + \frac{1}{N} \sum_{l=k+2}^N \langle R_{kl}^2 \rangle - \langle S^2 \rangle, \quad (34)$$

where $\langle R_{lk}^2 \rangle$ is obtained by exchanging k for l and vice versa in Eq. (28). Thus we have

$$\left. \begin{aligned} \langle S_k^2 \rangle &= a^2 \left\{ \frac{3k^2 - 3kN + N^2}{3N} + \frac{4}{3} D(N, k) \xi \right\}, \\ D(N, k) &= \frac{6}{5N^{3/2}} \{ k^{5/2} + (N-k)^{5/2} \} - \frac{8}{3N^{1/2}} \{ k^{3/2} + (N-k)^{3/2} \} \\ &\quad + \frac{1}{3N^2} \{ k^3 + (N-k)^3 \} + \frac{121}{84} N. \end{aligned} \right\} \quad (35)$$

Eqs. (28) and (35) will be used to calculate the intrinsic viscosity in the succeeding paper.

Eqs. (31) and (33) show that a polymer chain, owing to the repulsive interaction (volume effect), will expand more largely than a Gaussian case and, in good solvents, the energetical interactions between segments and solvents force the chain to expand more and more, whereas in poor solvents they work to shrink it. Therefore, when $T = \theta$, the volume effect counteracts the energetical interaction so that the polymer chain apparently behaves like a Gaussian chain. Accordingly θ defined by Eq. (24) is nothing but the Flory temperature¹²⁾ and becomes higher as ε_0 is large, namely in the poorer solvents.

In the above calculation, we have neglected all higher terms than the second corresponding to the order of interaction $\mu = 2$. Otherwise, the higher terms than the second of ξ would generally occur in Eqs. (31) and (33). Accordingly, these equations would have the validity only in the case of $|\xi| \ll 1$, that is in the vicinity of the θ temperature in poor solvents, and the range of ξ will be determined by comparison with experiments in the other paper.

§ 5. Statistical Properties of a Polymer Chain

Many studies have been proposed on the excluded volume effect of a polymer chain. Most of them have been dealing with the relationship between $\langle R^2 \rangle$ and N , which has already been discussed out. Here our attentions are focused on a few other statistical properties of a polymer chain in dilute solution which are easily deduced from the results obtained in the previous section.

(a) Suppose the Gaussian distribution function, the second moment of which is given by Eq. (31). We obtain for the $2m$ -th moment of this function

$$\langle R^{2m} \rangle_G = \frac{(2m+1)!}{6^m m!} N^m a^{2m} \left(1 + \frac{4}{3} m \xi \right). \quad (36)$$

Comparing Eq. (36) with Eq. (29), we know

that $\langle R^{2m} \rangle_G > \langle R^{2m} \rangle$ when $m \geq 2$ and $\xi > 0$: the Gaussian distribution function approaches zero slowly in the range of larger R than that corresponding to the maximum, while the distribution function of R for a real polymer chain increases gradually to a maximum, and then falls down to zero suddenly.

(b) Eqs. (31) and (33) lead us to

$$\frac{\langle R^2 \rangle}{\langle S^2 \rangle} = 6 \left(1 + \frac{2}{35} \xi \right). \quad (37)$$

When $\xi > 0$, the ratio $\langle R^2 \rangle / \langle S^2 \rangle$ is larger than the value 6 for the Gaussian chain, and increases with N .

These conclusions are in qualitative agreement with those obtained by Teramoto, Kurata and their coworkers⁸⁾ who directly counted the number of all possible configurations for the two-dimensional square lattice chains ($N \leq 20$) and the simple cubic lattice chains ($N \leq 8$).

§ 6. Light Scattering

Here we calculate the angular distribution $P(\theta)$ in the light scattering, using the same model as before, and propose a procedure to evaluate $\langle S^2 \rangle$ by the dissymmetry method. $P(\theta)$ is expressed in the form,¹³⁾

$$P(\theta) = \int_{-\infty}^{+\infty} \rho(R_{kl}) \exp \left(\frac{2\pi i \mathbf{s} \cdot \mathbf{R}_{kl}}{\lambda'} \right) d\mathbf{R}_{kl}, \quad (38)$$

where λ' is the wave length in the medium, θ the scattering angle, ρ the radial distribution function for segments of the same polymer chain, $\mathbf{s}$ the vector difference between unit vectors in the directions of the incident and scattered lights, and the magnitude s is given by

$$s = |\mathbf{s}| = 2 \sin \frac{\theta}{2}. \quad (39)$$

The integration in Eq. (38) extends over all directions as well as magnitudes of $\mathbf{R}_{kl}$ at constant s .

Now, using the partition function $\Omega(R_{kl})$, we may write $\rho(R_{kl})$ as

$$\rho(R_{kl}) = \frac{2}{N^2} \sum_{k < l} C \Omega(R_{kl}), \quad (40)$$

where C is the normalization constant and

$$C^{-1} = \int_0^\infty 4\pi R_{kl}^2 \Omega(R_{kl}) dR_{kl} . \tag{41}$$

Inserting Eq. (40) in Eq. (38), $P(\theta)$ can be expanded in the form,

$$\left. \begin{aligned} P(\theta) &= 1 - \alpha_1 \left(2 \sin \frac{\theta}{2} \right)^2 + \alpha_2 \left(2 \sin \frac{\theta}{2} \right)^4 - \dots + (-1)^m \alpha_m \left(2 \sin \frac{\theta}{2} \right)^{2m} + \dots , \\ \alpha_m &= \frac{2}{(2m+1)! N^2} \left(\frac{2\pi}{\lambda'} \right)^{2m} \sum_{k \leq l} \langle R_{kl}^{2m} \rangle . \end{aligned} \right\} \tag{42}$$

In particular, from Eq. (32) α_1 becomes

$$\alpha_1 = \frac{4\pi^2}{3(\lambda')^2} \langle S^2 \rangle . \tag{43}$$

Substituting Eq. (26) into α_m of Eq. (42), and replacing summation by integration over k and l , $P(\theta)$ can be finally rewritten as

$$P(\theta) = \frac{2}{u^2} (e^{-u} - 1 + u) + \xi \sum_{m=1}^\infty \frac{(-1)^m}{m!} C_m u^m , \tag{44}$$

where

$$u = \frac{8\pi^2}{3} \frac{Na^2}{(\lambda')^2} \sin^2 \frac{\theta}{2} , \tag{45}$$

$$\begin{aligned} C_m &= 2 \sum_{p=1}^m \frac{(-1)^{p+1}}{p^2 - 1/4} \binom{m}{p} \left[\frac{4p}{(m+3/2)(m+5/2)(p+1/2)} - \frac{m+2p+3/2}{(m+p+1)(m+p+2)(m+5/2)} \right. \\ &\quad + (2p-1) \sum_{q=0}^{2p} \frac{(-1)^{q+1}}{p-q-1/2} \binom{2p}{q} \left\{ \frac{1}{m+5/2} \sum_{s=0}^{m-p} \frac{(-1)^s}{q+s+1} \binom{m-p}{s} \right. \\ &\quad \left. \left. - \frac{1}{m-p+1} \sum_{t=0}^{m-p+1} \frac{(-1)^t}{p+t+3/2} \binom{m-p+1}{t} \right\} \right] . \end{aligned} \tag{46}$$

The numerical values of $C_m (m \leq 7)$ are shown in Table I, which were calculated by Eq. (46). Fig. 3 gives the $\sqrt{u} - P(\theta)$ curves for various values of ξ , which were drawn taking account of the terms up to $m=7$ in Eq. (44) with the values of C_m in Table I. Similarly, the dissymmetry ratio z_{45} ($=P(45^\circ)/P(135^\circ)$) vs. $\sqrt{Na^2}/\lambda'$ is plotted in Fig. 4.

Table I. The Values of C_m .

m	1	2	3	4	5	6	7
C_m	0.4254	0.3889	0.3240	0.2699	0.2279	0.1953	0.173

The angular variation method leads us to α_1 in Eq. (43) and hence $\langle S^2 \rangle$ itself. On the other hand, in the dissymmetry method, Na^2 is customarily determined by using the curve for $\xi=0$ (Gaussian) in Fig. 4. Accordingly

Fig. 3. Angular Distribution.

Na^2 obtained in such a way is not strictly equivalent to either $\langle R^2 \rangle$ or $6\langle S^2 \rangle$ at non-Flory temperatures. Following is our method to

determine $\langle S^2 \rangle$ by the dissymmetry method. We first read the value of Na^2 from the observed value of z_{45} at the θ temperature and the curve for $\xi=0$ in Fig. 4; and next we determine ξ from the observed value of z_{45} at the other temperature and from the value of Na^2 obtained above, using Fig. 4. Inserting these values of Na^2 and ξ in Eq. (33), we obtain $\langle S^2 \rangle$. This method, however, is not applicable to a good solvent system, for the equations obtained here are derived only for small ξ .

Fig. 4. Dissymmetry Ratio.

The agreement between the value of $\langle S^2 \rangle$ determined by this method and that by the angular variation method has to be checked experimentally. This is an interesting problem, but we will leave it untouched in the present paper.

In conclusion, we are greatly indebted to Professor Ichiro Sakurada of this University for his indispensable advice and constant encouragement during the course of this research. Thanks are tendered also to Prof. Akio Nakajima, Dr. Ei Teramoto, Dr. Misazo

Yamamoto and Prof. Hiroshi Inagaki for their stimulating discussions, and to the Ministry of Education of the Japanese Government for a grant-in-aid. One of the authors (M. K.) wishes to express his sincere thanks also to Professor Mikio Tamura who gave him helpful discussions with ever increasing interest.

Theory of Dilute Polymer Solutions (II)*

Osmotic Pressure

By Hiromi YAMAKAWA

Department of Textile Chemistry, Kyoto University, Kyoto, Japan

(Received October 2, 1957)

A statistical-mechanical theory of dilute polymer solutions is developed following the solution theory of McMillan and Mayer, and the osmotic second virial coefficient A_2 is calculated taking account of the intra- and intermolecular interactions. The final expression for A_2 is expressed in terms of the molecular constants such as the molecular weight, segment size and bond length. The molecular weight dependence of A_2 is improved at least in the vicinity of the Flory point in comparison with the theories of Flory-Krigbaum and Isihara-Koyama.

§ 1. Introduction

According to the general theory of solutions developed by McMillan and Mayer,¹⁾ the osmotic second virial coefficient A_2 can be expressed in terms of the reduced phase integrals of the solute molecules, namely one-body phase integrals at the infinite dilution. In the case of chain polymer solutions, however, the reduced phase integrals themselves are cumbersome owing to the *liquid-like* character, and the calculation of A_2 cannot be completed, in general, unless some approximations are made. For example, Flory and Krigbaum,²⁾ and recently Orofino and Flory³⁾ developed theories of polymer solutions by introducing the Gaussian approximation for the spatial distribution of segments about the molecular center of mass, and derived the expressions for A_2 , which indicate a gradual decrease of A_2 with the molecular weight. This seems to be a good success of their theories, though there remains some phenomenological parameters uneliminated and the agreement with the experimental data is no more than semi-quantitative. Recently, Isihara and Koyama⁴⁾ improved the Flory and Krigbaum theory²⁾ with respect to the approximation for the radial distribution function for segments, but the Gaussian character of polymer chains is still assumed. In these theories, furthermore, n -segment distribution functions about the molecular center of mass are approximated by the products of one-segment distribution functions. Since the volume effect dominating A_2 introduces a non-

Gaussian character into the chain behaviors as was shown in TPS I,** and since, by introducing the *factorization approximation* into the segment distribution function mentioned above, the effect of the spatial correlation between segments is almost ignored, we found it necessary to re-examine the theory of dilute polymer solutions with respect to these points.

In this paper, we are concerned with the calculation of the two-body phase integral of polymer chains. The method of expanding the one-body phase integral developed in TPS I can be conveniently extended to the present problem. The contributions to A_2 of the *intra*- and *intermolecular* interactions are able to be separated by proper introduction of a *partial* one-body phase integral. Although a similar approach to the problem has already been attempted by Zimm,⁵⁾ he has been neglected the influences of the intramolecular interactions. In the last section our excluded volume function ($\mathcal{F}$ -function), which occurs in A_2 , will be compared with those obtained by Flory-Krigbaum²⁾ and Isihara-Koyama,⁴⁾ and the difference among them will be discussed.

§ 2. Formulation

In this section, the formulation will be given in order to derive the theoretical expression for the second virial coefficient of the osmotic pressure of chain polymer solutions.

As in TPS I, we make use of the pearl-necklace model and the continuous medium approximation. Consider two polymer chains

* For the preliminary reports of this work see ref. 12.

** Part I of this series.⁵⁾ This paper will be cited as TPS I.

in dilute solutions; their segments are attached numbers $0_s, 1_s, 2_s, \dots, N_s$ from one end to the other, where the subscript s ($=1$ or 2) indicates the distinction of two polymer chains. The coordinates of the segments, as before, are denoted by $(0_s), (1_s), \dots, (N_s)$, and the coordinate set and the number set of n segments are represented by $\{n_s\} = (1_s)(2_s) \dots (n_s)$ and $[n_s] = 1_s, 2_s, \dots, n_s$, respectively.

According to the solution theory of McMillan and Mayer,¹⁾ the osmotic pressure π is expanded in powers of the concentration c (in g/cc) as follows,

$$\pi = RT \left(\frac{1}{M} c + A_2 c^2 + A_3 c^3 + \dots \right) \quad (1)$$

with

$$A_n = - \frac{(n-1)N_0^{n-1}}{M^n} B_n, \quad (2)$$

where R is the gas constant, T the temperature, M the polymer molecular weight, A_n the n -th virial coefficient, N_0 Avogadro's number, and B_n the irreducible integral. In particular, B_2 , equal to the cluster integral

b_2 , is given by

$$B_2 = b_2 = \frac{1}{2!V} \iint \dots \int_V g_2\{N_1+1_1+N_2+1_2\}, T \times d\{N_1+1_1+N_2+1_2\}, \quad (3)$$

where V is the volume of the system. g_2 is defined as

$$g_2\{N_1+1_1+N_2+1_2\} = F_2\{N_1+1_1+N_2+1_2\} - F_1\{N_1+1_1\}F_1\{N_2+1_2\}, \quad (4)$$

where F_1 and F_2 are the one-body and two-body distribution functions of McMillan and Mayer, respectively. It must be noted here that F_1 , F_2 and the related functions all refer to the state of infinite dilution of solute polymers and are functions of T , though the symbol T is omitted in Eq. (4) for simplicity's sake. Inserting Eq. (3) in Eq. (2), A_2 can be rewritten as

$$A_2 = - \frac{N_0}{2VM^2} \iint \dots \int_V g_2\{N_1+1_1+N_2+1_2\} \times d\{N_1+1_1+N_2+1_2\}. \quad (5)$$

The distribution functions F_1 and F_2 are related to the potentials of mean force Φ_1 and Φ_2 respectively as follows,

$$\left. \begin{aligned} F_1\{N_s+1_s\} &= C \exp[-\Phi_1\{N_s+1_s\}/kT] \\ F_2\{N_1+1_1+N_2+1_2\} &= C' \exp[-\Phi_2\{N_1+1_1+N_2+1_2\}/kT], \end{aligned} \right\} \quad (6)$$

where C and C' are the normalization constants. In the continuous medium approximation, Φ_1 and Φ_2 are given by the sums of potentials $\phi(r_{is}j_t)$ of segment pairs ($r_{is}j_t = |(j_t) - (i_s)|$; $s, t = 1, 2$):

$$\left. \begin{aligned} \Phi_1\{N_s+1_s\} &= \sum_{\substack{0 \leq j_s < j_s \leq N \\ j_s \neq 1}} \phi(r_{is}j_s) \equiv \sum \phi(r_{i_1 i_2}), \\ \Phi_2\{N_1+1_1+N_2+1_2\} &= \Phi_1\{N_1+1_1\} + \Phi_1\{N_2+1_2\} + \sum_{i_1, i_2} \phi(r_{i_1 i_2}), \\ &\equiv \sum \phi_{i_1 i_1} + \sum \phi_{i_2 i_2} + \sum \phi_{i_1 i_2}. \end{aligned} \right\} \quad (7)$$

g_2 is a correction term which would represent the amount by which the two-body distribution function F_2 deviates from the independent value given by the product of the one-body distribution functions F_1 's, so that g_2 approaches zero as all r_{i_1, i_2} 's become infinite.* Accordingly, C' is equal to C^2 and g_2 can be rewritten as

$$\begin{aligned} g_2\{N_1+1_1+N_2+1_2\} &= C^2 \exp(-\sum \phi_{i_1 j_1}/kT) \exp(-\sum \phi_{i_2 j_2}/kT) [\exp(-\sum \phi_{i_1, i_2}/kT) - 1] \quad (8) \\ &= C^2 (1 + \sum_{\substack{0 \leq i_1 < j_1 \leq N \\ j_1 - i_1 \neq 1}} f_{i_1 j_1} + \sum \sum f_{i_1 j_1} f_{k_1 i_1} + \dots) \\ &\quad \times (1 + \sum_{\substack{0 \leq i_2 < j_2 \leq N \\ j_2 - i_2 \neq 1}} f_{i_2 j_2} + \sum \sum f_{i_2 j_2} f_{k_2 i_2} + \dots) \quad (8') \\ &\quad \times (\sum_{i_1, i_2} f_{i_1 i_2} f_{j_1 j_2} + \dots), \end{aligned}$$

* The definition of g_2 is somewhat different from that of the correlation function $g_2(r)$ in the theory of liquids, which has the property: $\lim_{r \rightarrow \infty} g_2(r) = 1$.

where

$$f_{i_s j_t} = \exp(-\phi_{i_s j_t}/kT) - 1, \quad (9)$$

and C can be determined by the normalization condition of F_1 . That is,

$$C^{-1} = \frac{1}{V} \iint \cdots \int_V \exp(-\sum \phi_{i_s j_s}/kT) d\{N_s + 1_s\}, \quad (10)$$

We are now in a position to give the expansion form of A_2 from the standpoint of successive approximation. The situation is very complicated, because there exist the intra- and inter molecular interactions simultaneously. In the case of a single polymer chain, we defined the *order of interaction* by the difference between the number of segments in the state of interaction and the number of clusters. In the present paper, the order of interaction, for simplicity, is expressed by the number of *bonds* in a cluster diagram (See Fig. 1). This would not be the source of appreciable error in so far as the terms of considerably higher order are not concerned, since N is large enough.

We begin by introducing the *partial* one-body phase integral*

$$\Omega^\kappa\{\kappa_s\} = \iint \cdots \int [1 + \sum_{\substack{0 \leq i_s < j_s \leq N \\ j_s - i_s = 1}} f_{i_s j_s} + \cdots] d\{N_s + 1_s - \kappa_s\}, \quad (11)$$

where the integration extends over all the coordinates of segments of the same chain except some κ segments under the conditions of constant bond length a . It is obvious that Ω^κ , when $\kappa=2$, results in $\Omega(R_{kl})$ discussed in TPS I. On performing the term-by-term integrations over the coordinates of segments except ones in the state of *intermolecular* interaction in Eq. (5), A_2 , using $\Omega^\kappa\{\kappa_s\}$, can be rewritten as

$$A_2 = -\frac{N_0}{2VM^2} (G_1 + G_2 + \cdots), \quad (12)$$

where

$$G_\kappa = \sum_{\text{conf.}} G_\kappa([\kappa_1][\kappa_2]), \quad (13)$$

$$\left. \begin{aligned} G_1([1_1][1_2]) &= C^2 \iint f_{i_1 i_2} \Omega^1(i_1) \Omega^1(i_2) d(i_1) d(i_2), \\ G_2([2_1][2_2]) &= C^2 \iiint (f_{i_1 i_2} f_{j_1 j_2} + f_{i_1 j_2} f_{j_1 i_2}) \Omega^2(r_{i_1 j_1}) \Omega^2(r_{i_2 j_2}) d(i_1) d(j_1) d(i_2) d(j_2), \\ &\dots \dots \dots \\ G_\kappa([\kappa_1][\kappa_2]) &= C^2 \iint \cdots \int \sum \Pi f_{i_1 j_2} \Omega^\kappa\{\kappa_1\} \Omega^\kappa\{\kappa_2\} d\{\kappa_1 + \kappa_2\}, \\ &\dots \dots \dots \end{aligned} \right\} \quad (14)^{**}$$

The summation sign in Eq. (13) denotes summation over all the ways in which κ segments are selected from the chain 1 and the same number of segments from the chain 2. From Eq. (10), we obtain immediately

$$\Omega^1(i_1) = \Omega^1(i_2) = C^{-1}. \quad (15)$$

Hence, $G_1([1_1][1_2])$ simplifies to

$$G_1([1_1][1_2]) = \iint f_{i_1 i_2} d(i_1) d(i_2). \quad (16)$$

* In TPS I, the partial phase integral was used for an ideal (Gaussian) chain.

** Even if the symmetry numbers of the chains are taken into account in the integrand, they are cancelled out by those occurring in C^2 ; that is, A_2 is independent of the symmetry number.

In the following, we shall consider $G_\kappa([\kappa_1][\kappa_2])$ for $\kappa \geq 2$.

In general, the expansion terms of $\Omega^\kappa\{\kappa_s\}$ are arranged in ascending order of interaction as in the case of $\Omega(R_{kl})$:

$$\Omega^\kappa\{\kappa_s\} = \sum_{\nu_s=0}^N B_{\nu_s}^\kappa\{\kappa_s\}, \quad (17)$$

where ν_s is the order of *intramolecular* interaction. If we denote the orders of *intermolecular* and *overall* interactions by $\kappa-1$ and μ respectively, we must have the relation: $\mu+1=\kappa+\nu_1+\nu_2$ ($2 \leq \kappa \leq \mu+1$). Accordingly, if we consider in $G_\kappa([\kappa_1][\kappa_2])$ the terms up to the order μ of overall interaction, $G_\kappa([\kappa_1][\kappa_2])$ reduces to

$$G_{\kappa\mu}([\kappa_1][\kappa_2]) = (C_{\kappa\mu})^2 \iint \cdots \int \sum \Pi f_{i_1 j_2} \left[\sum_{0 \leq \nu_1 + \nu_2 \leq \mu - \kappa + 1} B_{\nu_1}^\kappa\{\kappa_1\} B_{\nu_2}^\kappa\{\kappa_2\} \right] d\{\kappa_1 + \kappa_2\} \quad (18)$$

with

$$(C_{\kappa\mu})^{-1} = \iint \cdots \int \sum_{\nu_s=0}^{\mu-\kappa+1} B_{\nu_s}^\kappa\{\kappa_s\} d\{\kappa_s - 1_s\}. \quad (19)$$

There must be dropped some of the terms in $(C_{\kappa\mu})^{-2}$, which do not correspond to those in the integrand in Eq. (18). If we denote the sum of $G_{\kappa\mu}([\kappa_1][\kappa_2])$ over all the configurations by $G_{\kappa\mu}$, A_2 is finally given by

$$A_2 = -\frac{N_0}{2VM^2} (G_1 + \sum_{\kappa=2}^{\mu+1} G_{\kappa\mu}) \quad (20)$$

with the specified value of μ . The degree of approximation for A_2 , of course, increases with increasing μ .

In order to perform the calculation of A_2 in the following section, we adopt the same forms of $f(r)$ and of the partition function of an ideal chain $\Omega_0(r, n)$ as in TPS I:

$$f(r) = \begin{cases} -1 & ; r \leq b \\ \frac{\epsilon_0}{kT} \exp\left(-\frac{3}{2\lambda^2} r^2\right) & ; r > b \end{cases} \quad (21)$$

$$\Omega_0(r, n) = \frac{(4\pi a^2)^n}{(2\pi n a^2/3)^{3/2}} \exp\left(-\frac{3}{2n a^2} r^2\right) \quad (n \geq 2). \quad (22)$$

And the diameter of segment b , the bond length a and a parameter λ are assumed to satisfy the condition:

$$G_{22} = \sum_{i_1, j_1} \sum_{i_2, j_2} 2(C_{22})^2 \iiint f(r_{i_1 i_2}) f(r_{j_1 j_2}) [B_{0_1}^2(r_{i_1 j_1}) B_{0_2}^2(r_{i_2 j_2}) + 2B_{1_1}^2(r_{i_1 j_1}) B_{0_2}^2(r_{i_2 j_2})] d(i_1) d(j_1) d(i_2) d(j_2). \quad (27)$$

$B_{0_1}^2(r_{i_1 j_1})$ and $B_{1_1}^2(r_{i_1 j_1})$ are given by the following equations, as have already been calculated in TPS I.

$$B_{0_1}^2(r_{i_1 j_1}) = (4\pi a^2)^{N-(j_1-i_1)} \Omega_0(r_{i_1 j_1}, j_1 - i_1), \quad (28)$$

$$b \ll \lambda \leq a. \quad (23)$$

§ 3. Calculations of $G_{\kappa\mu}$

We shall concern ourselves with the case of $\mu=2$. Then, from Eq. (20), A_2 becomes

$$A_2 = -\frac{N_0}{2VM^2} (G_1 + G_{22} + G_{32}). \quad (24)$$

(i) Calculation of G_1

From Eqs. (13), (16) and (21) with the approximation (23), we obtain

$$G_1 = 4\pi V N^2 \int_0^\infty f(r) r^2 dr = -\frac{4\pi V}{3} N^2 b^3 \left(1 - \frac{\Theta}{T}\right) \quad (25)$$

with

$$\Theta = \left\{ \left(\frac{\pi}{6} \right)^{1/2} \left(\frac{\lambda}{b} \right)^3 - 1 \right\} \left(\frac{\epsilon_0}{k} \right), \quad (26)$$

where Θ is the Flory temperature discussed in TPS I.

(ii) Calculation of G_{22}

Although the products of f 's in the integrand of $G_{22}([2_1][2_2])$ are $f_{i_1 i_2} f_{j_1 j_2}$ and $f_{i_1 i_2} f_{j_1 j_2}$, it is easy to see that these make the same contribution to A_2 . Hence, G_{22} can be written as

$$B^2_1(r_{i_1j_1}) = \sum_{k_1, l_1}^{(2-1)} F_1(r_{i_1j_1}, [200]) + \sum_{k_1, l_1}^{(2-2)} F_1(r_{i_1j_1}, [020])$$
$$+ \dots + \sum_{k_1, l_1}^{(2-6)} F_1(r_{i_1j_1}, [101])$$

(29)

with

$$F_1(r_{i_1j_1}, [200]) = -(4\pi a^2)^{N-(j_1-i_1)} \left(\frac{6}{\pi}\right)^{1/2} (l_1-k_1)^{-3/2} \left(\frac{b}{a}\right)^3 \left(1-\frac{\Theta}{T}\right) \Omega_0(r_{i_1j_1}, j_1-i_1),$$
$$F_1(r_{i_1j_1}, [020]) = -(4\pi a^2)^{N-(j_1-i_1-l_1+k_1)} \left(\frac{6}{\pi}\right)^{1/2} (l_1-k_1)^{-3/2} \left(\frac{b}{a}\right)^3 \left(1-\frac{\Theta}{T}\right)$$
$$\times \Omega_0(r_{i_1j_1}, j_1-i_1-l_1+k_1),$$

.....

(30)

The first term in Eq. (27) corresponds to cluster diagram (2-0) illustrated in Fig. 1, and the functions F_1 's correspond to cluster diagrams (2-1) to (2-6) respectively. The summation signs in Eq. (29) denote summations over k_1 and l_1 , the ranges of which would be rather obvious from the cluster diagrams.

The integrations in Eq. (27) can be easily performed by the Fourier and inverse transformations:^{6),7)}

Fig. 1. Cluster Diagrams.

$$G_{22} = \sum_{i_1, j_1} \sum_{i_2, j_2} 2V(C_{22})^2 \int_0^\infty 4\pi r_{i_1 i_2}^2 f(r_{i_1 j_2}) F(r_{i_1 i_2}) dr_{i_1 i_2},$$

(31)

where

$$F(r_{i_1 i_2}) = \frac{1}{8\pi^3} \int \exp(-i\mathbf{q} \cdot \mathbf{r}_{i_1 i_2}) H(\mathbf{q}) d\mathbf{q},$$

(32)

$$H(\mathbf{q}) = \alpha(\mathbf{q}) \beta(\mathbf{q}) \gamma(\mathbf{q}),$$
$$\alpha(\mathbf{q}) = \int [B^2_{01}(r_{i_1 j_1}) + 2B^2_{11}(r_{i_1 j_1})] \exp(i\mathbf{q} \cdot \mathbf{r}_{i_1 j_1}) d\mathbf{r}_{i_1 j_1},$$
$$\beta(\mathbf{q}) = \int f(r_{j_1 j_2}) \exp(i\mathbf{q} \cdot \mathbf{r}_{j_1 j_2}) d\mathbf{r}_{j_1 j_2},$$
$$\gamma(\mathbf{q}) = \int B^2_{02}(r_{i_2 j_2}) \exp(i\mathbf{q} \cdot \mathbf{r}_{i_2 j_2}) d\mathbf{r}_{i_2 j_2},$$

(33)

$$(C_{22})^{-2} = (4\pi a^2)^{2N} \left[1 - 2 \sum_{\substack{0 \leq k_1 < l_1 \leq N \\ l_1 - k_1 \neq 1}} (l_1 - k_1)^{-3/2} \left(\frac{6}{\pi}\right)^{1/2} \left(\frac{b}{a}\right)^3 \left(1 - \frac{\Theta}{T}\right) \right].$$

(34)

The calculations eventually lead us to

$$G_{22} = -G_1 \dot{\gamma}_{20} \xi \left(1 - \frac{\dot{\gamma}_{21}}{\dot{\gamma}_{20}} \xi\right),$$

(35)

where

$$\xi = \left(\frac{6}{\pi}\right)^{1/2} \left(\frac{b}{a}\right)^3 \left(1 - \frac{\Theta}{T}\right) N^{1/2},$$

(36)

$$-\frac{N^{3/2}}{2} r_{20} = \sum_{(2-0)} (j_1 - i_1 + j_2 - i_2)^{-3/2}, \quad (37)$$

$$\begin{aligned} \frac{N^3}{4} r_{21} = & \sum_{(2-2)} (l_1 - k_1)^{-3/2} [\{j_1 - i_1 + j_2 - i_2 - (l_1 - k_1)\}^{-3/2} - (j_1 - i_1 + j_2 - i_2)^{-3/2}] \\ & + 2 \sum_{(2-4)} (l_1 - k_1)^{-3/2} \left[\left\{ j_1 - i_1 + j_2 - i_2 - \frac{(l_1 - i_1)^2}{l_1 - k_1} \right\}^{-3/2} - (j_1 - i_1 + j_2 - i_2)^{-3/2} \right] \\ & + \sum_{(2-6)} (l_1 - k_1)^{-3/2} \left[\left\{ j_1 - i_1 + j_2 - i_2 - \frac{(l_1 - i_1)^2}{l_1 - k_1} \right\}^{-3/2} - (j_1 - i_1 + j_2 - i_2)^{-3/2} \right]. \end{aligned} \quad (38)$$

Eq. (38) shows that clusters (2-1) and (2-3) make no contribution to A_2 and the contributions of clusters (2-4) and (2-5) are the same. Since we know that the intramolecular cluster corresponding to (2-2) makes main contribution to the mean radius of gyration of the polymer chain,⁶⁾ the second and third sums in Eq. (28), for simplicity, are neglected. Then, replacing summations by integrations, we obtain for the numerical values of r_{20} and r_{21} ,

$$r_{20} = \frac{32}{15} (7 - 4\sqrt{2}) = 2.865, \quad (39)$$

$$\begin{aligned} r_{21} & \simeq \frac{4}{N^3} \sum_{(2-2)} \dots \\ & = 8 \left\{ \frac{304}{45} - \frac{11\sqrt{2}}{3} + 3 \ln(1 + \sqrt{2}) - \pi \right\} = 8.78. \end{aligned} \quad (40)$$

(iii) Calculation of G_{32}

There exist six products of f 's in the integrand of G_{32} , which reduce to two $f_{i_1 i_2} f_{j_1 j_2} f_{k_1 k_2}$'s and four $f_{i_1 i_2} f_{j_1 k_2} f_{k_1 j_2}$'s. Therefore, G_{32} can be written as

$$\begin{aligned} G_{32} = & \sum_{i_1 j_1 k_1} \sum_{i_2 j_2 k_2} 2(C_{32})^2 \iint \dots \\ & \times \int [f(r_{i_1 i_2}) f(r_{j_1 j_2}) f(r_{k_1 k_2}) \\ & + 2f(r_{i_1 i_2}) f(r_{j_1 k_2}) f(r_{k_1 j_2})] B_{0_1}^3 \{3_1\} B_{0_2}^3 \{3_2\} \\ & \times d(i_1) d(j_1) d(k_1) d(i_2) d(j_2) d(k_2) \end{aligned} \quad (41)$$

with

$$(C_{32})^2 = (4\pi a^2)^{-2N}. \quad (42)$$

The first and second terms in Eq. (42) correspond to clusters (3-01) and (3-02) respectively. And $B_{0_s}^3 \{3_s\}$ is given by

$$\begin{aligned} B_{0_s}^3 \{3_s\} \\ = (4\pi a^2)^{N - (i_s - k_s)} \Omega_0(r_{j_s i_s}, j_s - i_s) \Omega_0(r_{j_s k_s}, k_s - j_s). \end{aligned} \quad (43)$$

Since the integrations in Eq. (41) can be performed in like manner as in G_{22} , the method need not be reproduced. The result is

$$G_{32} = G_1 r_{30} \xi^2, \quad (44)$$

where

$$\begin{aligned} \frac{N^3}{2} r_{30} = & \sum_{(3-01)} (k_1 - j_1 + k_2 - j_2)^{-3/2} \\ & \times (j_1 - i_1 + j_2 - i_2)^{-3/2} \\ & + 2 \sum_{(3-02)} \{(k_1 - j_1 + k_2 - j_2)(j_1 - i_1 + j_2 - i_2) \\ & + (k_1 - j_1)(k_2 - j_2)\}^{-3/2}. \end{aligned} \quad (45)$$

Replacing summations by integrations, we obtain for the numerical value of r_{30}

$$r_{30} = 8 \left(\pi - \frac{8}{3} \right) + 5.93 = 9.73. \quad (46)$$

§ 4. The Second Virial Coefficient and Comparison with Other Theories

From Eqs. (24), (25), (35) and (44), we obtain the final expression for the osmotic second virial coefficient,

$$A_2 = \frac{2\pi N_0 b^3}{3M_0^2} \left(1 - \frac{\Theta}{T} \right) \mathcal{F}(\xi), \quad (47)$$

where

$$M_0 = \frac{M}{N}, \quad (48)$$

$$\mathcal{F}(\xi) = 1 - r_{20} \left(1 - \frac{r_{21}}{r_{20}} \right) \xi + r_{30} \xi^2 \quad (49)$$

$$= 1 - r_{20} \xi + (r_{21} + r_{30}) \xi^2 - \dots \quad (49')$$

up to the terms of order ξ^2 . Here, r_{20} , r_{21} and r_{30} have the positive values given by Eqs. (39), (40) and (46) respectively. But strictly speaking, r_{21} would have somewhat larger value than the above one, owing to the neglect of the minor sums in Eq. (38).

Eq. (49') shows that the influence of intramolecular interactions (represented by r_{21} to the present approximation) would appear in higher terms than the second of ξ ; in other words, the (intramolecular) excluded volume effect may be considered to have no influence on the second virial coefficient in the vicinity of the Θ temperature in poor solvents, but increases gradually with increasing temper-

ature and forces the second virial coefficient, which is the measure of the excluded volume of a pair of two polymer molecules, to become larger. In so far as we are concerned with the terms up to the first of ξ , Eq. (47) is essentially equivalent to Zimm's formula* derived without taking account of the intramolecular interactions.

From the general theory developed in § 2 and Eq. (49), we suggest that the excluded volume function $\mathcal{F}(\xi)$, if account is taken of the higher order interactions, may be expressed in the form,

$$\mathcal{F}(\xi) = 1 - \gamma_{20}\alpha_1(\xi)\xi + \gamma_{30}\alpha_2(\xi)\xi^2 - \dots \quad (50)$$

$\alpha_1(\xi)$, $\alpha_2(\xi)$, etc. are the correction factors which would represent the influences of the intramolecular excluded volume on the second virial coefficient. It is easy to see that all these functions decrease with increasing temperature in poor solvents, namely increasing ξ , and take the value of unity at $T = \theta$.

According to the Flory-Krigbaum theory,²⁾ the function $\mathcal{F}$ is given by

$$\left. \begin{aligned} \mathcal{F}(X) &= 1 - \frac{X}{2!2^{3/2}} + \frac{X}{3!3^{3/2}} - \dots, \\ X &= 2(\alpha^2 - 1) = 3^{3/2} \frac{\xi}{\alpha^3}, \end{aligned} \right\} \quad (51)**$$

where α is a linear intramolecular deformation factor. Therefore, $\mathcal{F}$ may be rewritten as

$$\mathcal{F}(\xi) = 1 - 0.919 \frac{\xi}{\alpha^3} + 0.866 \frac{\xi^2}{\alpha^6} - \dots \quad (\text{the F. K. theory}) \quad (52)$$

Comparing Eq. (52) with Eq. (50), α^{-3} , α^{-6} , etc. are easily found to correspond to $\alpha_1(\xi)$, $\alpha_2(\xi)$, etc. respectively and to just similarly behave as these do. In our theory, if the partial one-body phase integral is assumed to have the form,

* See reference 6. His coefficient of ξ is half smaller than ours because of miss counting of clusters.

** According to the statistical theory of a single polymer chain present in dilute solutions developed by Flory,⁸⁾ α , using our parameter ξ , satisfies the relation:

$$\alpha^5 - \alpha^3 = (3^{3/2}/2)\xi.$$

Recently Orofino and Flory³⁾ have improved the theory, in which a correction term, dependent on temperature and the polymer molecular weight, has been added on the right-hand side of the above equation.

$$\Omega^{\kappa}\{\kappa_s\} = \prod_{\substack{0 \leq i_s < j_s \leq N \\ i_s, j_s \in [\kappa_s]}} \Omega_0\left(\frac{r_{i_s j_s}}{\alpha}, j_s - i_s\right), \quad (53)$$

namely if the polymer chain is assumed to be a Gaussian one uniformly expanded by a factor α , it is easily shown that $\mathcal{F}$ can be expressed by

$$\mathcal{F}(\xi) = 1 - \gamma_{20} \frac{\xi}{\alpha^3} + \gamma_{30} \frac{\xi^2}{\alpha^6} - \dots, \quad (54)$$

which is equivalent to the Flory-Krigbaum equation (52) except the expansion coefficients. From Eq. (33) in TPS I (the mean radius of gyration) and from the values of γ_{20} and γ_{21} , it would be expected that if $\alpha_1(\xi)$ is written in the form α^{-n} , n is somewhat larger than 3. This discrepancy might be attributed to a non-Gaussian character of the chain.

On the other hand, according to the Isihara-Koyama theory,⁴⁾ the function $\mathcal{F}$ is given by

$$\mathcal{F}(\xi) = 1 - 1.024\xi + 1.134\xi^2 - \dots \quad (\text{the I. K. theory}) \quad (55)***$$

The intramolecular excluded volume effect has been ignored in their theory, namely all $\alpha_n(\xi) \equiv 1$.

The essential difference between our theory and the F. K. or I. K. theory is that the expansion coefficients γ_{20} , γ_{30} , etc. in the former are considerably greater than the corresponding coefficients in the latter two. This could be interpreted as follows: in the F. K. and I. K. theories the important chain character of the connections of segments has been lost owing to the introduction of their factorized distribution approximation into the distribution function for κ segments about the molecular center of mass, while in our theory the correlation between segments, namely the connections of segments, which seem to be closely related to the *liquid-like* behavior of the chain, have been explicitly taken into account, even when the approximation (55) is used. In the I. K. theory, slightly larger coefficients than in the F. K. theory have been obtained with taking account of the distinguishability between segments i and j .

In conclusion, it must be noticed that in the experimental verification our large expansion coefficients will improve the molecular

*** The argument of $\mathcal{F}(X)$ in the I. K. theory is equal to $3^{3/2}\xi$.

weight dependence of the second virial coefficient at least in the vicinity of the θ temperature since ξ is proportional to $M^{1/2}$. This dependence has been underestimated in the F. K. theory.^{9), 10), *}

The author wishes to express his hearty thanks to Professors Ichiro Sakurada and Akio Nakajima who gave him kind encouragement and helpful discussions. Thanks are tendered also to members of the Research Group on Polymer Science of this University, especially to Professors Michio Kurata and Ei Teramoto, for their advices and stimulating discussions.

Theory of Dilute Polymer Solutions (III) Intrinsic Viscosity

By Hiromi YAMAKAWA* and Michio KURATA**

Department of Textile Chemistry and* *Department of Industrial Chemistry, Kyoto University, Kyoto, Japan*

(Received October 2, 1957)

A theory of the intrinsic viscosity $[\eta]$ of chain polymer solutions is developed on the basis of the Kirkwood and Riseman scheme, taking some modifications concerning the excluded volume effect into account. If the volume effect is represented by the linear expansion factor α of the root mean square radius of gyration, it is concluded that $[\eta]$ is proportional to α^2 for the free-draining molecule and $\alpha^{2.43}$ for the non-free-draining molecule. This implies that the effective hydrodynamic radius of the polymer coil is not proportional to the statistical one in the limit, where the rigid sphere model is asymptotically valid; in other words, the more the polymer chain is expanded, the deeper the solvent molecules penetrate into the polymer coil.

§ 1. Introduction

Theories of the intrinsic viscosity $[\eta]$ of chain polymer solutions have been developed by Debye-Bueche (D.B.),¹⁾ Kirkwood-Riseman (K.R.),²⁾ and Flory-Fox (F.F.).³⁾ The D.B. and K.R. theories have the apparent difference in their mathematical analyses, but equivalent are the physical meanings involved by them:

the molecular weight dependence of $[\eta]$ is uniquely related to the variation of the velocity gradient of fluids in the polymer coil, which is subjected to the hydrodynamic interactions between segments. Combining with Stokes' law, these theories render us the smaller diameter of the segment than that to be expected. This would take its rise in their

Gaussian model and none other. On the other hand, the F.F. theory is established on Einstein's rigid sphere model and attributes the molecular weight dependence of $[\eta]$ to the intramolecular deformation of the chain due to the thermodynamic interactions between segments.

If $[\eta]$, following Flory and Fox, is written in the form,

$$[\eta] = 6^{3/2} \phi \frac{(\langle S^2 \rangle_0)^{3/2}}{M} \alpha^3,$$

α reduces to unity (Gaussian) and ϕ depends on the molecular weight in the D.B. and K.R. theories, while ϕ assumes its asymptotic value independent of the molecular weight and α varies with the molecular weight in the F.F. theory. Since, however, in deriving the above formula Flory and Fox have introduced the intuitive assumption that the effective hydrodynamic radius of the polymer coil is proportional to the statistical one, their theory is of empirical nature. In addition this assumption is not necessarily satisfied according to the recent experimental data.⁴⁾

The K.R. theory seems to be superior to the D.B. theory in their model and formulations in so far as linear polymers are concerned. In the present paper, for this reason, we study the intrinsic viscosity of a chain polymer solution in the manner of Kirkwood and Riseman, taking into consideration the thermodynamic interactions between segments as well as the hydrodynamic ones. And we discuss the proportionality between the hydrodynamic and statistical radii.

§ 2. Model and Average Quantities

Although the pearl-necklace model and the continuous medium approximation are adopted⁵⁾ in this paper as before, for convenience, the segments are attached numbers $-n, \dots, -1, 0, +1, \dots, +n$ in place of $0, 1, 2, \dots, N$. Thus we have the relation, $N=2n$.

If we denote the distance between segments i and j by R_{ij} ($j > i$) and the distance between the molecular center of mass and segment i by S_i , we obtain the following expressions for various average quantities over chain configurations from Eqs. (28) and (35) in TPS I;^{*}

$$\langle R_{ij}^2 \rangle = (j-i)a^2 + \xi \frac{4(j-i)a^2}{3\sqrt{2}n^{1/2}} \left[\frac{8}{3}(j-i)^{1/2} - 4(n-i)^{1/2} + 4(n+j)^{1/2} + \frac{j-i}{\sqrt{2}n^{1/2}} - \frac{8}{3(j-i)} \{ (n+i)^{3/2} - (n-i)^{3/2} - (n+j)^{3/2} + (n-j)^{3/2} \} \right], \quad (1)$$

$$\langle S_i^2 \rangle = \frac{(3i^2 + n^2)a^2}{6n} + \xi \frac{4a^2}{3\sqrt{2}n^{1/2}} \left[\frac{3}{5n} \{ (n+i)^{5/2} + (n-i)^{5/2} \} - \frac{8}{3} \{ (n+i)^{3/2} + (n-i)^{3/2} \} + \frac{1}{6\sqrt{2}n^{3/2}} \{ (n+i)^3 + (n-i)^3 \} + \frac{121\sqrt{2}}{42} n^{3/2} \right], \quad (2)$$

$$\langle S_i \cdot S_j \rangle = \frac{1}{12n} \{ 3(i+j^2) - 6(j-i)n + 2n^2 \} a^2 + \xi \frac{\sqrt{2}a^2}{3n^{1/2}} \left[-\frac{1}{6\sqrt{2}n^{3/2}} \{ (n+i)^3 + (n-i)^3 + (n+j)^3 + (n-j)^3 \} + \frac{3}{5n} \{ (n+i)^{5/2} + (n-i)^{5/2} + (n+j)^{5/2} + (n-j)^{5/2} \} - \frac{1}{\sqrt{2}n^{1/2}} (j-i)^2 - \frac{8}{3} (j-i)^{3/2} - \frac{16}{3} (n-i)^{3/2} - \frac{16}{3} (n+j)^{3/2} + 4(j-i)(n-i)^{1/2} + 4(j-i)(n+j)^{1/2} + \frac{121\sqrt{2}}{21} n^{3/2} \right], \quad (3)$$

with

$$\xi = \left(\frac{6}{\pi} \right)^{1/2} \left(\frac{b}{a} \right)^3 \left(1 - \frac{\Theta}{T} \right) N^{1/2}, \quad (4)$$

where b is the diameter of segment, a its constant bond length, and Θ the Flory temperature. When $T=\Theta$, Eqs. (1) to (3), which have their validity in the vicinity of the Θ temperature, reduce to the corresponding formulae used by Kirkwood and Riseman for

the Gaussian chain.

$\langle 1/R_{ij} \rangle$ can be evaluated in the same way as $\langle R_{ij}^2 \rangle$, using the partition function $\Omega(R_{ij})$ mentioned in TPS I, but the result is very complicated, as shown in Appendix I. As will

* Part I of this series⁵⁾ is cited as TPS I.

be discussed in the next section, this is closely related to the Oseen tensor, and becomes the kernel of the K.R. integral equation which determines the hydrodynamic interactions between segments. Now, therefore, if $\langle 1/R_{ij} \rangle$ is written as

$$\left\langle \frac{1}{R_{ij}} \right\rangle = \beta \left\langle \frac{1}{R_{ij}} \right\rangle_0, \quad (5)$$

where the subscript 0 indicates a Gaussian chain, and if β is assumed to be independent of i and j in order to simplify the further calculations, then Eq. (5) can be immediately rewritten as

$$\beta = \frac{\frac{1}{2n^2} \sum_{i < j} \left\langle \frac{1}{R_{ij}} \right\rangle}{\frac{1}{2n^2} \sum_{i < j} \left\langle \frac{1}{R_{ij}} \right\rangle_0}. \quad (6)$$

Namely β is a correction factor which would represent the amount by which the average quantity of $\langle 1/R_{ij} \rangle$ over i and j deviates from that for the Gaussian chain. Since, however, it is almost impossible to evaluate the sum in the numerator of Eq. (6), the correction factor of $\langle 1/R_{ij} \rangle_0$ is assumed to be approximately equal to the inverse square root of that of $\langle R_{ij}^2 \rangle$. Then β becomes

$$\left. \begin{aligned} \beta &= \frac{\frac{1}{2n^2} \sum_{i < j} \alpha_{ij}^{-1} \left\langle \frac{1}{R_{ij}} \right\rangle_0}{\frac{1}{2n^2} \sum_{i < j} \left\langle \frac{1}{R_{ij}} \right\rangle_0}, \\ \alpha_{ij} &= \left(\frac{\langle R_{ij}^2 \rangle}{\langle R_{ij}^2 \rangle_0} \right)^{1/2}. \end{aligned} \right\} \quad (6')$$

Calculating the sums in Eq. (6'), eventually we obtain for $\langle 1/R_{ij} \rangle$

$$\left\langle \frac{1}{R_{ij}} \right\rangle = \left(\frac{6}{\pi} \right)^{1/2} \frac{1}{(j-i)^{1/2} a} \left\{ 1 - 2 \left(\pi - \frac{44}{15} \right) \xi \right\}. \quad (7)$$

§ 3. Kirkwood-Riseman Integral Equation and Intrinsic Viscosity

According to Kirkwood and Riseman,²⁾ when a polymer chain is introduced into a continuous medium of solvent molecules in a state of stationary two-dimensional viscous flow between parallel plane boundaries, the force F_i of frictional resistance exerted on the fluid by segment i is given by

$$F_i = -\frac{\zeta \dot{\epsilon}}{2} [e_x(S_i \cdot e_y) + e_y(S_i \cdot e_x)] - \zeta \sum_{\substack{s=-n \\ s \neq i}}^{+n} T_{is} \cdot F_s \quad (-n \leq i \leq +n). \quad (8)$$

Here ζ is a friction constant characteristic of the fluid and the segment, $\dot{\epsilon}$ is the velocity gradient, and e_x, e_y, e_z are unit vectors defining a coordinate system with origin at the molecular center of mass with e_x parallel to the stream lines of the unperturbed flow and e_y perpendicular to the plane boundaries. And the Oseen tensor T_{is} has the form,

$$T_{is} = \frac{1}{8\pi\eta_0 R_{is}} \left(\mathbf{1} + \frac{R_{is} R_{is}}{R_{is}^3} \right), \quad (9)$$

where η_0 is the viscosity coefficient of the solvent fluid.

Following the analyses of Burgers and Kirkwood-Riseman, the expression for the intrinsic viscosity is

$$[\eta] = \lim_{c \rightarrow 0} \frac{\eta - \eta_0}{\eta_0 c} \quad (10)$$

$$= -\frac{N_0}{100M\eta_0 \dot{\epsilon}} \sum_{i=-n}^{+n} \langle (S_i \cdot e_x)(F_i \cdot e_y) \rangle, \quad (11)$$

where η is the viscosity coefficient of the solution, c the concentration in grams per 100 ml, $M (=NM_0)$ the molecular weight, and N_0 Avogadro's number.

If we define φ_{ij} by the relation,

$$\langle (S_j \cdot e_x)(F_i \cdot e_y) \rangle = -\frac{na^2 \zeta \dot{\epsilon}}{9} \varphi_{ij}, \quad (12)$$

then from Eqs. (11) and (12), $[\eta]$ may be expressed in the form,

$$[\eta] = \left. \begin{aligned} &\frac{N_0 \zeta a^2 M}{3600 \eta_0 M_0^2} F, \\ &F = \frac{1}{n} \sum_{i=-n}^{+n} \varphi_{ii}. \end{aligned} \right\} \quad (13)$$

For large n , the sum defining F may be replaced by the integral

$$\left. \begin{aligned} F &= \int_{-1}^{+1} \varphi(x, x) dx, \\ \varphi_{ij} &= \varphi(x, y), \quad x = \frac{i}{n}, \quad y = \frac{j}{n}. \end{aligned} \right\} \quad (14)$$

Now, according to Kirkwood and Riseman, ignoring the fluctuation of T_{is} and approximating it by $\langle T_{is} \rangle$, we obtain

$$\begin{aligned} \langle T_{is} \rangle &= \frac{\mathbf{1}}{6\pi\eta_0} \left\langle \frac{\mathbf{1}}{R_{is}} \right\rangle \\ &= \frac{\mathbf{1}}{(6\pi^3)^{1/2} a \eta_0} \frac{1}{|i-s|^{1/2}} \left\{ 1 - 2 \left(\pi - \frac{44}{15} \right) \xi \right\}, \end{aligned} \quad (15)$$

and then φ_{ij} could be determined as the solutions of the following simultaneous equation,

$$\varphi_{ij} = f_{ij} - \frac{\lambda}{n^{1/2}} \left\{ 1 - 2 \left(\pi - \frac{44}{15} \right) \xi \right\} \sum_{s \neq i}^{+n} \frac{\varphi_{sj}}{|i-s|^{1/2}} \quad f_{ij} = \frac{3}{2na^2} \langle \mathbf{S}_i \cdot \mathbf{S}_j \rangle, \quad (17)$$

$$(-n \leq i \leq +n, \quad -n \leq j \leq +n) \quad (16)$$

with

$$\lambda = \frac{\zeta}{(12\pi^3)^{1/2} a \eta_0} \left(\frac{M}{M_0} \right)^{1/2}. \quad (18)$$

For large n , Eq. (16) reduces to the integral equation,

$$\varphi(x, y) = f(x, y) - \lambda \left\{ 1 - 2 \left(\pi - \frac{44}{15} \right) \xi \right\} \int_{-1}^{+1} \frac{\varphi(t, y)}{|x-t|^{1/2}} dt, \quad (19)$$

where

$$\left. \begin{aligned} f(x, y) &= f^0(x, y) + \xi f^1(x, y), \\ f^0(x, y) &= \frac{1}{8} \{ 3(x^2 + y^2) - 6|x-y| + 2 \}, \\ f^1(x, y) &= \begin{cases} u(x, y); & y \geq x \\ u(y, x); & y < x, \end{cases} \\ u(x, y) &= \frac{1}{12} \{ (1+x)^3 + (1-x)^3 + (1+y)^3 + (1-y)^3 \} + \frac{3\sqrt{2}}{10} \{ (1+x)^{5/2} + (1-x)^{5/2} \\ &\quad + (1+y)^{5/2} + (1-y)^{5/2} \} - \frac{1}{2} (x-y)^2 - \frac{4\sqrt{2}}{3} (y-x)^{3/2} - \frac{8\sqrt{2}}{3} (1-x)^{3/2} \\ &\quad - \frac{8\sqrt{2}}{3} (1+y)^{3/2} + 2\sqrt{2} (y-x)(1-x)^{1/2} + 2\sqrt{2} (y-x)(1+y)^{1/2} + \frac{121}{21}. \end{aligned} \right\} \quad (20)$$

If Eq. (19) is solved with respect to $\varphi(x, y)$, $[\eta]$ is obtained by Eq. (13) and (14). Although, when $\xi=0$, Eq. (19) is nothing but the K.R. integral equation for Gaussian chain, it is clear that the integral equation (19) is of the same type as the K.R.'s whenever ξ is equal to zero or not. But, as has been pointed out by Zimm⁶⁾ and Kirkwood,^{7), 8)} the integral equation of this type can not analytically be solved.

If $\varphi(x, y)$ and $f(x, y)$ are expanded in Fourier series of the forms

$$\left. \begin{aligned} \varphi(x, y) &= \sum_{k=-\infty}^{+\infty} \varphi_k(y) e^{i\pi k x}, \\ f(x, y) &= \sum_{k=-\infty}^{+\infty} f_k(y) e^{i\pi k x}, \end{aligned} \right\} \quad (21)$$

respectively, then Eq. (19) is transformed into the following set of linear equations for the Fourier coefficients,

$$\varphi_k(y) + \lambda \left\{ 1 - 2 \left(\pi - \frac{44}{15} \right) \xi \right\} \sum_{l=-\infty}^{+\infty} a_{kl} \varphi_l(y) = f_k(y). \quad (k=0, \pm 1, \pm 2, \dots) \quad (22)$$

When the matrix elements a_{kl} are approximated by the values which are asymptotically valid for large k and l , a_{kl} becomes

$$a_{kl} = \begin{cases} \frac{8\sqrt{2}}{3} & ; \quad k=l=0 \\ \left(\frac{2}{|k|} \right)^{1/2} \delta_{kl} & ; \quad k \neq 0. \end{cases} \quad (23)$$

With the approximation (23), inserting the solutions of Eq. (22) in Eq. (21), we find

$$\left. \begin{aligned} \varphi(x, y) &= \frac{f_0(y)}{1 + \frac{8\sqrt{2}}{3} \lambda \left\{ 1 - 2 \left(\pi - \frac{44}{15} \right) \xi \right\}} \\ &\quad + \sum_{k=-\infty}^{+\infty} \frac{f_k(y)}{1 + \lambda \left\{ 1 - 2 \left(\pi - \frac{44}{15} \right) \xi \right\} \left(\frac{2}{|k|} \right)^{1/2}} e^{i\pi k x}. \end{aligned} \right\} \quad (24)$$

Since it can be easily shown that $f_0(y) \equiv 0$, $\varphi(x, y)$ given by Eq. (24), when $\xi=0$, reduces to the approximate solution obtained by Kirkwood and Riseman.²⁾ Adopting the approximate solution (24), we obtain, after laborious calculations,

$$\begin{aligned} F(x) &= \frac{6}{\pi^2} \sum_{k=1}^{\infty} \frac{1}{k^2} \frac{1}{1 + \left\{ 1 - 2 \left(\pi - \frac{44}{15} \right) \xi \right\} \chi/k^{1/2}} \\ &\quad \times \left[1 + \frac{2}{3} \xi \left\{ 1 + 2\pi^{1/2} \frac{C(2\pi k)}{(\pi k)^{1/2}} + \frac{3}{2} \pi^{1/2} \frac{S(2\pi k)}{(\pi k)^{3/2}} \right\} \right], \end{aligned} \quad (25)$$

where

$$\left. \begin{aligned} x &= \sqrt{2} \lambda = \lambda_0 N^{1/2}, \\ \lambda_0 &= \frac{\zeta}{(6\pi^3)^{1/2} a \eta_0}, \end{aligned} \right\} \quad (26)$$

and Fresnel's integrals $C(y)$ and $S(y)$ are defined as

$$\left. \begin{aligned} C(y) &= \int_0^y \frac{\cos t}{(2\pi t)^{1/2}} dt, \\ S(y) &= \int_0^y \frac{\sin t}{(2\pi t)^{1/2}} dt. \end{aligned} \right\} \quad (27)$$

The higher terms of ξ than the second have to be neglected in the expansion of $F(x)$ in powers of ξ , as for various average quantities discussed in § 2. $[\eta]$ can then be expressed in the form,

$$[\eta] = \frac{N_0 \zeta a^2}{3600 \eta_0 M_0} N F_0(\lambda_0 N^{1/2}) \left[1 + \frac{F_1(\lambda_0 N^{1/2})}{F_0(\lambda_0 N^{1/2})} \xi \right], \quad (28)$$

where

$$F_0(x) = \frac{6}{\pi^2} \sum_{k=1}^{\infty} \frac{1}{k^2} \frac{1}{1+x/k^{1/2}}, \quad (29)$$

$$\left. \begin{aligned} F_1(x) &= F_1^1(x) + F_1^2(x), \\ F_1^1(x) &= \frac{4}{\pi^2} \sum_{k=1}^{\infty} \frac{1}{k^2} \frac{1}{1+x/k^{1/2}} \\ &\quad \times \left[1 + 2\pi^{1/2} \frac{C(2\pi k)}{(\pi k)^{1/2}} + \frac{3}{2} \pi^{1/2} \frac{S(2\pi k)}{(\pi k)^{3/2}} \right], \\ F_1^2(x) &= \frac{12}{\pi^2} \left(\pi - \frac{44}{15} \right) \sum_{k=1}^{\infty} \frac{1}{k^{5/2}} \frac{x}{(1+x/k^{1/2})^2}. \end{aligned} \right\} \quad (30)$$

$F_1^1(x)$ and $F_1^2(x)$ are associated with correction terms which would represent the amounts by which $\langle S_i \cdot S_j \rangle$ and $\langle 1/R_{ij} \rangle$ deviate from those for a Gaussian chain, respectively. Although the functions $F_0(x)$ and $F_1(x)$ obtained above are not rigorously correct, the hydrodynamic behavior of a Gaussian chain could be completely understood throughout $F_0(x)$ given by Eq. (29), as has been discussed by Kirkwood and others.⁸⁾ According to Kirkwood and Riseman,²⁾ $x F_0(x) \rightarrow 1.588$ as $x \rightarrow \infty$, but its correct asymptotic value is 1.259.⁹⁾ Therefore, it must be only remarked that some corrections for the values of $F_0(x)$ and $F_1(x)$ obtained above are required. However, the coefficient of ξ , $F_1(x)/F_0(x)$ seems to be correct, because such corrections in the numerator and denominator might be cancelled out one another.

$F_1(x)/F_0(x)$ has the numerical value 1.276 (=134/105) in the limit for $x=0$, as shown in Appendix II. The results of the numerical calculations for $F_1(x)/F_0(x)$ are summarized in Table I with the asymptotic value 1.551 for $x=\infty$. Remembering that the mean square radius of gyration of a polymer chain is given by

$$\langle S^2 \rangle = \frac{N a^2}{6} \left(1 + \frac{134}{105} \xi \right), \quad (31)$$

and defining the linear intramolecular deformation α as

$$\alpha^2 = \frac{\langle S^2 \rangle}{\langle S^2 \rangle_0} = 1 + \frac{134}{105} \xi, \quad (32)$$

we obtain the following expressions for the intrinsic viscosity in the two interesting extreme cases:

(i) in the limit for $\lambda_0 N^{1/2} \rightarrow 0$,

$$[\eta] = \frac{N_0 \zeta}{600 \eta_0 M_0} \langle S^2 \rangle_0 \left(1 + \frac{134}{105} \xi \right) \quad (33)$$

$$= \frac{N_0 \zeta}{600 \eta_0 M_0} \langle S^2 \rangle_0 \alpha^2 \quad (33')$$

(ii) in the limit for $\lambda_0 N^{1/2} \rightarrow \infty$,

$$[\eta] = \frac{\pi^{3/2} N_0}{100} [x F_0(x)]_{x \rightarrow \infty} \frac{(\langle S^2 \rangle_0)^{3/2}}{M} (1 + 1.551 \xi) \quad (34)$$

$$= \frac{\pi^{3/2} N_0}{100} [x F_0(x)]_{x \rightarrow \infty} \frac{(\langle S^2 \rangle_0)^{3/2}}{M} \alpha^{3.43}. \quad (34')$$

In general, $[\eta]$ is proportional to $\alpha^{2\gamma}$, where $\gamma \simeq 105 F_1(x)/134 F_0(x)$ in the vicinity of the θ temperature. γ varies monotonically from 1 to 1.215 as x increases from 0 to ∞ . The values of γ for various values of x are also given in Table I.

§ 4. Comparison with the Flory-Fox Theory and Discussions

As is well known, according to the empirical theory of Flory and Fox,³⁾ the intrinsic viscosity is given by

$$[\eta] = 6^{3/2} \phi \frac{(\langle S^2 \rangle_0)^{3/2}}{M} \alpha^3, \quad (35)$$

where ϕ is a universal constant for any polymer-solvent pair, independent of temperature

and the polymer molecular weight. Eq. (35) has been derived, based on the Einstein rigid sphere model, by introducing the assumption that the effective hydrodynamic radius of the polymer coil is proportional to the statistical one. But, in the following, it will be shown what assumptions lead us to Eq. (35) in terms of the K.R. theory.

If $\langle S_i \cdot S_j \rangle$ and $\langle 1/R_{ij} \rangle$ are assumed to be expressed in the forms,

$$\langle S_i \cdot S_j \rangle = \alpha^2 \langle S_i \cdot S_j \rangle_0, \quad (36)$$

$$\left\langle \frac{1}{R_{ij}} \right\rangle = \alpha^{-1} \left\langle \frac{1}{R_{ij}} \right\rangle_0 \quad (37)$$

respectively, where α is defined by Eq. (32), then the integral equation for $\varphi(x, y)$ becomes

$$\varphi(x, y) = \alpha^2 f^0(x, y) - \frac{\lambda}{\alpha} \int_{-1}^{+1} \frac{\varphi(t, y)}{|x-t|^{1/2}} dt, \quad (38)$$

and it leads us to

$$F(x) = \frac{6}{\pi^2} \sum_{k=1}^{\infty} \frac{1}{k^2} \frac{\alpha^2}{1 + x/\alpha k^{1/2}}. \quad (39)$$

Here, consider the limit for $x \rightarrow \infty$, and $[\eta]$ results in

$$[\eta] = \frac{\pi^{3/2} N_0}{100} [x F_0(x)]_{x=\infty} \frac{\langle \langle S^2 \rangle_0 \rangle^{3/2}}{M} \alpha^3, \quad (40)$$

which is equivalent to the F.F. formula (35).

The only difference between our formula (34') and F.F.'s (35) or (40) is the exponent of α in the limit for $x \rightarrow \infty$. When the coefficients of ξ are compared, the asymptotic values of $F_1^1(x)/F_0(x)$ and $F_1^2(x)/F_0(x)$ are 1.135 and 0.416* respectively in the former, and 1.276 (=134/105) and 0.638 (=67/105) in the latter. It follows, therefore, that the numerical values of $F_1^1(x)/F_0(x)$ become smaller without averaging the correction factor of $\langle S_i \cdot S_j \rangle_0$. And the difference between the asymptotic values of $F_1^2(x)/F_0(x)$ in either theory arises from that between Eqs. (7) and (37). When averaged in such a way as mentioned in §2, the correction factor of $\langle S_i \cdot S_j \rangle_0$ proves to be α^2 , whereas that of $\langle 1/R_{ij} \rangle$ not to be α^{-1} . Accordingly, in view of the averaging, Eq. (37) might be unreasonable.

It may be concluded that the exponent of α in the expression for the intrinsic viscosity is smaller than three, according to our theory,

* Without such averaging as in Eq. (5), it would be expected that this value becomes somewhat smaller.

in the limit where Einstein's rigid sphere model is asymptotically valid, though the detailed discussions could not be given because of many approximations involved. This implies that the effective hydrodynamic radius is, there, not proportional to the statistical one. If we denote the hydrodynamic radius by S_H , from Eq. (34') we obtain

$$S_H \propto \langle \langle S^2 \rangle_0 \rangle^{1/2} \alpha^{0.81}. \quad (41)$$

On the other hand, the statistical radius is proportional to the first power of α . So the degree of expansion of the former is lower than that of the latter. This situation may be interpreted as follows. For the root mean square distance $\langle \langle S_i^2 \rangle \rangle^{1/2}$ between segment i and the molecular center of mass, Eq. (35) in TPS I gives

$$\langle \langle S_i^2 \rangle \rangle^{1/2} = \begin{cases} \frac{1}{\sqrt{3}} N^{1/2} a (1 + 0.61\xi) & \text{for } i = \pm n, \\ \frac{1}{2\sqrt{3}} N^{1/2} a (1 + 0.50\xi) & \text{for } i = 0. \end{cases} \quad (42)$$

Hence,

$$\left(\frac{\langle \langle S_{\pm n}^2 \rangle \rangle}{\langle \langle S_0^2 \rangle \rangle} \right)^{1/2} = 2(1 + 0.11\xi). \quad (42')$$

These equations indicate that the excluded volume effect has the larger influence on the segments near the ends than on the intermediate segments; those are located, on the average, in the *skin* part of the polymer coil and these in the *core* part. Accordingly, the expansion of polymer chain does not occur *uniformly* in the inside of the coil, but mainly in the *skin* part. Therefore, the more the polymer chain is expanded owing to the thermodynamic interaction between segments, the deeper the solvent molecules penetrate into the coil.

When Eq. (34) is rewritten in the form that $[\eta]$ is proportional to α^3 as in Eq. (35), Φ may be expressed as

$$\Phi = \frac{(\pi/6)^{3/2} \Lambda_0}{100} [x F_0(x)]_{x=\infty} (1 - 0.363\xi). \quad (43)$$

Eq. (43) shows that Flory's universal constant Φ decreases with increasing temperature, namely increasing ξ , in the poor solvent system ($\theta > 0$).

Finally we discuss the molecular weight dependence of the intrinsic viscosity. From Eq. (28), it is easy to see that the molecular weight dependence of $[\eta]$ is attributed only to

$NF_0(\lambda_0 N^{1/2})$ at the θ temperature. This matter has already been discussed out by Kirkwood and Riseman. But ξ makes contribution to the molecular weight dependence at other temperatures, and Flory's considerations may be supported.

In conclusion, we are indebted to Professors Ichiro Sakurada and Akio Nakajima of Kyoto

University for their stimulating discussions and kind encouragement. Thanks are tendered also to Dr. Misazo Yamamoto for his indispensable advice, and to the Ministry of Education for a grant-in-aid.

Appendix I. $\left\langle \frac{1}{R_{ij}} \right\rangle$

$$\begin{aligned} \left\langle \frac{1}{R_{ij}} \right\rangle = & \left(\frac{6}{\pi} \right)^{1/2} \frac{1}{(j-i)^{1/2} a} - \xi \left(\frac{3}{\pi} \right)^{1/2} \frac{1}{(j-i)^{1/2} n^{1/2} a} \left[4 \sum_{p=1}^{\infty} \frac{C_p p}{(p+1/2)(p^2-1/4)} \right] (j-i)^{1/2} \\ & + \sum_{p=1}^{\infty} \left(\frac{C_p}{p+1/2} \right) \sum_{q=0}^{2p} \frac{(-1)^{q+1}}{p-q+1/2} \binom{2p}{q} (j-i)^{-p} \\ & \times \{ (n+i)^q (n+j)^{p-q+1/2} - (n+i)^{p+1/2} + (n-i)^{p-q+1/2} (n-j)^q - (n-j)^{p+1/2} \} \\ & + \sum_{p=1}^{\infty} \left(\frac{C_p}{p^2-1/4} \right) (j-i)^p \{ (2n)^{-p+1/2} - (n-i)^{-p+1/2} - (n+j)^{-p+1/2} \}, \end{aligned}$$

where

$$C_p = \frac{(2p)!}{2^{2p}(p!)^2}.$$

Appendix II. $\lim_{x \rightarrow 0} \frac{F_1(x)}{F_0(x)}$

From tables of the Riemann ζ -function, we have

$$\zeta(2) = \sum_{k=1}^{\infty} \frac{1}{k^2} = \frac{\pi^2}{6}. \quad (\text{A.II.1})$$

If we consider the functions $(1+x)^{3/2} + (1-x)^{3/2}$ and $(1+x)^{5/2} + (1-x)^{5/2}$ for $-1 \leq x \leq +1$, and expand them in Fourier series, putting $x=1$ with taking account of Eq. (A.II.1) respectively, then we obtain

$$\text{and } \left. \begin{aligned} \pi^{1/2} \sum_{k=1}^{\infty} \frac{C(2\pi k)}{(\pi k)^{5/2}} &= \frac{1}{15}, \\ \pi^{1/2} \sum_{k=1}^{\infty} \frac{S(2\pi k)}{(\pi k)^{7/2}} &= \frac{4}{315}. \end{aligned} \right\} \quad (\text{A.II.2})$$

By using Eqs. (A.II.1) and (A.II.2), we have

$$\lim_{x \rightarrow 0} F_0(x) = \frac{6}{\pi^2} \sum_{k=1}^{\infty} \frac{1}{k^2} = 1,$$

$$\begin{aligned} \lim_{x \rightarrow 0} F_0(x) = & \frac{4}{\pi^2} \sum_{k=1}^{\infty} \frac{1}{k^2} \left[1 + 2\pi^{1/2} \frac{C(2\pi k)}{(\pi k)^{1/2}} \right. \\ & \left. + \frac{3}{2} \pi^{1/2} \frac{S(2\pi k)}{(\pi k)^{3/2}} \right] = \frac{134}{105}. \end{aligned}$$

Hence,

$$\lim_{x \rightarrow 0} \frac{F_1(x)}{F_0(x)} = \frac{134}{105}.$$

Quadrupole Moment of Nb⁹³ and Test of the Hyperfine Structure Formulas

By Kiyoshi MURAKAWA

*Institute of Science and Technology, University of Tokyo,
Komaba-machi, Meguro-ku, Tokyo*

(Received October 5, 1957)

The hyperfine structure (hfs) of the spectrum of Nb I was studied by means of a liquid air-cooled hollow cathode discharge tube and a Fabry-Pérot etalon. The quadrupole moment of Nb⁹³ was deduced to be -0.29 barn and -0.20 barn ($1 \text{ barn} = 10^{-24} \text{ cm}^2$) from the levels $4d^3 5s^2 \text{ } ^4F_{3/2}$ and $4d^4 5s \text{ } ^6D_{5/2}$ respectively, in which no shielding correction is included. Assuming that the shielding correction in this case is zero, we get $Q(\text{Nb}^{93}) = -0.25 \pm 0.15$ barn.

The interval factors of the levels $4d^3 5s^2 \text{ } ^4F_{3/2, 5/2, 7/2, 9/2}$ and $4d^4 5s \text{ } ^6D_{3/2, 5/2, 7/2, 9/2}$ were measured and compared with hfs formulas, and a small but definite discrepancy was detected.

§ 1. Introduction

The hyperfine structure (hfs) of the spectrum of Nb I was first measured by Ballard¹⁾ (referred to as B), and the nuclear spin of Nb⁹³ was determined to be $9/2$. Further measurement was made by Meeks and Fisher²⁾ (referred to as MF); they studied the interval factors of some levels of Nb I and compared them with their calculations. They expressed the interval factor of the level ^6D_J of the configuration d^4s (which was assumed to be of LS -coupling) in the form

$$A(^6D_J) = c(J)a(s) + c'(J)a(d^4) + c''(J)b(d^4),$$

in which $a(s)$ is the coupling coefficient of the s electron, and $a(d^4)$ and $b(d^4)$ are (according to their definitions) the orbital and spin parts, respectively, of the coupling coefficient for the d^4 electron group.

In order to calculate the quadrupole moment, the wave-functions must be reviewed more critically, and such an investigation was carried out by the author some years ago³⁾. The present report will treat the problem more thoroughly and will show that the present hfs theory is somewhat inadequate for reproducing observed interval factors.

§ 2. Experimental Procedure

The spectrum of Nb I was obtained by a liquid-air cooled hollow cathode discharge tube that was described previously⁴⁾. In order to resolve the hfs, a Fabry-Pérot etalon was used. Some important lines were accompani-

ed by close lying lines. The most remarkable of them is given in Table I, in which the wavelength was taken from Meggers and King⁵⁾. In the case of the present investigation also such lines appeared on the plate,

Table I. Group of close lying lines.

Main line	Close lying lines
$\lambda 5665.63 (120)$	$5664.70(100)$, $5666.86(9)$
$\lambda 5271.526(60c)$	$5269.910(6)$, $5272.48(5)$
$\lambda 4648.949(100)$	$4649.255(40)$, $4649.622(2)$
$\lambda 4523.409(200)$	$4522.545(6)$, $4523.727(5)$, $4524.127(20)$
$\lambda 4195.096(80)$	$4195.515(4)$, $4195.660(15)$

and an example is reproduced in Fig. 1. In the case of $\lambda 4523$, it is almost certain that more lines than given by Meggers and King lie close to the main line. It was therefore necessary to use thin spacers in the measurement of the hfs of these lines.

The result of measurement is shown schematically in Figs. 2–11, in which Figs. 2, 3, 4 and 5 can be used for the determination of $Q(\text{Nb}^{93})$. The other figures are used only for the determination of interval factors.

§ 3. Calculation of the Quadrupole Moment

The term analysis of the spectrum of Nb I was published by Meggers and Scribner⁶⁾, and their term notation will be employed here. (The multiplet $d^3s^2 4F - d^3sp^4 G$ was classified in the present work on the basis of the

hfs.) Of the even terms of Nb I, $4d^45s^6D$, ^4D and $4d^35s^2^4F$ are known. For examining the quadrupole effect the levels $4d^35s^2^4F_{3/2}$ and $4d^45s^6D_{3/2}$ seem to be the most suited.

Fig. 1. Enlargement of interference patterns of Nb I.

Fig. 2. Hfs of Nb I λ5271.5 and λ4523.4.

The hfs of the level $4d^35s^2^4F_{3/2}$ can be obtained from the line λ5271.5 as shown in Fig. 2. As shown in Table I, two lines lie close, so the measurement of the hfs was somewhat difficult. The accuracy of the measurement is, however, just sufficient for determining the order of magnitude and sign of Q . The hfs of the level $4d^35s^2^4F_{3/2}$ (see Fig. 2) can be represented by the interval factor $A = 0.02187 \text{ cm}^{-1}$ and the quadrupole coupling constant $B = 0.0031 \times 10^{-3} \text{ cm}^{-1}$.

We can calculate $Q(\text{Nb}^{93})$ from $B(d^3^4F_{3/2})$. In the case of Nb I, $d^3s^2^4F$ lies higher than d^4s^6D , so we will have to take the interaction between the configurations d^3s^2 and d^4s into account. Since only the terms $d^3s^2^4F$, d^4s^6D and ^4D are known, it is not possible to determine the interaction accurately, but the following consideration would be sufficient for

a one-digit calculation.

We shall make the assumption that the configurations d^3s^2 and d^4s are of good LS -coupling. Let ζ_a denote the spin-orbit interaction parameter of the $4d$ -electron. We shall use the same notations as Condon and Shortley⁷⁾ for the other parameters. We get $\zeta_a = 475$ and 438 from $d^3s^2^4F$ and d^4s^6D respectively, the mean value being $\zeta_a = 450$. From the multiplet structure of d^4s^6D and ^4D , we get $G_2 = 1692$. The parameters F_2 , F_4 and H_2 cannot be deduced from the data

published by Meggers and Scribner⁶⁾, so we shall assume that F_2 , F_4 and H_2 for Nb I are the same as those for Mo I, namely $F_2 = 759$, $F_4 = 54.2$ and $H_2 = (1/35)R^2(dd, ds) = 357.3$, as given by Trees and Harvey⁸⁾ for Mo I.

Center of gravity (c.g.) of d^4s^6D lies at 634.44 , where the ground level $d^4s^6D_{1/2}$ is taken as the origin. That of $d^3s^2^4F$ lies at 2120.7 . Under the above-mentioned assumption for F_2 and F_4 , we get

$$d^4s^4F^a = 13320,$$

$$d^4s^4F^b = 27912.$$

Each of these two wave-functions can be expressed as a linear combination of the wave-functions $d^4(^3F)s$ and $d^4(^3_4F)s$ defined by Racah⁹⁾. Putting

$$d^4s^4F = c_1[d^4(^3_2F)s^4F] + c_2[d^4(^3_4F)s^4F],$$

we get

$$c_1 = -0.4516, \quad c_2 = 0.8922 \quad \text{for } d^4s^4F^a$$

$$c_1 = 0.8922, \quad c_2 = 0.4516 \quad \text{for } d^4s^4F^b.$$

The wave-function $d^4(^3_4F)s^4F$ contained in $d^4s^4F^a$ and $d^4s^4F^b$ perturbs the wave-function $d^3s^2^4F$. We thus get

$$d^3s^2^4F' = K_1[d^3s^2^4F] + K_2[d^4(^3_4F)s^4F],$$

$$K_1^2 = 0.952, \quad K_2^2 = 0.048,$$

where the prime on the left hand side denotes the actual wave-function.

We shall put $\omega = 3 \cos^2 \theta - 1$ for brevity. Then we have

$$\begin{aligned} & (d^3s^2^4F_{3/2}' | \omega / r^3 | d^3s^2^4F_{3/2}') \\ &= K_1^2 (d^3s^2^4F_{3/2} | \omega / r^3 | d^3s^2^4F_{3/2}) \\ &+ K_2^2 (d^4(^3_4F)s^4F_{3/2} | \omega / r^3 | d^4(^3_4F)s^4F_{3/2}). \end{aligned}$$

In this expression, we omit M for brevity,

since $M=J$. In the case of Nb I we have

$$K_1^2(d^3s^2^4F_{3/2}|\omega/r^3|d^3s^2^4F_{3/2})=0.1306 \langle r^{-3} \rangle,$$

$$K_2^2(d^4(^3_4F)s^4F_{3/2}|\omega/r^3|d^4(^3_4F)s^4F_{3/2})$$

$$=-0.01207 \langle r^{-3} \rangle.$$

We shall show later that the effective charge on the d -electron obtained from the hfs of various levels is to some extent ambiguous, but $Z_a^*=23.5$ that was obtained earlier³⁾ would be a sufficient approximation for the present purpose. Putting this value and $I=9/2$, $J=3/2$ and the above-mentioned value of B and $(^4F_{3/2}|\omega/r^3|^4F_{3/2})$ in the usual formula we get

$$Q'(\text{Nb}^{93})=-0.29 \text{ barn} \quad \text{from } d^3s^2^4F_{3/2},$$

where the prime means that no shielding correction is included, and 1 barn = 10^{-24} cm^2 .

In the hfs of $\lambda 4523.4$ (see Fig. 2) the hfs of the upper level is not resolved. Since the quadrupole effect of this level is expected to be somewhat larger than that of $d^3s^2^4F_{3/2}$, no attempt has been made to calculate Q from the hfs of $\lambda 4523.4$.

The hfs of $\lambda 4648.9$ is shown in Fig. 3. The

Fig. 3. Hfs of Nb I $\lambda 4648.9$ and $\lambda 4616.2$.

hfs of the upper level $d^3sp^4G_{5/2}$ is not resolved. Let A , B and A' , B' denote the interval factor and the quadrupole coupling constant of the lower and the upper level respectively. Then we get from the hfs of $\lambda 4648.9$:

$$A-(7/5)A'=0.02523,$$

$$B-(28/15)B'=0.0016 \times 10^{-3}.$$

Since $A=0.02187$, we get $A'=-0.00240$. A simple calculation shows that B' should be

far smaller than B , so $(28/15)B'$ can be neglected. Then we get $B=0.0016 \times 10^{-3}$. This is to be compared with $B=0.0031 \times 10^{-3}$ obtained from $\lambda 5271.5$. The discrepancy lies within the experimental uncertainty, and has no physical meaning.

From the hfs of $\lambda 4523.4$ (Fig. 2) and $\lambda 4616.2$ (Fig. 3) we can eliminate $B(d^3sp^4F_{3/2})$, and get $B(d^3s^2^4F_{3/2})$. This procedure is,

Fig. 4. Hfs of Nb I $\lambda 4195.1$ and $\lambda 4168.1$.

Fig. 5. Hfs of Nb I $\lambda 4143.2$ and $\lambda 4116.9$.

however, not so accurate, so no detailed calculation will be given here. But it is easy to show that Q' calculated in this way is in satisfactory agreement with Q' obtained from the level $d^3s^2^4F_{3/2}$.

The hfs of $\lambda 4195.1$ is shown in Fig. 4. At least two lines lie close, and the measurement is difficult. The hfs of $\lambda 4143.2$ (Fig.

5) was measured, assuming that the hfs of the upper level is not resolved. On the other hand the measurement of the hfs of $\lambda 4116.9$ which has the common upper level shows that the quadrupole effect in the upper level is negligible. We get, therefore, from the hfs of $\lambda 4143.2$ that $B(d^4s^6D_{3/2}) = -0.0052 \times 10^{-3} \text{ cm}^{-1}$.

The following formula was deduced previously¹⁰⁾:

$$(d^4s^6D_{3/2}|\omega/r^3|d^4s^6D_{3/2}) = -\frac{2}{4375}(584 R_2' - 91 R_2'' + 132 S_2) \langle r^{-3} \rangle.$$

Putting $\zeta_a = 450$, $Z_a^* = 23.5$, $J = 3/2$, $I = 9/2$ and the above-mentioned value of B and the matrix element of ω/r^3 in the usual formula, we get

$$Q'(\text{Nb}^{93}) = -0.20 \text{ barn from } d^4s^6D_{3/2}.$$

According to the calculations of Sternheimer¹¹⁾, the atomic core shields or antishields the nuclear quadrupole coupling, so that the quadrupole moment Q' deduced from the hfs of atomic spectra must be multiplied by the factor $1+\Delta$, namely the true quadrupole moment Q is given by

$$Q = (1+\Delta)Q'.$$

(Sternheimer's $1/(1-R)$ is our $1+\Delta$).

Concerning the deep d -electrons, Sternheimer obtained positive Δ for the state $3d^94s^2$ of Cu I and negative Δ for the state $5d^4$ of W I. One would be probably permitted to assume that for the states $4d^35s^2^4F$ and $4d^45s^6D$ the shielding correction Δ would be

small, based on the interpolation between Cu I and W I. We shall, therefore, assume that $\Delta = 0$ for the above-mentioned states, till an accurate calculation is available. Then the true quadrupole moment Q is given by

$$Q(\text{Nb}^{93}) = -0.20 \pm 0.15 \text{ barn}.$$

Cotts and Knight¹²⁾ had previously observed nuclear resonance of Nb^{93} in KNbO_3 and found definite evidence of the existence of a quadrupole moment in Nb^{93} . Speck and Jenkins¹³⁾ studied the hfs of Nb I $\lambda 5271$, and obtained $A = (21.7 \pm 0.1) \times 10^{-3} \text{ cm}^{-1}$ and $B = (-0.0044 \pm 0.0027) \times 10^{-3} \text{ cm}^{-1}$ for the level $4d^35s^2^4F_{3/2}$, and deduced $Q(\text{Nb}^{93}) = -0.4 \pm 0.3$ barn. It is, however, difficult to see in what way a negative value of Q results from a negative value of $B(d^3s^2^4F_{3/2})$.

§ 4. Test of the Hyperfine Structure Formulas

From the hfs shown in Figs. 6, 7, 8 and 9 we can deduce the interval factors of $d^3s^2^4F_{7/2}$

Table II. Hfs of Nb I

and ${}^4F_{9/2}$, and, together with those of ${}^4F_{3/2}$ and ${}^4F_{5/2}$, they are listed in Table II. From the hfs shown in Figs. 10 and 11 the interval factors of $d^4s^6D_{5/2}$, ${}^6D_{7/2}$ and ${}^6D_{9/2}$ were deduced and listed in Table II. The off-diagonal components in $\lambda 4139.7$ were extremely difficult to measure, so the measured interval factor $A(d^4s^6D_{9/2})$ can claim no great accuracy. The term $d^3s^2{}^4F$ will be treated at first.

The following formulas (for LS -coupling) were deduced previously³⁾:

Fig. 7. Hfs of Nb I $\lambda 4672.1$.

Fig. 8. Hfs of Nb I $\lambda 5344.2$ and $\lambda 4713.5$.

Fig. 9. Hfs of Nb I $\lambda 4675.4$ and $\lambda 4606.8$.

$$A(d^3 \ ^4F_{9/2}) = \frac{1}{9} (8a_d' + a_d'' + 8a_d'''),$$

$$A(d^3 \ ^4F_{7/2}) = \frac{1}{315} (281a_d' + 34a_d'' + 128a_d'''),$$

$$A(d^3 \ ^4F_{5/2}) = \frac{1}{875} (712a_d' + 163a_d'' - 424a_d'''),$$

$$A(d^3 \ ^4F_{3/2}) = \frac{1}{125} (59a_d' + 66a_d'' - 368a_d'''),$$

$$a_d' = a(d_{5/2}), \quad a_d'' = a(d_{3/2}), \quad a_d''' = a(d_{5/2, 3/2}).$$

(1)

In the previous work³⁾ the following theoretical formulas were assumed to be valid:

$$a_d' = \frac{48}{35} \langle 1/r^3 \rangle F_2' 1.585 \left(\frac{\mu}{I} \right) \times 10^{-3} \text{ cm}^{-1},$$

(2)

$$a_d'' = \frac{48}{15} \langle 1/r^3 \rangle F_2'' 1.585 \left(\frac{\mu}{I} \right) \times 10^{-3} \text{ cm}^{-1}, \quad (3)$$

$$a_d''' = -\frac{1}{5} \langle 1/r^3 \rangle G_2 1.585 \left(\frac{\mu}{I} \right) \times 10^{-3} \text{ cm}^{-1}, \quad (4)$$

$$a_d' = \frac{3}{7} \frac{F_2'}{F_2''} a_d''. \quad (5)$$

In the work concerning the hfs of $3d^9 4s^2$ of Cu I¹⁴, the author found that the formula (5) obtained by eliminating $\langle r^{-3} \rangle$ from (2) and (3) is not in agreement with the empirical facts. We shall, therefore, abandon the relations (2), (3), (4) and (5) in treating the term $d^3 s^2 {}^4F$ of Nb I and consider a_d' , a_d'' and a_d''' in (1) as independent variables. Inserting the values of $A(d^3 {}^4F_J)$ given in Table II into the formulas (1) and solving the

simultaneous equations, we get

$$a_d' = 0.0088, \quad a_d'' = 0.0247, \quad a_d''' = -0.0016$$

In the case of $d^3 s^2 D_{5/2, 3/2}$ of Cu I, the formula (5) was found to be invalid; a_d' was found to be too small to satisfy the relation (5). In the case of $d^3 {}^4F$ of Nb I also, the discrepancy shows the same tendency.

On the other hand the relation between a_d'' and a_d''' is obtained from (3) and (4), and is given by

$$a_d''' = -\frac{1}{16} \frac{G_2}{F_2''} a_d''. \quad (6)$$

This relation seems to be satisfied by $d^3 {}^4F$ of Nb I within experimental error or at least approximately.

We now turn our attention to the term $d^4 s {}^6D$ of Nb I. The interval factors (in LS -coupling case) are given by:

$$\left. \begin{aligned} A(d^4 s {}^6D_{9/2}) &= \frac{1}{9} a(s) + \frac{1}{45} (38 a_d' + 2 a_d'' + 64 a_d'''), \\ A(d^4 s {}^6D_{7/2}) &= \frac{37}{315} a(s) + \frac{1}{1575} (1613 a_d' - 223 a_d'' + 1864 a_d'''), \\ A(d^4 s {}^6D_{5/2}) &= \frac{23}{175} a(s) + \frac{2}{875} (509 a_d' - 129 a_d'' + 512 a_d'''), \\ A(d^4 s {}^6D_{3/2}) &= \frac{13}{75} a(s) + \frac{1}{375} (473 a_d' - 163 a_d'' + 664 a_d'''), \\ A(d^4 s {}^6D_{1/2}) &= \frac{7}{15} a(s) + \frac{1}{75} (98 a_d' - 58 a_d'' + 544 a_d'''). \end{aligned} \right\} \quad (7)$$

If we assume the relations (2), (3) and (4), then it can easily be shown that the observed values of $A(d^4 s {}^6D_J)$ cannot be fitted in the formulas (7) unambiguously. We shall, therefore, try to abandon the relations (2), (3) and (4) and solve the equations (7) by considering $a(s)$, a_d' , a_d'' and a_d''' as independent variables and putting the observed values of $A(d^4 s {}^6D_J)$ given in Table II into (7). It can easily be shown that the rank of the matrix of the equations (7) is 3, whereas we have four independent variables $a(s)$, a_d' , a_d'' and a_d''' . The four variables are, therefore, linearly dependent. For example, we get

$$a_d'' + a_d''' = 0.0120.$$

If we assume the relation (6), then we get $a_d''' = 0.0128$, which value is so different from that obtained from the term $d^3 s^2 {}^4F$ that it can hardly be accepted.

If we consider all of the relations (2), (3), (4) and (7) as approximate, then we get

$$\begin{aligned} a(s) &= 0.161, & a_d' &= 0.0083, \\ a_d'' &= 0.0232, & a_d''' &= -0.0015. \end{aligned}$$

This is to be compared with the previous approximation³⁾ $a_d'' = 0.0222$, $a(s) = 0.172$ (misprinted as 0.217).

From the above discussions we can conclude that the hfs formulas (2), (3) and (4) for the d -electrons do not have a rigorous validity. The inaccuracy of the hfs formulas for the d -electrons in the case of Nb I is, however, not so serious as in the case of V I¹⁵, and we shall consider the effective charge on the d -electrons of Nb I $Z_a^* = 23.5$ that was deduced previously³⁾ as being sufficient for a one- or two-digit discussion of Q .

The hfs of $4d^4 5s {}^6D_{9/2}$, ${}^6D_{7/2}$ and ${}^6D_{5/2}$ that are published in the present paper are still preliminary. The author hopes to be able to

improve the experimental set-up and to increase the accuracy of measurement of these hfs in the future.

The kindness of Professor S. Makishima (Department of Applied Chemistry) of eliminating iron from the niobium sample that was used in the present experiment is greatly appreciated.

Note added in proof. The small discrepancy between hfs theory and experiment in the Nb I levels containing d -electrons has been, in the meantime, solved. For example the mixing of $4d^3 5s 6s$ in $4d^3 5s^2$ can account for the observed interval factors of $4d^3 5s^2 {}^4F$.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 1, JANUARY, 1958

Note on the Information Capacity of a Coloured Picture

By Hiroshi SATO

University of Electro-communications

(Received September 20, 1957)

The information capacity of a coloured picture is obtained taking into account the restriction inherent to the human perception of colour. Calculations are made concerning a one-dimensional picture, and the result is used as an upper bound for the capacity of a two-dimensional picture.

§ 1. Introduction

The information capacity^{1),2)} of a coloured picture will be larger than that of a monochrome picture as colour enhances information. By adopting the usual trichromatic theory of colour perception, the information capacity will increase to a value three times as large as that of a monochrome picture. Meanwhile, by the recent advances in colour television researches it is found that we need trichrome only for the part of the picture where the brightness changes slowly, while for the part where the brightness changes rapidly from place to place the use of a monochrome is sufficient for preception. This roughness in colour preception is utilized in the transmission of colour television as a principle of

"mixed highs". Thus now, the increase of the information by addition of colour is supposed to be very small.

Seki³⁾ tried to obtain the information capacity of a coloured picture by dividing it to very large number of small picture elements in which all the chromatic property can be regarded as uniform. In this paper, we solve this problem in the case of a one-dimensional picture that has an almost rigorous solution and use the result to estimate the capacity of a two-dimensional picture.

In § 2, 3, the information capacity of a one-dimensional picture is obtained and the method is criticized in § 4. In § 5, it is shown that the result of the one-dimensional case can be used as an upper bound for the capacity of

two-dimensional picture.

2. Formulation of a One-dimensional Problem

A one-dimensional picture consists of a very large number N of picture elements in each of which the chromatic properties can be regarded as uniform and each of which can take some definite number of chromatic states. In order to obtain the information capacity taking into account the roughness of our colour perception, it is more convenient to consider a picture as composed of groups of picture elements rather than of picture elements themselves. A group of picture elements is a successive sequence of picture elements and every picture elements in the same groups should take the same chromatic states simultaneously. A number of picture elements in a group is called the length of the group, and a group of length l is assumed to take b_l different chromatic states. When a picture is composed of $m_1, m_2, \dots, m_l, \dots, m_N$ groups of length $1, 2, \dots, l, \dots, N$ respectively, the following relation holds:

$$\sum_{l=1}^N l m_l = N. \quad (1)$$

If we write the total number of groups in picture as M ,

$$\sum_{l=1}^N m_l = M. \quad (2)$$

For a given set of number of groups $m_1, m_2, \dots, m_N$ which satisfies Eq. (1), the number of ways in which these groups can be arranged is

$$\frac{M!}{\prod_l m_l!}, \quad (3)$$

and for every arrangements the number of different possible pictures is

$$\prod_l (b_l)^{m_l}, \quad (4)$$

since the groups of length l can take b_l different states. Therefore for a given $m_1, m_2, \dots, m_N$, the number of different possible pictures P is the product of (3) and (4),

$$P = \frac{M!}{\prod_l m_l!} \prod_l (b_l)^{m_l}, \quad (5)$$

where M is defined in Eq. (2). In order to obtain the total number of different possible pictures P_0 , we have only to sum (5) over all possible sets of numbers $m_1, m_2, \dots, m_N$ which

satisfies Eq. (1),

$$P_0 = \sum P. \quad (6)$$

(This is not quite correct as will be discussed in §4.) The information capacity of this one-dimensional picture is then,

$$C = \log P_0. \quad (7)$$

(All throughout this paper we use natural logarithm for the sake of convenience.) We shall next evaluate this by the usual method of maximum term evaluation, since N is very large. According to that method, we have only to take the logarithm of the maximum term of the right-hand side of Eq. (6) to obtain

$$C = \log P_0 \simeq \log P_{\max} \quad (8)$$

so that the expression (5) should be maximized by changing the variables $m_1, m_2, \dots, m_N$ under the subsidiary condition (1). For the sake of convenience we introduce new variables p_l defined by

$$p_l = \frac{m_l}{M}, \quad l=1, 2, \dots, N \quad (9)$$

in place of m_l , then Eqs. (1), (2) are reduced to

$$M \sum_l l p_l = N, \quad (1')$$

$$\sum_l p_l = 1, \quad (2')$$

and the logarithm of the expression (5) becomes by means of Stirling's formula

$$\log P \simeq M \sum_l p_l (\log b_l - \log p_l), \quad (10)$$

retaining important terms only. Our problem is now to optimize the expressions (10) changing variables $M, p_1, p_2, \dots, p_N$ under the subsidiary conditions (1'), (2'). After multiplying to the left-hand sides of (1') and (2') by $-\beta$ and α , adding them to (10) and putting the differential coefficients to zero, we obtain

$$\sum_l p_l (\log b_l - \log p_l - \beta l) = 0, \quad (11)$$

$$M (\log b_l - \log p_l - 1 - \beta l) + \alpha = 0, \quad l=1, 2, \dots, N. \quad (12)$$

From Eqs. (11) and (12) we can easily show

$$\alpha = M$$

and

$$p_l = b_l e^{-\beta l}, \quad l=1, 2, \dots, N, \quad (13)$$

so that Eqs. (1') and (2') take the following forms

$$M \sum_l l b_l e^{-\beta l} = N, \quad (1'')$$

$$\sum_l b_l e^{-\beta l} = 1. \quad (2'')$$

When we assume an appropriate form for b_l , as is actually done in the next section, we can first get β from (2''), and then p_l and M from (13) and (1''). Further, the capacity is obtained by putting (13) into (10) and taking Eq. (1'') into account as follows:

$$C = \beta N. \quad (14)$$

Therefore, in order to obtain the information capacity per picture element, the only thing to do is to solve β from Eq. (2).

Letting $x = e^{-\beta}$, Eq. (2) can be written as

$$\sum_l b_l x^l = 1, \quad (2''')$$

which we call the characteristic equation.

§ 3. Calculation of the Capacity of a One-dimensional Picture

We assume here that the number of levels of each colour components are the same as is usually admitted as a first approximation in the colour television case. It is further assumed that only monochrome is used for the groups whose lengths are less than l_1 , dichrome for those whose lengths are between l_1 and $l_2 - 1$, and trichrome for those whose lengths are above l_2 . Then the numbers of possible states of groups can be written

$$\begin{aligned} b_l &= L, & \text{for } 1 \leq l < l_1 \\ &= L^2, & \text{for } l_1 \leq l < l_2 \\ &= L^3, & \text{for } l_2 \leq l \end{aligned} \quad (15)$$

where L is the number of levels of each colour components and the distance between successive levels are taken as small as possible so far as they can be distinguished by human perception.

The characteristic equation in this case can be written as

$$x^{l_2} + \frac{1}{L} x^{l_1} + \frac{L+1}{L^2(L-1)} x - \frac{1}{L^2(L-1)} = 0, \quad (16)$$

after a little manipulation letting N tend to infinity. For numerical calculation, we take here that L is of the order of 10^2 , then it is shown that for the case $l_2 > l_1 \geq 3$ the ratio of increment of the capacity to the capacity of an overall monochrome picture is less than one percent. Therefore we omit such cases and calculate next two cases. The results are shown in Table I. Here $\beta_0 = \log L$ means the information capacity of an overall mono-

chrome picture, r is the ratio of increment of the capacity to the capacity of a monochrome picture defined by $r = (\beta - \beta_0)/\beta_0$. Needless to say that for very large l_1, l_2 the capacity is almost equal to β_0 since in this case trichrome or dichrome is not used for the most part of the picture.

In case we do not use dichrome, b_l can be written as follows:

$$\begin{aligned} b_l &= L, & \text{for } 1 \leq l < l_2 \\ &= L^3, & \text{for } l_2 \leq l \end{aligned} \quad (15')$$

and the characteristic equation is

$$x^{l_2} + \frac{1}{L(L+1)} x - \frac{1}{L(L^2-1)} = 0. \quad (16')$$

The results are tabulated in Table II. Again calculations are made in cases when the ratio of increment is above one percent.

Table I. Increment of the capacity when monochrome, dichrome and trichrome are used.

	x	$\beta - \beta_0$	r for $L=100$
$l_1=2, l_2=3$	$0.54/L$	0.59	0.13
$l_1=2, l_2 \geq 4$	$0.62/L$	0.48	0.10

Table II. Increment of the capacity when monochrome and trichrome are used.

	x	$\beta - \beta_0$	r for $L=100$
$l_2=2$	$L^{-\frac{1}{2}}(1-L^{-\frac{1}{2}})$	$\frac{1}{2} \log L + \frac{1}{2} L^{-\frac{1}{2}}$	0.51
$l_2=3$	$0.68/L$	0.38	0.08

§ 4. Critique of the Method

In order to check the validity of our method we first consider the case when all picture elements can take trichrome freely. Since every elements can take L states independently, the capacity of the picture should be

$$C = N \log L^3. \quad (17)$$

If we apply our method to this problem, the number of possible states of a group of length l is

$$b_l = L^3, \quad \text{for all } l$$

and from (2'') we obtain

$$\beta = \log(L^3 + 1),$$

and

$$C = N \log(L^3 + 1). \quad (18)$$

This result is a little different from the e

pected value (17), although the difference is very small when L is very large. This comes from the fact that by our method some pictures are counted more than once. In the above example, we can get the correct result (17) from one term in the right-hand side of (6) that corresponds to $m_1=N, m_2=m_3=\dots=m_N=0$. In this example all other terms are redundant.

Similar criticism holds in the general case. In the right-hand side of Eq. (6), among the possible pictures which are composed of the groups $l_1, l_2, \dots, l_{s-1}, l_s, l_{s+1}, \dots, l_m$, those pictures whose s 'th and $s+1$ 'th groups take the same chromatic state are counted again in the division into the groups $l_1, l_2, \dots, l_{s-1}, l'_s, l_{s+2}, \dots, l_m$, where $l'_s=l_s+l_{s+1}$. In this way our method gives a larger value as the capacity, but as is seen from the result of the above example, the error would be so small (of the order of $1/L^3$ in β) that we can safely neglect this error.

§ 5. Two-dimensional Pictures

As it seems difficult to solve the two-dimensional problem in the same line of thought as in the one-dimensional case, we will here utilize the previous result to obtain the upper bound of the capacity of a two-dimensional picture.

Let the two-dimensional picture consist of picture elements arranged in rectangular way N horizontally N' vertically. We assume that the picture is composed of rectangular groups of picture elements the number of possible states of which are determined by their horizontal length l just the same way as Eq. (15). So the vertical length of the group is quite irrelevant in determining the number of states. We restrict the property of the two-dimensional picture as above, but it seems that it is not too severe a restriction. For example, such a sort of pictures that are composed of squares are involved in the above defined class of pictures.

Let the information capacity per picture element of such a two-dimensional picture be β_2 , and that of the corresponding one-dimensional

picture be β_1 , and we can get the following relation:

$$NN'\beta_2 \leq NN'\beta_1, \tag{19}$$

or

$$\beta_2 \leq \beta_1. \tag{19'}$$

The above relation is derived from the following consideration. The right-hand side of Eq. (19) represents the capacity of such a two-dimensional picture that is an independent vertical collection of N' horizontal one-dimensional pictures, while the left-hand side represents a true capacity of our two-dimensional picture that has a statistical correlation not only in a horizontal direction but also in a vertical one. Therefore, Eq. (19) is the result of Shannon's wellknown inequality¹⁾. Or we may as well interpret it as follows. All the pictures considered in the left-hand side are involved in the right-hand side.

We can easily obtain the lower bound because for the monochrome picture every b_i are bounded by those of the coloured picture,

$$NN' \log L \leq NN'\beta_2, \tag{20}$$

or

$$\log L \leq \beta_2. \tag{20'}$$

In conclusion we have the result as follows:

$$\log L \leq \beta_2 \leq \beta_1,$$

or if we write the ratio of increment of the capacity to the capacity of the monochrome picture r_1, r_2 in one- and two-dimensional cases, we obtain

$$0 \leq r_2 \leq r_1, \tag{21}$$

where r_1 is calculated in § 4 to be 0.13 and 0.10 for the cases $l_1=2, l_2=3$ and $l_1=2, l_2 \geq 4$ respectively.

Electron Collection and Electron Sheath

By Takayoshi OKUDA and Kenzo YAMAMOTO
Faculty of Engineering, University of Nagoya,
Nagoya

(Received October 15, 1957)

In this paper, we deal with an anomalous electron collection made by positive probe, the mechanism of which is to drain off electrons, independent of electron sheath.

So far we have considered either the electron collection limited by the sheath area or the electron collection determined by the orbital motion, both are also applicable to ion collection made by negative probe.

There is the question now, "What is the relation between electron sheath and electron collection?" For our answer, we must measure the radius of the electron sheath. This can be done by using the variable-length probe method, which is described in the other paper¹⁾ in connection with measuring radius of ion sheath. With ion sheath in high density plasma, there is good agreement between the measured radius and the theoretical radius when an appropriate space charge equation is used.

Table I. The measured and the evaluated sheath radius in Ar plasma of discharge current of 50 mA.
 $r_p=0.075$ cm.

p (mm Hg)	V (V)	sheath radius (cm)		
		a_1	a_2	a_3
0.003	4	0.077	0.150	—
"	10	0.082	0.245	—
0.02	4	0.076	0.172	—
"	10	0.081	0.233	—
0.2	4	0.094	0.146	0.165
"	10	0.101	0.183	0.212
1.0	4	0.096	0.187	0.141
"	10	0.097	0.198	0.155

In the same way, we measure the radius of the electron sheath in various conditions in Ar discharge plasma. In Table I we give the measured radius a_1 as well as the evaluated radii, a_2 and a_3 corresponding respectively to space charge equations in practical units:

$$i_e = 14.66 \cdot 10^{-6} \frac{l}{r_p} \frac{V^{3/2}}{\beta^2} \quad (1)$$

$$i_e = 55.5 \cdot 10^{-14} \frac{l}{r_p^2} \frac{K_0}{p} \frac{V^2}{\phi_c^2} \quad (2)$$

where i_e is electron current (A), l length of cylindrical probe (cm), r_p radius of probe (cm), V positive probe voltage (V), p pressure (mm Hg), K_0 mobility of electron at 1 mm Hg ($\text{cm}^2 \cdot \text{mm Hg} / \text{V} \cdot \text{sec}$) ($K_0=3.17 \cdot 10^5$ for Ar), and β^2, ϕ_c geometrical factors of function of a/r_p .

By Langmuir's theory, our experimental condition is the sheath area limited because $r_p \gg a - r_p$. In Table I we see that the measured radius is always smaller than the theoretical radius. Furthermore, anomalous behavior of the radius is readily found by plotting the measured radius against the positive voltage, as shown in Fig. 1. From this

Fig. 1. Plots of electron current vs. positive probe voltage (solid line) and sheath radius vs. positive probe voltage (dotted line).

figure we can confirm that there is little expansion of the electron sheath and that there is no relation between the plot of the sheath radius vs. the positive probe voltage and the plot of the electron current vs. the positive probe voltage. Should the collection mechanism be the sheath area limited, both slopes would be the same.

In low pressure where Eq. (1) is valid, the theoretical slope must be 0.72~0.15 at random electron current densities of 0.1~100 mA/cm², and at 1 mm Hg where Eq. (2) is valid, theoretical slope must be 0.48~0.15 at random electron current densities of 0.1~100 mA/cm². Fig. 1 shows the steep rise of the electron current with increasing positive probe voltage, far exceeding the theoretical expectation.

All these experimental results support the reasonable conclusion that electron collection is not caused by sheath area limited mechanism, but that it is a drainage mechanism which can be regarded as an increase of plasma density occuring close to the boundary of the sheath-plasma.

Afterglow of Pure and Mixed Gases

By Susumu TAKEDA

*Department of Electrical Engineering,
Faculty of Engineering,
Yokohama National University*

(Received November 2, 1957)

The most interesting and remarkable fact in the actual counting tube is known to be that the maximum counting speed can very much increased by adding some amount of Hydrogen to the rare gas used¹⁾. In order to investigate the mechanism of the deionization of the discharge tube, the decay of electron density was studied here by the microwave method²⁾. In the present experiment DC pulse is added to ignite a post discharge.

Fig. 1.

Fig. 1 shows the relation of $1/n$ and t for various peak currents in Argon, showing no constant slope for $t < 300 \mu s$. When a small amount of Hydrogen is added, these become quite linear as shown in Fig. 2 and 3 for different peak currents and pulse widths respectively, because metastable ions of puer gas that will ionize and apparently decrease the decay in the early period would be broken by Hydrogen molecules.

Fig. 2.

Fig. 3.

The difference of slopes in each line in both figures is supposed to be due to the different content of Hydrogen ion. The small current gives a similiar effect as short width as expected from the wave form of the voltage as shown in these figures.

Judging from the voltage form in pure Argon and Hydrogen, the time of growth of Argon, ions may be longer than that of Hydrogen ions, and it can be supposed that the latter density would be larger in the shorter pulse or the smaller current in such a mixed gas.

The conclusions are follows,

- (1) In the rare gases as Argon where the recombination predominates over diffusion the decay in the early period of afterglow is slower than that deter-

mined by their recombination coefficients.

(2) When mixed with Hydrogen, only a small amount of Hydrogen affects very much and makes $1/n$ linear even in the early period.

(3) $1/n$ have different slopes for various currents and pulse widths. The reason will be that the amount of positive ions of Hydrogen is different respectively.

The author sincerely appreciates Prof. K. Honda of Tokyo University, Mr. K. Takatsu who is a member of Electric Communication Laboratory and Mr. K. Ogawa of Matsuda Research Laboratory of Tokyo Shibaura Electric Company. He also thanks Mr. Y. Ishikawa of our university for his technical assistance.

Dielectric Properties of Lead Titanate and Its Solid Solutions at Low Temperature under Strong Electric Field

Shoichiro NOMURA

*Institute of Science and Technology,
University of Tokyo, Tokyo, Japan*

and

Jinzo KOBAYASHI

*Department of Applied Physics,
Waseda University, Tokyo, Japan*

(Received December 5, 1957)

Lead titanate PbTiO_3 is well known to be ferroelectric at room temperature. X-ray and dielectric studies have revealed that it transforms into another phase at low temperature^{1,2)}. However, the low temperature transition of PbTiO_3 is very sluggish, a retardation always occurs when a transformation point is passed. This may be the principal reason why this transition was masked in some investigations by others on PbTiO_3 . Even when we could recognize the transformation to occur, it was difficult to determine the transition temperature exactly because of its sluggish nature.

With this in view we studied the polarization vs. temperature characteristics of PbTiO_3 and its solid solutions at low temperature by applying strong a.c. field, and found that their transformations were markedly affected by the applied field. Some results

on these natures are reported here briefly.

We used disk-shaped ceramics as the specimens ca 2.3 cm in diameter and 0.08 cm thick; electrodes being dried silver paste. Temperature dependencies of the maximum polarization P_{max} were measured by using Sawyer-Tower circuit and an oscilloscope. Fig. 1 shows P_{max} vs. temperature relations for PbTiO_3 which were obtained from D-E loops for several different field strengths, the frequency used being 50 cycle/sec. We can obviously recognize that an anomaly occurs on each curve and these transition points stand out and shift to the lower temperature side by increasing the applied field strength.

Fig. 1. Maximum polarization vs. temperature curves for PbTiO_3 . Field strengths are (a) 15.7 KV/cm, (b) 11.7 KV/cm, (c) 5.8 KV/cm and (d) 3.5 KV/cm.

Fig. 2. Maximum polarization vs. temperature curves for $\text{Pb}(0.8\text{Ti}-0.2\text{Sn})\text{O}_3$. Field strengths are (a) 11.5 KV/cm and (b) 4.6 KV/cm.

Similar results were obtained for PbTiO_3 solid solutions series. One of them, $\text{Pb}(0.8\text{Ti}-0.2\text{Sn})\text{O}_3$ for example, is shown in Fig. 2. The effect of the applied field on the transition temperatures is shown in Fig. 3. It is noted that the falling rates of the transition point are very large and reach $-3.1 \times 10^{-3} \text{ } ^\circ\text{C}/\text{volt}/\text{cm}$ for PbTiO_3 and $-1.9 \times 10^{-3} \text{ } ^\circ\text{C}/\text{volt}/\text{cm}$ for $\text{Pb}(0.8\text{Ti}-0.2\text{Sn})\text{O}_3$. Then the transition temperature for the normal states can be

obtained by extrapolating these curves to zero field; -30°C for PbTiO_3 and -80°C for $\text{Pb}(0.8\text{Ti}\cdot 0.2\text{Sn})\text{O}_3$ respectively. If we compare the present results on PbTiO_3 with the former measurement of dielectric constant²⁾, it is obvious that there exist

Fig. 3. Transition temperatures as a function of field strength.

some discrepancies between them. In our recent experiments, however, we obtained dielectric constant vs. temperature curves, showing the characteristics similar to (d) in Fig. 1, which corresponds to a weak applied field. Therefore we may suppose that some of the discrepancies were brought about by the sluggish nature of the phase transformation.

It is concluded that several measurements under strong electric fields are effective to determine the exact transition point in such materials, PbTiO_3 and its solid solutions that have sluggish transformations.

The details of our results will be reported shortly.

Directional Correlations of Gamma Rays in Te^{124}

By Takeo HAYASHI

Department of Physics, Saikyo University, Kyoto

(Received August 30, 1957)

The directional correlations of the 2.11–0.605 Mev and 1.71–0.605 Mev gamma-gamma cascades in Te^{124} have been measured by using a coincidence spectrometer newly designed. Both of the correlation functions are compatible with the sequence 3 (D, Q) 2 (Q) 0, where quadrupole admixture in the first radiation is expected to be very small. The false coincidences occurring in this type of circuit are also described in some details.

§ 1. Introduction

In early studies the spins and parities of the excited states in Te^{124} were assigned indirectly on the basis of the informations about the spin and parity of the ground state in Sb^{124} as well as the degree of forbiddenness of the beta transitions from this ground state to the concerned excited states in Te^{124} . In those days, however, the informations concerning the first beta ray spectrum of Sb^{124} had many inconsistencies^{1, 2, 3, 4)}, so that no spin and parity assignment could be obtained for this state. In the following years the internal conversion coefficient for the 0.605 Mev gamma ray in Te^{124} was measured by Metzger⁵⁾. The result of his measurement, in conjunction with an empirical rule⁶⁾ proposed just then concerning the first excited states of even-even nuclei, seemed to show that the 0.605 Mev state should be 2^+ . Based upon these informations Morita and Yamada⁷⁾ have shown that the directional correlation^{8, 9)} between the 2.317 Mev beta ray and the 0.605 Mev gamma ray can be explained theoretically by assigning 3^- to the ground state in Sb^{124} , and this led to the spin and parity assignments for the excited states in Te^{124} by taking account of ft values for the concerned transitions.

Now this situation has stimulated the direct determination of the spins of the excited states in Te^{124} by the measurement of the angular correlations between the cascade gamma rays. In the early experiments^{9, 10, 11)}, however, no appreciable anisotropy could be observed before Kraushaar and Goldhaber¹²⁾ investigated the 1.71–0.605 Mev cascade and found that the form of the correlation function agreed with that of a 3–2–0 cascade.

They also reported that the first radiation may be mainly dipole with a small admixture of quadrupole. But, since they measured, by the use of integral discrimination in their pulse height analysis, all the gamma rays above 0.1 Mev in one channel and 0.7 Mev in the other respectively, their results contained, besides the main contribution from the 1.71–0.605 Mev cascade, unknown part due to the 2.11–0.605 Mev transitions. Such an ambiguity was removed by Metzger¹³⁾ who measured the 2.11–0.605 Mev angular correlation separately from the contribution due to the 1.71–0.605 Mev cascade. However, he reported his result only briefly, probably because of weak intensity of the 2.11 Mev gamma ray. Moreover, the assignment of 3^- to both of the 2.72 Mev and 2.32 Mev levels seems to cast some questions on the 3^- assignment to the ground state in Sb^{124} , since the ft values of the beta disintegrations between the concerned states are much greater than the expected value for the 3^- – 3^- transition. Under these circumstances, therefore, it seems worth while to study the 2.11–0.605 Mev angular correlation more precisely and to reinvestigate, at the same time, the 1.71–0.605 Mev cascade subject to the correction for the contribution from the ascertained 2.11–0.605 Mev cascade.

§ 2. Methods and Apparatus

The RCA 5819 photomultiplier tubes mounted with thallium-activated sodium iodide crystals of $1\frac{1}{2}$ in. $\phi \times 1$ in. were used as detectors. The source material obtained from Radiochemical Centre in England was SbCl_3 in 5 N HCl, and since about two months had elapsed after its production when the

present work was started, the contribution from the impurity of Sb^{122} in the source material need not be considered. For the purpose of avoiding extranuclear interaction the source was used in liquid form. It was prepared by dropping the solution into the 1 mm diameter hole of a glass source container with thin wall thickness and by sealing the top of the hole in order to avoid the evaporation of the solvent. The distance between the source and the front face of each crystal was 5 cm. Since the slightest asymmetry in the source position would seriously change the observed correlation, care

was taken for the setting of the source, and small setting correction was made to the raw experimental data. The protection against the spurious coincidence counts due to the radiations scattered in the other crystal was not necessary, because the discriminator windows were placed outside the shifted energies due to the Compton scattering. The energetic beta rays were slowed down with thin absorbing materials and were excluded in a similar manner.

A block diagram of the electronic circuits is shown in Fig. 1. This coincidence spectrometer is, in its basic idea, similar to that of

Fig. 1. Block diagram of the coincidence spectrometer.

Stanford and Pieper¹⁴⁾, but was newly designed by the present author. In the coincidence counting with pulse height discrimination we cannot achieve high resolving power with good coincidence efficiency as far as we apply output pulses from a pulse height analyzer directly to a coincidence circuit, even when the output pulses are shaped into narrow ones by a pulse shaping circuit and are then fed to the coincidence circuit. The cause of this defect is that the process of pulse height selection imposes a time delay upon the pulse output. Moreover, this delay depends on the height and shape of the pulses at the input of the pulse height analyzer and it spreads over the order of magnitude of the pulse rise time. Therefore, the coincidence pulse at a photomultiplier output is not always in strict coincidence at the input of the coincidence circuit. In our circuit, however, this difficulty is avoided as follows. The

pulse from the linear amplifier is divided into two parts, the one part of which is, when the gate in Fig. 1 is opened, applied to the mixing tube of the coincidence circuit through the limiting amplifier and the pulse shaper without suffering any time delay caused by the process of pulse height analysis. While the other part is fed to the pulse height analyzer, and when the pulse has a desirable height, its output pulse, after having been properly shaped through the gating univibrator, opens the gate circuit. Since the gate should have been opened precisely just before the one part of the pulse come to the gate, a delay-line having suitable time delay must be placed between the linear amplifier and the gate circuit in order to compensate the delay-time spent in the pulse height analyzer. In view of the pulse height attenuation and the slow-down of the pulse leading edge in the delay-line, however, it is desirable

that the length of the delay-line should be as short as possible. Since the conventional pulse height analyzer has a rather long delay-time ($1\text{ }\mu\text{ sec}$ or more)^{16, 18}, some devises were applied to the pulse height analyzer itself in order to minimize the time delay as short as $0.3\text{ }\mu\text{ sec}$ without deteriorating reliability and rapidity in its anticoincidence operation. With this improvement the delay-time in the delay-line could be made as short as $0.5\text{ }\mu\text{ sec}$, while in the circuit of Stanford and Pieper the required delay amounted to about $3\text{ }\mu\text{ sec}$. Thus the present measurements were performed in good efficiency with the resolving time of $6\times 10^{-8}\text{ sec}$. The measured rise times of the linear amplifier and window amplifier in the pulse height analyzer were $0.08\text{ }\mu\text{ sec}$ and $0.06\text{ }\mu\text{ sec}$ respectively. A delay-line placed between the limiting amplifier and the pulse shaper was used for measuring accidentals. It may be mentioned here that our coincidence spectrometer can also be used as two independent single channel pulse height analyzers by changing the grid voltage of the mixing tube in the coincidence circuit. Further details of this circuit are described elsewhere¹⁷.

§ 3. Measurements and Results

The measurement of the gamma ray

Fig. 2. Gamma ray spectrum of antimony trichloride source. The brackets represent the positions of the windows of the pulse height analyzers for the present experiment.

spectrum was carried out by means of the pulse height analyzer described above. The result obtained is shown in Fig. 2. According

Fig. 3. Proposed decay scheme for Te^{124} as given by Lazar.

Fig. 4 (A). Coincidence spectrum of the 2.11 Mev gamma ray in Te^{124} .

Fig. 4 (B). Coincidence spectrum of the 1.71 Mev gamma ray in Te^{124} .

to the decay scheme proposed by Lazar¹⁸⁾ (Fig. 3) the 2.11 and 1.71 Mev gamma rays should be in coincidence only with the 0.605 Mev gamma ray. This was ascertained by measuring the coincidence spectra of both gamma rays. The results are shown in Fig. 4 (A) and (B). These spectra indicate that both of the 2.11 and 1.71 Mev gamma rays are coincident only with the 0.605 Mev gamma ray and the scheme of Kern et al.¹⁹⁾ insisting that the 2.11 Mev transition should go to the ground level seems to be doubtful.

The directional correlations of the 2.11-0.605 Mev cascade and the 1.71-0.605 Mev cascade were then measured. The windows of the pulse height analyzers were placed, as shown in Fig. 2, so as to include only the full-energy pulse spectrum peak of the gamma ray. The true coincidence counts were about 20/min for the 2.11-0.605 Mev cascade and 200/min for the 1.71-0.605 Mev cascade respectively. The result for the 2.11-0.605 Mev cascade is shown, with its statistical errors, in Fig. 5. Since the 2.11 Mev gamma

Fig. 5. Directional correlation of the 2.11-0.605 Mev cascade in Te^{124} . The solid curve represents $N(\theta) = (8035 \pm 104) - (417 \pm 73)P_2(\cos \theta)$.

ray is of the highest energy emitted from the source, the measurement of the angular correlation of this cascade is a clean one and needs no consideration of the interference due to the other cascade except for the false coincidence event which will be described in § 4. The most fitted theoretical curve as corrected for the finite geometry²⁰⁾ is drawn by a solid line. It corresponds to the curve for a 3-2-0 (D, Q-Q) ($\delta = -0.025$), where δ is the ratio of the reduced matrix element of the quadrupole radiation to that of the dipole radiation. The normalized correlation function obtained for this cascade can be expressed as

$$W(\theta) = 1 - (0.052 \pm 0.006)P_2(\cos \theta),$$

where the term of $P_4(\cos \theta)$ has been neglected due to the smallness of the value of δ^2 and only the interference term of the dipole and quadrupole radiations has been included in the coefficient of $P_2(\cos \theta)$. The result of the 1.71-0.605 Mev cascade is shown in Fig. 6. The most fitted curve in this case is also

Fig. 6. Directional correlation of the 1.71-0.605 Mev cascade in Te^{124} . The solid curve represents $N(\theta) = (18600 \pm 160) - (1183 \pm 103)P_2(\cos \theta)$.

the one for a 3-2-0 (D, Q-Q), in which δ is estimated to be -0.010 . The correlation formula for this case is given as

$$W(\theta) = 1 - (0.064 \pm 0.004)P_2(\cos \theta),$$

where the term of $P_4(\cos \theta)$ has been neglected by the same reason as in the former case. The interference effect of the Compton component of the 2.11 Mev gamma ray having energy of about 1.71 Mev upon the angular correlation of the 1.71-0.605 Mev cascade could be neglected because of similar correlation functions for both cascades and the weak intensity of the 2.11 Mev gamma ray. The present results are in agreement with those obtained by Metzger¹³⁾ as well as by Kraushaar and Goldhaber¹²⁾.

Recently, Dzhelepov et al.²¹⁾ have found a few kinds of gamma rays in Te^{124} other than those as reported by Lazar¹⁸⁾. Among them the 1.330 Mev gamma ray seems to correspond to the crossover transition between the levels A and C in Lazar's scheme. While, from the viewpoint of its energy value, the 1.370 Mev gamma ray should be emitted in the D-B or F-C transition and if it is emitted in the F-C transition, the 1.330 Mev gamma ray must be in coincidence with the 1.370 Mev gamma ray. Thus a measurement of the coincidence event between the two gamma rays was carried out. However,

no appreciable coincidence count could be found which would be expected from the gamma ray intensity given by Dzhelepov et al. This result tells us that, unlike Lazar's scheme, at least the main part of the 1.36 Mev gamma ray as reported by him should be emitted in the D-B transition.

§ 4. Estimation of False Coincidence Counts

Next we shall discuss the false coincidence counts which will occur in the coincidence spectrometer of our type. As described in § 2, the true coincidence counts are obtained by subtraction of the counts measured by delaying the pulse in one channel with respect to the other from those measured without the time delay. Some question is remained whether this operation gives us true data or not. Consideration on this matter is especially necessary for the coincidence measurement of a weak cascade subject to the disturbance of strong cascades. The trouble peculiar to the circuits of our type is caused at the gate or the slow coincidence circuit shown in Fig. 1. It will occur as described below.

Now, the output pulse of the gating univibrator and that of the linear amplifier described in § 2 are shown schematically in Fig. 7 (A) and (B) respectively. When the ampli-

Fig. 7. Occurrence of the false coincidence in the gate circuit.

- (A) The pulse from the gating univibrator.
- (B) The pulse from the linear amplifier.
- (C) Simple coincidence between the pulses given in (A) and (B).
- (D) Chance coincidence caused by another preceding pulse.
- (E) Chance coincidence caused by another succeeding pulse.

tude of the output pulse from the linear amplifier falls within the upper and lower levels of the window in the pulse height analyzer—hereafter this kind of pulse is called the selected pulse—the two pulses should be in coincidence as shown in Fig. 7 (C). However, as shown in Fig. 7 (D) and (E), it will possibly happen that another pulses, which precede or succeed the selected pulses, are fed to the gate circuit within the time interval

less than the resolving time of this circuit. Among such chance coincidence events the one occurred as shown in Fig. 7 (E) has no effect upon the true counts because of the large dead time of the scaling circuit. Accordingly in the fast coincidence circuit placed in succession to the gate circuit too, the occurrences of another coincidence events are expected between the above-mentioned gate output pulses which are fed to this circuit. Possible cases of these expected coincidence events including the true and chance coincidences are summarized in Fig. 8

Fig. 8. Possible cases of coincidences between the pulses in channel 1 and 2. Detailed explanation is given in Table I.

and Table I. The changes of these coincidence rates when one channel is delayed by 0.5μ sec with respect to the other are also shown in Table I. The total counting rate measured by adjusting in such a way that both channels should have no delay with each other is represented as N_{total} . Since this rate is composed of all cases in (1) and (2) of Table I, it can be written as

$$N_{total} = N_{1a} + N_{1b} + N_{1c} + N_{1d} + N_{2a} + N_{2b} + N_{2c} + N_{2d} + N_{2e}. \quad (4.1)$$

While the chance coincidence rate N_{chance} measured as described above is given by

$$N_{chance} = N_{2a} + N_{2c} + N_{2d}, \quad (4.2)$$

so that the counting rate which is regarded

Table I.

Possible cases of coincidence			Assumed counting rate	Counting rate when one channel is delayed with respect to the other
(1) Cases in which the selected pulses are in true coincidence	a	Simple true coincidence.	N_{1a}	0
	b	The selected pulses A and B are preceded by other coincidence pulses.	N_{1b}	0
	c	The selected pulses are preceded by another pulse pair which is in chance coincidence within $2\tau_f$.	N_{1c}	0
	d	Preceding A (or B) another pulse in chance coincidence with B (or A) is fed.	N_{1d}	0
(2) Cases in which the selected pulses are in chance coincidence	a	Simple chance coincidence.	N_{2t}	N_{2z}
	b	The selected pulses are preceded by other coincidence pulses.	N_{2b}	0
	c	The selected pulses are preceded by other pulses which are in chance coincidence with each other.	N_{2c}	N_{2c}
	d	Preceding A (or B) another pulse which is in chance coincidence with B (or A) is fed.	N_{2d}	N_{2d}
	e	Preceding A (or B) another pulse which is in coincidence B (or A) is fed.	N_{2e}	0

nominally as the true coincidence can be represented as

$$N_{\text{true}} = N_{\text{total}} - N_{\text{chance}}$$

$$= (N_{1a} + N_{1b} + N_{1c} + N_{1d}) + N_{2b} + N_{2e}. \quad (4.3)$$

Before going into further theoretical consideration, notations for some quantities to be used and their definitions will be given.

N_{t1}, N_{t2} : total rates of pulses which come out from the linear amplifier in channel 1 and 2 respectively;

N_{s1}, N_{s2} : rates of the selected pulses in channel 1 and 2 respectively;

N_{ns1}, N_{ns2} : rates of non-selected pulses, or of pulses whose amplitudes fall outside of the given window position in channel 1 and 2 respectively;

n_{s1}, n_{s2} : rates of the selected pulses which belong to N_{s1} and N_{s2} respectively and are not in coincidence with the pulses in the other channel;

$C_{s1, s2}$: rate of the selected pulses which belong to N_{s1} in channel 1 and to N_{s2} in channel 2 and are in coincidence with each other;

$C_{s1, ns2}$: rate of pulses which belong to N_{s1} in channel 1 and to N_{ns2} in channel 2 and are in coincidence with each other;

$C_{ns1, s2}$: rate of pulses which belong to N_{ns1} in channel 1 and to N_{s2} in channel 2;

n_{ns1}, n_{ns2} : rates of pulses which belong to N_{ns1} and N_{ns2} respectively and are not in coincidence with the pulses in the other channel;

$C_{ns1, ns2}$: rate of pulses which belong to N_{ns1} and N_{ns2} and are in coincidence with each other;

$2\tau_s$: resolving time of the gate (slow coincidence) circuit;

$2\tau_f$: resolving time of the fast coincidence circuit.

It will immediately be seen that the following relations can hold:

$$\left. \begin{aligned} N_{t1} &= N_{s1} + N_{ns1}, & N_{t2} &= N_{s2} + N_{ns2}, \\ N_{s1} &= n_{s1} + C_{s1, s2} + C_{s1, ns2}, & N_{s2} &= n_{s2} + C_{s1, s2} + C_{ns1, s2}, \\ N_{ns1} &= n_{ns1} + C_{ns1, ns2} + C_{s2, ns1}, & N_{ns2} &= n_{ns2} + C_{ns1, ns2} + C_{s1, ns1}, \end{aligned} \right\} \quad (4)$$

and in ordinary cases

$$n_{s1} \geq \begin{cases} c_{s1, s2}, \\ c_{s1, ns2}; \end{cases} \quad n_{s2} \geq \begin{cases} c_{s1, s2}, \\ c_{ns1, s2}; \end{cases} \quad n_{ns1} \geq \begin{cases} c_{ns1, ns2}, \\ c_{ns1, s2}; \end{cases} \quad n_{ns2} \geq \begin{cases} c_{ns1, ns2}, \\ c_{s1, ns2}. \end{cases} \quad (4.5)$$

Making use of these notations the counting rates of the output pulses in the gate circuits are given by

$$\left. \begin{aligned} &N_{s1}(1-\tau_s N_{ns1}) + \tau_s N_{ns1} N_{s1} \quad (\text{for channel 1}), \\ &N_{s2}(1-\tau_s N_{ns2}) + \tau_s N_{ns2} N_{s2} \quad (\text{for channel 2}), \end{aligned} \right\} \quad (4.6)$$

respectively. Here the correction for the suppression^{22), 23)} of the pulses due to the dead time in the pulse height analyzer has been neglected. The first quantity in (4.6) gives the rate of the pulses which come out from the gate circuit without receiving any chance coincidence event, while the second corresponds to that of the pulses which are in chance coincidences with N_{ns1} and N_{ns2} pulses. The factor 2 in front of τ_s has been omitted, since in this case it is sufficient to consider only the case of Fig. 7 (D).

Now it is expected in the fast coincidence output that the following cases, together with the corresponding counting rates, should occur between the two pulses expressed in (4.6).

$$\left. \begin{aligned} \text{Case (1):} & \quad c_{s1, s2} \{ (1-\tau_s n_{ns1})(1-\tau_s n_{ns2}) - \tau_s (c_{ns1, ns2} + c_{ns1, s2} + c_{s1, ns2}) \}; \\ \text{Case (2):} & \quad c_{s1, s2} [\tau_s \{ n_{ns1}(1-\tau_s n_{ns2}) + n_{ns2}(1-\tau_s n_{ns1}) \} \\ & \quad + 2\tau_s \tau_f n_{ns1} n_{ns2} + \tau_s' (c_{ns1, ns2} + c_{ns1, s2} + c_{s1, ns2})]; \\ \text{Case (3):} & \quad 2\tau_f (n_{s1} + c_{s1, ns2})(1-\tau_s N_{ns1})(n_{s2} + c_{s2, ns1})(1-\tau_s N_{ns2}); \\ \text{Case (4):} & \quad \{ c_{s1, ns2}(1-\tau_s N_{ns1})\tau_s (n_{s2} + c_{ns1, s2}) + c_{ns1, s2}(1-\tau_s N_{ns2})\tau_s' (n_{s1} + c_{s1, ns2}) \} \\ & \quad + \{ 2\tau_f n_{s1}(1-\tau_s N_{ns2})\tau_s (n_{s2} + c_{ns1, ns2} + c_{s1, ns2})(n_{s2} + c_{ns1, s2}) \\ & \quad + 2\tau_f n_{s2}(1-\tau_s N_{ns2})\tau_s (n_{s1} + c_{ns1, s2} + c_{s1, ns2})(n_{s1} + c_{s1, ns2}) \}; \\ \text{Case (5):} & \quad 2\tau_f \tau_s^2 (n_{ns1} + c_{ns1, ns2} + c_{ns1, s2})(n_{s1} + c_{s1, ns2})(n_{ns2} + c_{ns1, s2} + c_{s1, ns2})(n_{s2} + c_{ns1, s2}); \\ \text{Case (6):} & \quad \tau_s' c_{ns1, ns2} (n_{s1} + c_{s1, ns2})(n_{s2} + c_{ns1, s2}). \end{aligned} \right\} \quad (4.7)$$

It is to be noticed that in some terms of the formulas for cases (2), (4) and (6) the notation τ_s' has been used instead of τ_s^* .

In the above formulas (4.7), (1) gives the

* As described in § 4 some portion of $c_{s1, s2}$ is lost in the gate circuit due to the chance coincidence with the pulses belonging, for instance, to $c_{ns1, ns2}$ by the rate of $\tau_s c_{s1, s2} c_{ns1, ns2}$. Now $c_{ns1, ns2}$ as well as $c_{s1, s2}$ are the coincidence counts, so that all of $\tau_s c_{s1, s2} c_{ns1, ns2}$ should be restored if the gates of both channels were opened simultaneously without suffering any variable time delay caused by the process of the pulse height selection. But since the gates for both channels are not always opened simultaneously or at least within the time difference corresponding to the magnitude of the resolving time of the fast coincidence circuit, some portion of the lost pulses cannot be restored. Therefore, by using the quantity $\tau_s' (0 < \tau_s' < \tau_s)$ the restored portion can be expressed effectively, for instance, as $\tau_s' c_{s2, s2} c_{ns1, ns2}$, while the lost portion being $\tau_s c_{s1, s2} c_{ns1, ns2}$. This situation will be the same for $c_{ns1, s2}$ and $c_{s1, ns2}$.

rate of the true coincidence pulse which comes out without suffering any chance coincidence event. While (2) means the rate of the chance coincidence events which will occur between the true coincidence pulses and the other kinds of pulses and then be recorded as output pulses. All of the true coincidence pulses lost due to the chance coincidence events are not always restored by the process (2), namely (1)+(2) is expected to be a little less than $c_{s1, s2}$. And (1) corresponds to N_{1a} of Table I and the first, second and third term of (2) represent N_{1a} , N_{1c} and N_{1b} respectively. The formula (3) gives mainly the chance coincidence rate between the selected but non-coincident pulses, while (4), (5) and (6) indicate the fast coincidence events between the chance coincidence output pulses of the gate circuits themselves. The formulas (3), (5), (6) and the first and second term of (4) correspond to N_{2a} , N_{2c} , N_{2b} , N_{2c} and N_{2a} of Table I respectively. Other terms of smaller

order, including, for instance, the correction for γ proposed by Westcott et al.²²⁾, have been omitted in the above formulas.

In applying above considerations to the error estimation of our data on the directional correlations, it seems necessary to discuss, first of all, the effect of the false counts upon the term $(N_{1a} + N_{1b} + N_{1c} + N_{1d})$ in (4.3). Using (1) and (2) of (4.7) this term can be written as

$$\begin{aligned} & (N_{1a} + N_{1b} + N_{1c} + N_{1d}) \\ &= N_0 \{1 + XP_2(\cos \theta)\} \\ & \times [A + B\{1 + YP_2(\cos \theta) + ZP_4(\cos \theta)\}]. \end{aligned} \quad (4.8)$$

Here $N_0\{1 + YP_2(\cos \theta)\}$, being equal to $c_{s1, s2}$, expresses the true angular correlation, A represents the sum of all the factors in (1) and (2) of (4.7) except for those including $(c_{ns1, ns2} + c_{ns1, s2} + c_{s1, ns2})$, and $B\{1 + YP_2(\cos \theta) + ZP_4(\cos \theta)\}$ is the sum of the factors including $(c_{ns1, ns2} + c_{ns1, s2} + c_{s1, ns2})$ and expresses the angular correlation of $(c_{ns1, ns2} + c_{ns1, s2} + c_{s1, ns2})$. Thus, to a first approximation $(N_{1a} + N_{1b} + N_{1c} + N_{1d})$ becomes

$$\begin{aligned} & N_0 A \left\{ 1 + \left(X + \frac{B}{A} Y \right) P_2(\cos \theta) \right. \\ & \left. + \frac{B}{A} Z P_4(\cos \theta) \right\}, \end{aligned} \quad (4.9)$$

whose angular correlation differs from the true value by $(B/A)YP_2(\cos \theta)$ and $(B/A)ZP_4(\cos \theta)$.

Now applying to the formula (4.9) the practical values in the 2.11–0.605 Mev correlation measurement, such as $\tau_\gamma = 3 \times 10^{-8}$ sec, $\tau_\beta = 5 \times 10^{-7}$ sec, $N_{t1} \doteq N_{t2} \doteq 10^6/\text{min}$, $c_{s1, s2} = 20/\text{min}$ and other values as calculated from these by considering the spectrum shape, intensity ratios, detecting efficiencies and so forth, (B/A) was estimated to be less than $1/3000$. Thus assuming $X \doteq Y$ and $Z \ll X, Y$ in this case*, it was concluded that for the 2.11–0.605 Mev cascade the true correlation would not be changed by more than 0.03% on account of the contribution from the false coincidence events described above. Secondly, similar estimation was made for N_{2b} and N_{2c} in (4.3). The results show that N_{2b} and N_{2c}

should be less than 0.04% and 0.65% of $c_{s1, s2}$ respectively. Since more than half of N_{2b} and N_{2c} are contributed from the 1.71–0.605 Mev coincidence and its $W(\theta)$ is nearly the same as that of the 2.11–0.605 Mev cascade, the effect of these terms upon the correlation coefficient will become more trivial. For the 1.71–0.605 Mev correlation the above effects are expected to have smaller values because of the strong intensity of the measured cascade. Thus it is concluded that the correction for the abovementioned effect is unnecessary in the present correlation measurements. However, it may be noted that this is not always the case in other experiments.

§ 5. Discussions

A few assignments other than the 3–2–0 could be fitted with the experimental data. However, none of them could meet the other requirements. As to the two assignments proposed by Kraushaar and Goldhaber¹²⁾, we could also fit the data with the 2–1–0 (D, Q-D) combination, in which the mixing ratios were assumed to be -1.97 or 0.17 for the 2.11–0.605 Mev cascade and -1.94 or -0.19 for the 1.71–0.605 Mev cascade. The 1–1–0 (D, Q-D) in which $\delta = -7.72$ or -0.13 for the 2.11–0.605 Mev cascade and $\delta = -8.00$ or -0.13 for the 1.71–0.605 Mev cascade could be fitted with data. But, in the latter case some difference from the value of Kraushaar and Goldhaber was found in the mixing ratio. Moreover, a 3–1–0 (Q-D) combination nearly fits the data and a better agreement will be expected by small admixture of different multipoles having the same parity to both or either of the two radiations. However, the assignment of spin 1 to the 0.605 Mev level is not consistent with the results of the internal conversion measurements as well as with the usual assumption about even-even nuclei.

We have no definite information about the parities of both radiations except for an attempt of Tomlinson for the 1.71 Mev gamma ray cited by Metzger¹³⁾. However, combining his result with the empirical rule^{24, 25)} concerning the lowest excited states of odd spin in even-even nuclei and other theoretical considerations²⁶⁾, it may be concluded that the main component of the 1.71 Mev gamma ray is the electric dipole rather than the magnetic

* In the present experiment the disturbing cascade is mainly consist of the 1.71–0.605 Mev cascade and its directional correlation is similar to that of the 2.11–0.605 Mev cascade.

dipole. Thus, it will be seen that 3⁻ should be assigned to the 2.32 Mev level. Further experiment to determine the parity is necessary for the 2.11 Mev gamma ray.

The theoretical foundations for assigning spin 3 to both of the 2.72 and 2.32 Mev states seem to be rather difficult. In the single particle aspects^{27, 28)} it may be expected that, as the configurations of the last two protons and neutrons, the following ones:

$$\begin{aligned} &\{(g_{7/2})^2(0)\}_P\{(h_{11/2})^2(0)\}_N(0), \\ &\{(g_{7/2})^2(2)\}_P\{(h_{11/2})^2(0)\}_N(2), \\ &\{(g_{7/2})^2(0)\}_P\{(h_{11/2})^2(2)\}_N(2), \\ &\{(g_{7/2})^2(2)\}_P\{(h_{11/2})^2(2)\}_N(0, 2 \text{ or } 4), \\ &\{(g_{7/2})^1(h_{11/2})^1(3)\}_P\{(h_{11/2})^2(0)\}_N(3) \quad \text{and} \\ &\{(d_{5/2})^1(h_{11/2})^1(3)\}_P\{(h_{11/2})^2(0)\}_N(3) \end{aligned}$$

are reasonable for the levels A, B, C, D, E and F in Fig. 3 respectively. Confining our discussions to the levels measured by the present author, the dipole transition from the 2.32 Mev level can be explained by the above configurations. But the same transition from the higher 3 level will become the two particle transition and then should be forbidden in these configurations. This situation becomes worse when the beta decays from Sb¹²⁴ too are taken into consideration. However, as pointed out by Crayson and Nordheim²⁹⁾, the *d*_{5/2} proton configuration must in this region (*Z*=50–55) be mixed with *g*_{11/2} orbits, while on the neutron side (*N*=69–80) there is the irregular fill-in of the *h*_{11/2} orbits and the re-appearance holes in the *g*_{7/2} and *d*_{5/2} shells. These will mix the configurations strongly and some of the difficulties described above may be dissolved by considering the configurational mixings for the concerned states.

Acknowledgement

The author expresses his hearty gratitude to Professor K. Kimura of Kyoto University for his sustained interest and encouragement throughout the present work. He is also deeply indebted to his colleagues, Messrs. M. Kawamura and A. Aoki, who have been in cooperation during the whole experiments. This work was partly supported by a grant-

in-aid for scientific research of the Ministry of Education.

Excitation Curves of the $N^{14}(d, n)O^{15}$ Reaction

By Susumu MORITA

*Department of Physics, Faculty of Science,
Kyushu University, Fukuoka, Japan*

(Received October 30, 1957)

The excitation curves of the $N^{14}(d, n)O^{15}$ reaction were measured with a thin plastic scintillator and a pulse height analyser in the energy range of deuterons from 1.00 to 2.15 MeV. Three excitation functions were obtained at the directions of 0, 90 and 165 degrees (lab. system) with respect to the incident deuterons.

The curves obtained at 0 and 165 degrees show remarkable peaks at the deuteron energies, $E_d=1.6$ and 1.9 MeV, respectively, while the curve obtained at 90 degrees is nearly flat.

§ 1. Introduction

In our previous work,¹⁾ the angular distribution of neutrons from the $N^{14}(d, n)O^{15}$ reaction leading to O^{15} ground state was measured in the angular range of 0 to 165 degrees (lab. system) with the deuterons of energy of 1.96 MeV. The results show the forward peak at 30 degrees, which can be fitted well by the stripping theory, and a remarkable increase of the neutron yield in the backward direction was found, the intensity of neutrons at 165 degrees reaching 2.3 times that of the forward peak.

As it seemed to us that these results gave an important information for the analysis of deuteron induced reaction, we were interested to extend the investigation on this reaction to the measurements of the excitation function and of the variation of angular distribution of neutrons with the deuteron energy.

In the present work, the excitation curves of this direction were measured in the energy range of deuterons from 1.00 to 2.15 MeV, and in the reaction of 0, 90 and 165 degrees (lab. system) with respect to the incident deuterons.

§ 2. Experimental Procedure

The experimental arrangement, except the neutron detector, was reported in detail in the previous work.¹⁾ The energy of the deuteron beam, accelerated by the Van de Graaff Generator at the Kyushu University, was calibrated by the resonances of the $F^{19}(p, \alpha\gamma)O^{18}$ reaction and the energy spread of the beam was estimated to be less than 0.5 percent. The deuterons entered into the target chamber through a nickel foil of 1.3 mg/cm² in thickness. The chamber was 2.0 cm in depth and was filled with nitrogen gas of

pressure of 20.0 cmHg. The energy loss of the deuterons in the nickel foil and the nitrogen gas was evaluated to be about 250 KeV for the deuteron energy of 2 MeV, based on the data obtained by S. K. Allison and S. D. Warshaw.²⁾

A plastic scintillator, made by National Radiac Co., of 10 mm in diameter and 1 mm in thickness and a EMI 6097 photomultiplier tube was used as the neutron detector and the pulses from the photomultiplier tube were fed to a linear amplifier and were analysed by a twenty channel pulse height analyser.

In the case of $N^{14}(d, n)O^{15}$ reaction with deuterons of about 2 MeV, it was expected that the reaction would be accompanied with the rather intense gamma-rays of about 5 MeV due to the process leading to the first excited state of O^{15} . But allowing for the response curves and their range-energy relations in the scintillator for proton and electron, we hoped to be able to make the maximum pulse height for recoil proton much larger than that for the gamma-rays by choosing a suitable thickness for the scintillator.

The pulse height distributions for $N^{14}(d, n)O^{15}$ reaction were measured with plastic scintillators of 10 mm in diameter and of 1, 2 and 3 mm in thickness, respectively, and the results obtained are shown in Fig. 1, in which the angles show the directions relative to the incident deuteron. From these results, the plastic scintillator of 1 mm in thickness was selected as the most suitable one.

The pulse height distributions from the recoil protons in this plastic scintillator due to the neutrons from the $N^{14}(d, n)O^{15}$ reaction leading to the O^{15} ground state and those from the $D(d, n)He^3$ reaction are shown in Fig. 2

together with the pulse height distribution due to the gamma-ray of 6 MeV from the $F^{19}(p, \alpha\gamma)O^{16}$ reaction.

Fig. 1. Pulse height spectra of recoil protons from the $N^{14}(d, n)O^{15}$ reaction, measured with plastic scintillators of 10 mm in diameter and 1, 2 and 3 mm in thickness.

Fig. 2. Pulse height spectra of recoil protons from the neutrons of the $N^{14}(d, n)O^{15}$ and those of the $D(d, n)He^3$ reaction. The pulse height spectrum due to the gamma-ray of 6 MeV from the $F^{19}(p, \alpha\gamma)O^{16}$ reaction is also shown.

In Figs. 1 and 2, the flat portion of the pulse height distribution corresponds to the recoil protons, as is expected, and the steep rise in the lower energy region in the case

of $N^{14}(d, n)O^{15}$ reaction shows the presence of the gamma-ray of 5 MeV.

The rather gentle slopes at the high energy end would be attributed to the end effect of the thin plastic scintillator, that is, a proton may escape from the crystal before giving up its full energy. The corrections for the end effect were calculated³⁾ and one of the corrected pulse height distribution is shown in Fig. 3. In this figure, the pulse height distribution is integrated and the number of pulses above a height S is plotted against S . It should be noted that the linearity of the plot is improved in the corrected curve. The extrapolation of the straight portion gives the pulse height corresponding to the end point and thus allows conversion to an energy spectrum. Thus, the pulse height distributions were replotted against the energy values of protons and then, we took the total counts in the pulse height distribution larger than 80 percent of the maximum energy as a measure

Fig. 3. Integrated recoil proton energy spectrum for neutrons from the $N^{14}(d, n)O^{15}$ reaction. The curve (A) shows the result of the end effect correction.

of the neutron intensity. These counts were corrected for the variation of (n, p) scattering cross section with the energy of the neutron.

The amount of stray neutrons was estimated to be less than a few percent of that of the direct neutrons, by inserting an iron absorber of 10 cm thickness between the target and detector.

The distances between the target and detector were 5.3 cm in the observation at 0 and 90 degrees and 16.5 cm in the case of 165 degrees.

§ 3. Results and Discussion

The excitation functions obtained at 0, 90 and 165 degrees (lab. system) with respect to the direction of incident deuteron are shown as curves (A), (B) and (C), respectively, in Fig. 4. The value of the absolute cross sec-

of deuteron beam in the target gas.

In our previous result¹⁾ obtained with deuterons of 1.96 MeV, the ratio of the neutron intensity at 0, 90 and 165 degrees was evaluated as 1:0.5:3.4 and the value of this ratio in the present work, is obtained as 1:0.4:3.1 from Fig. 4. These ratios are in good agreement with each other despite the difference in the methods of neutron detection.

It is to be noted that the curves (A), (B) and (C) show quite different behaviour; that is, the excitation curves obtained at 0 and 165 degrees show remarkable peaks at 1.6 and 1.9 MeV, respectively, while the curve (B) obtained at 90 degrees is nearly flat and similar to the curve (A) in its general tendency. Moreover, the curve (A) shows minimum at 1.9 MeV, where the curve (C) reaches the maximum. It was found from these facts that the remarkable increase in neutron intensity in the backward direction, obtained in the previous work, will disappear with a small change in the energy of deuterons and the angular distribution of neutrons will be sensitive to the deuteron energy.

It will be worthwhile to investigate the change of angular distribution with deuteron energy in more detail.

The author wishes to express his cordial thanks to Prof. I. Nonaka, Mr. N. Kawai and all other staffs of the nuclear laboratory of Kyushu University for their support and discussions throughout this work. This work has been supported by the Scientific Research Expenditure of the Ministry of Education.

$\text{Co}^{59}(n, \alpha)\text{Mn}^{56}$ and $\text{Mn}^{55}(n, \alpha)\text{V}^{52}$ Reactions Induced by 14.8-Mev Neutrons

By Isao KUMABE, Eiko TAKEKOSHI*, Hiroshi OGATA, Yoshikazu TSUNEOKA
and Shinpei ŌKI

Department of Physics, Faculty of Science, University of Kyoto

(Received November 1, 1957)

The angular and energy distributions of alpha particles resulting from $\text{Co}^{59}(n, \alpha)\text{Mn}^{56}$ and $\text{Mn}^{55}(n, \alpha)\text{V}^{52}$ reactions induced by 14.8-Mev neutrons were measured with Ilford C2 nuclear plates.

As in the case of $\text{Al}^{27}(n, \alpha)\text{Na}^{24}$ reaction, the angular distributions for the entire energy region are approximately 90° symmetrical and concave upward, and the energy distributions show that the alpha particles with energies below the Coulomb barrier are more emitted than has been expected. The curves on a semilog plot of the relative level density calculated from the energy distributions of the alpha particles cannot fit a straight line.

The total (n, α) cross sections of cobalt and manganese are $84 \text{ mb} \pm 15\%$ and $96 \text{ mb} \pm 15\%$ respectively. The results are compared with the predictions of the statistical theory of nuclear reactions.

§ 1. Introduction

Paul and Clarke¹⁾ carried out an extensive survey of (n, p) , (n, α) and $(n, 2n)$ reactions at 14.5 Mev. They have shown that the $(n, 2n)$ reaction cross sections are approximately in agreement with the evaporation theory. However, the cross sections of (n, p) and (n, α) reactions for heavy elements have had orders of magnitude larger than expected. They suggested the existence of the direct process in these cases. Experimental data of the angular and energy distributions on (n, α) reactions may give reliable information on these problems.

In the past few years several attempts²⁾ have been made to measure the dependence of the density of energy levels on excitation energy, which can be determined from reaction and inelastic scattering experiments in which particles are emitted from the compound nucleus produced by bombardment with energetic particles. However, these experimental results have been accompanied by ambiguities owing to the presence of non-compound-nucleus processes. On the other hand, data on (n, α) reactions have been considered to give more reliable information on the level density, since it seems improbable that alpha particles are emitted by direct

interactions.

In the previous paper³⁾, we have reported the angular and energy distributions of the alpha particles from the $\text{Al}^{27}(n, \alpha)\text{Na}^{24}$ reaction induced by 14.8-Mev neutrons. It has been found that the angular distribution of particles for the entire energy region is concave upward and approximately 90° symmetrical, and the curve on a semilog plot of the relative level density calculated from the energy distribution of alpha particles fits a straight line with a temperature of about

Fig. 1. Experimental arrangement.

Pt: platinum foil

Target of cobalt or manganese was attached onto the shaded regions of both surfaces of the platinum foil.

* Now at Atomic Energy Research Establishment of Japan.

1.45 Mev.

In this paper the measurements extended to the target nuclei of cobalt and manganese are reported.

§ 2. Experimental Procedure

The experimental arrangement is shown schematically in Fig. 1. The experimental method was described in detail in the previous paper³⁾ cited above. Targets of cobalt and manganese were respectively electroplated and vacuum evaporated onto platinum foil of thickness 60 mg/cm². Target thickness used was 3.7 mg/cm² for cobalt and 3.3 mg/cm² for manganese respectively.

§ 3. Results

The angular distributions in the center of mass system of the alpha particles from $\text{Co}^{59}(n, \alpha)\text{Mn}^{56}$ and $\text{Mn}^{55}(n, \alpha)\text{V}^{52}$ reactions for the entire energy region are shown in Fig. 2, and the energy distributions are

shown in Fig. 3. The corrections for stopped alpha particles and energy loss in the target materials were carried out in the same way as in the case of aluminium³⁾.

It is assumed that the relation between the measured alpha particle energy distributions and the energy level densities of the residual nucleus is provided by the following formula⁴⁾;

$$n(\epsilon)d\epsilon = \text{const } \epsilon \sigma_{\alpha}(\epsilon) \omega(\epsilon_r) d\epsilon,$$

where $n(\epsilon)d\epsilon$ = number of alpha particles emitted with energy between ϵ and $\epsilon + d\epsilon$, $\sigma_{\alpha}(\epsilon)$ ⁵⁾ is the cross section, including the effects of barrier penetration for a nuclear radius of $1.5 \times 10^{-13} A^{1/3}$ cm, for the formation of the compound nucleus in the same state of excitation by the reverse reaction, in which particles of energy ϵ strike the excited residual nucleus, and $\omega(\epsilon_r)$ is the density of energy level of the residual nucleus at excitation $\epsilon_r = \epsilon_{\text{max}} - \epsilon$, ϵ_{max} being the maximum energy which the emitted particle may have.

Fig. 2. Angular distributions of alpha particles from $\text{Co}^{59}(n, \alpha)\text{Mn}^{56}$ and $\text{Mn}^{55}(n, \alpha)\text{V}^{52}$ reactions. The dashed lines show the observed angular distributions, while the solid lines show the corrected angular distributions.

Fig. 3. Energy distributions of alpha particles from $\text{Co}^{59}(n, \alpha)\text{Mn}^{56}$ and $\text{Mn}^{55}(n, \alpha)\text{V}^{52}$ reactions. The histograms and dashed curves show the observed energy distributions, while the solid curves show the corrected energy distributions.

Fig. 4. The relative level densities $\omega=n/\epsilon\sigma_0$ of Mn^{56} and V^{52} .

Fig. 4 shows the results presented by plotting the measured energy spectra divided by $\epsilon\sigma_0(\epsilon)^{5)}$. The data cannot fit a straight line. It is found that the curves are both concave upward, and for Mn the nuclear temperature is about 0.85 Mev at the high energy side ($13 > \epsilon > 9$ Mev) and about 0.55 Mev at the low energy side ($9 > \epsilon > 7$ Mev) and for V about 1.0 Mev at the high energy side ($12 > \epsilon > 9$ Mev) and about 0.65 Mev at the low energy side ($9 > \epsilon > 7$ Mev). The temperatures at the further low energy side (< 7 Mev for Mn and < 7 Mev for V) are not included in the present discussion because

of the large contribution of the second alpha particles from ($n, n\alpha$) events.

The total (n, α) cross sections of Co and Mn are 84 and 96 mb respectively, which are fairly large as compared with that obtained by other authors^{1),6)} with activation method. However, it must be noted that the cross sections obtained by us contain large yield from the ($n, \alpha n$) and the ($n, n\alpha$) reactions. Combined systematic and statistical uncertainties are estimated to be roughly 15% in the total cross sections.

§ 4. Discussion

As in the case of aluminium³⁾, the angular distributions for the entire energy region are approximately 90° symmetrical and concave upward, and the energy distributions show that the alpha particles with energies below the Coulomb barrier are more emitted than has been expected.

The approximate 90° symmetry of the angular distributions of the alpha particles indicates the fact that most of the reactions probably occur through the formation of the compound nucleus, although the fairly large deviation from isotropy cannot be explained with the statistical theory of nuclear reactions⁷⁾. However, this may be explained by introducing a kind of selection rule for the emission of the alpha particles such as the isotopic spin selection rule.

Fig. 3 shows that the low energy alpha particles are more emitted than has been expected from the conventional statistical theory with the usual potential. It is considered that this may be explained by introducing a diffuse nuclear potential such as used by K. Kikuchi⁸⁾ in his recent paper, which can be expected to give considerably larger yield at the low energy side than the usual square-well potential. Indeed he has shown that our previous results³⁾ which give somewhat lower temperature than others' can be explained with the temperature of 2 Mev by introducing a diffuse potential.

It may be considered that the (n, α) cross sections larger than expected from the evaporation theory are not due to the non-com-

pound processes but the large penetrabilities, which are explained by introducing a diffuse potential. But these problems should be discussed in more detail in future. Further investigation on other elements is now in progress.

§ 5. Acknowledgments

The authors wish to thank Professor K. Kimura for many useful discussions and suggestions throughout the course of the present work. Thanks are also due to Mr. M. Kurauchi and Mr. B. Ikeo for their helps in preparing the targets. This work has been supported by the Scientific Research Expenditure of Ministry of Education.

The Thermoelectric, Galvanomagnetic and Thermomagnetic Effects of Monovalent Metals

By Mikio TSUJI

General Education Department, Kyushu University, Fukuoka

(Received October 11, 1957)

A Theory of the thermoelectric effects and transverse galvano- and thermomagnetic effects of monovalent metals is described on a model of general spherical energy band. Boltzmann's equation is solved by a variational method, and whence we get a formula of thermoelectric power which shows the possibility of positive thermoelectric power at high temperatures but not at low temperatures. The effect of the Umklapp processes on the time of relaxation at high temperatures is also investigated. Our simple model can derive the negative Ettingshausen and Ettingshausen-Nernst coefficients of noble metals at high temperatures.

§ 1. Introduction

In the theory of transport phenomena of metals, an assumption is usually made that the conduction electrons can be treated as quasi-free. The theory based on this simple assumption gives fairly good agreement with experiment for the electrical conductivity of monovalent metals, but rather poor agreement for the thermal conductivity of noble metals at low temperatures¹⁾. Especially for the thermoelectric, thermomagnetic and magneto-resistance effects, the assumption of quasi-free electrons gives a large discrepancy between the theory and experiments. For example the magneto-resistance effect is much larger than the results given by the theory based on the spherical energy surface model. For the magneto-resistance effect the anisotropy of band structure is essentially important²⁾. For the thermoelectric phenomena, the theory based on the free electron model gives a negative value of thermoelectric power, but the experiments show that the thermoelectric powers of noble metals and lithium are positive in sign, and those of rubidium and caesium change their signs from negative to positive as temperature decreases.

Jones³⁾ showed that the positive sign of thermoelectric power can be interpreted in terms of departures of the electronic energy-level structure from that postulated for quasi-free electrons. In his treatment, the anisotropy of the band structure is not essential, but a large increase of the density of states near the Fermi surface which is brought about by the anisotropy is essential for the occur-

rence of positive sign. Thus, the sign of thermoelectric power seems to be determined from the behavior of state density curve near the Fermi level, which should in turn be obtained from the electronic band structure of metals. But, the full determination of the electronic band structure is very complicated, and at present the theory does not give so reliable informations about the detailed nature of energy near the Fermi level.

Hence, we assume in the first approximation a spherical energy surface which is in a certain sense an averaged surface of real energy surface and is more general than that of quasi-free electrons. The same idea was suggested by Klemens⁴⁾ in his paper on the thermoelectric power of monovalent metals at high temperatures, in which he showed that the thermoelectric power of potassium is not anomalous, contrary to the result of MacDonald and Roy⁵⁾. Klemens¹⁾ has also investigated the thermal conductivities of monovalent metals on the same model and concluded that the thermal conductivities of noble metals at low temperatures are not interpreted by the spherical energy band model. The thermoelectric power of metals at low temperatures has never been studied on the model, and hence it seems to be worth while to study the behavior of the thermoelectric power of metals at all temperatures by using the model of the spherical energy surface.

In § 2 a transport equation for the conduction electrons which have a general spherical energy-level structure is set up by assuming

that the distribution function of lattice waves can be replaced by its thermal equilibrium value. Since the effect of non-equilibrium lattice distribution gives a negative contribution to the thermoelectric power⁶⁾, the assumption of the thermal equilibrium of lattice may be allowed for the purpose of a qualitative investigation of the possibility of the positive sign of the thermoelectric power. The 'Umklapp processes' are also disregarded on the derivation of the transport equation. An approximate solution of the transport equation by the variational method of Kohler⁷⁾ is given and the results are discussed. It is shown that there is a possibility of positive sign of the thermoelectric power at high temperatures, but no possibility for pure metals at low temperatures on the model of spherical energy surface. Hence the model is not appropriate to interpret the thermoelectric powers of metals at low temperatures. There is a reason, however, that we believe the model may be a good approximation at high temperatures at least semi quantitatively.

Therefore we further study on the case of high temperatures after § 3. At high temperatures, the effect of the non-equilibrium distribution of lattice waves may be disregarded, but the effect of Umklapp processes (we shall call them U-processes) may become important. The effect of U-processes on the electric and thermal conductivities were calculated by Bardeen⁸⁾ and Ziman⁹⁾, but their effect on the thermoelectric power has never been studied. In § 3 the effect of U-processes on the time of relaxation at high temperatures is considered.

By using the results obtained in § 3, the thermoelectric powers at high temperatures are calculated and the effects of impurities on the thermoelectric powers are discussed in § 4. It is shown that the U-processes give a positive contribution to the thermoelectric power.

In § 5 the transverse galvano- and thermomagnetic effects are calculated. An interpretation is given of the observation that the Ettingshausen, and Ettingshausen-Nernst coefficients of noble metals are negative. This had never been interpreted theoretically. A relation between thermoelectric power and Ettingshausen coefficient is derived. The relation shows fairly good agreement with experiments. The effects of impurity on the

Ettingshausen and Ettingshausen-Nernst effects are also considered.

Our results obtained in § 2 are also applicable to the calculation of the influence of exchange and correlation of electrons on the transport phenomena of metals. In the appendix, we calculate the effects by using Bohm and Pines' curve and correct the errors in the calculation of Barrier¹⁰⁾.

§ 2. General Theory based on Spherical Energy Surface Model

2.1. The Transport Equation

Assuming that the energy $E(\mathbf{k})$ of an electron depends only on the absolute value of wave vector $\mathbf{k}$, we expand $E(\mathbf{k})$ at the Fermi surface as

$$E(\mathbf{k}) = \zeta + \alpha(k - k_0) + \frac{1}{2}\beta(k - k_0)^2 + \dots \quad (1)$$

where $k = |\mathbf{k}|$, k_0 is the value of k at the Fermi surface, ζ is the Fermi level, and α and β are constants independent of k . The frequency $\nu(\mathbf{q})$ of a lattice wave is assumed to be related to the lattice wave vector $\mathbf{q}$ by $\nu(\mathbf{q}) = u_0 q / 2\pi$, where u_0 is the (constant) velocity of sound, and the vector $\mathbf{q}$ is assumed to lie inside a sphere of radius

$$q_0 = \left(\frac{3}{4\pi}\right)^{1/3} \frac{2\pi}{a},$$

where a is the lattice constant.

When the electric field $\mathbf{F}$ and the temperature gradient $\text{grad } T$ are in the x direction, the appropriate form of the electron distribution function $f(\mathbf{k})$ is

$$f(\mathbf{k}) = f_0(E) - k_x c(\eta) \frac{\partial f_0}{\partial E}, \quad (2)$$

where $\eta = (E - \zeta) / \kappa T$, f_0 is the Fermi function $1/(e^\eta + 1)$ and κ is the Boltzmann constant. The rate of change of f due to the field is given by

$$\left[\frac{\partial f}{\partial t}\right]_r = \frac{k_x}{\hbar k} \frac{dE}{dk} \frac{\partial f_0}{\partial E} \left(eF + T \frac{\partial}{\partial x} \frac{\zeta}{T} + \frac{E}{T} \frac{\partial T}{\partial x} \right), \quad (3)$$

where $-e$ is the charge of an electron. For the scattering of electrons by the impurity atoms and the lattice defects, a time of relaxation τ exists, and is given by¹¹⁾

$$\frac{1}{\tau} = \frac{1}{\hbar} \frac{dE}{dk} N_i Q, \quad (4)$$

where N_i is the number of impurity atoms per unit volume and Q is the scattering cross section of an impurity atom. Hence the rate

of change of f due to the impurity scattering is given by

$$\left[\frac{\partial f}{\partial t} \right]_1 = - \frac{f - f_0}{\tau} = \frac{k_x}{\hbar} \frac{dE}{dk} \frac{\partial f_0}{\partial E} N_i Q c(\eta) . \quad (5)$$

Assuming the scattering potential to be

$$V(r) = \frac{ze^2}{r} \exp(-r/r_0) ,$$

Barrie¹²⁾ has calculated the scattering cross section Q and has obtain

$$Q = 2\pi z^2 e^4 k^{-2} \left(\frac{dE}{dk} \right)^{-2} \left\{ \ln(1 + 4k^2 r_0^2) - \frac{4k^2 r_0^2}{4k^2 r_0^2 + 1} \right\} , \quad (6)$$

where $z+1$ is the valency of impurity atoms. If we expand the term in the bracket in a power series of η , we have

$$Q = k^{-2} \left(\frac{dE}{dk} \right)^{-2} P \{ 1 + \gamma_1 \kappa T \eta + \gamma_2 (\kappa T \eta)^2 + \dots \} , \quad (7)$$

where P is a constant independent of k . Actually it is sufficient for our purpose to retain the right side of (7) up to the second term.

If we disregard the 'Umklapp processes' and assume that the lattice waves are in thermal equilibrium, the term due to the lattice scattering in the first approximation may be written in the form^{13), 14)}

$$\begin{aligned} \left[\frac{\partial f}{\partial t} \right]_2 &= k_x \frac{\partial f_0}{\partial E} \frac{3\pi C^2}{2Mu_0} \left(\frac{dE}{dk} \right)^{-1} \left(\frac{T}{\Theta} \right)^3 \\ &\times \int_{-\Theta/T}^{\Theta/T} \left[c(\eta) - c(\eta+z) \right] \left\{ 1 + \frac{\kappa T z}{k dE/dk} - \frac{q_0^2}{2k^2} \left(\frac{T}{\Theta} \right)^2 z^2 \right\} \frac{e^\eta + 1}{e^{\eta+z} + 1} \frac{1}{|1 - e^{-z}|} z^2 dz , \end{aligned} \quad (8)$$

where M is the mass of lattice ion, Θ is the Debye characteristic temperature and C is the interaction constant between electrons and lattice waves used by Wilson¹⁵⁾ and is equal to 2/3 of the interaction constant used by Sommerfeld and Bethe¹³⁾. Eq. (8) is sufficiently good approximation to obtain the leading terms of the electrical and thermal conductivities, but not to obtain the thermoelectric powers at low temperatures.

Eq. (8) is obtained, for example, from Eq. (9.33.7) of Wilson's text¹⁵⁾, by using the approximation that

$$\begin{aligned} \frac{1}{\pi \hbar} \Omega(E_{k+q} - E_k \pm \hbar \nu_q) &= \delta(E_{k+q} - E_k \pm \hbar \nu_q) \\ &= \delta \left\{ \frac{dE}{dk} \left(q \cos \theta + \frac{q^2}{2k} \right) \pm \hbar \nu_q \right\} = \frac{1}{q dE/dk} \delta \left\{ \left(\cos \theta + \frac{q}{2k} \right) \pm \frac{\hbar \nu_q}{q dE/dk} \right\} , \end{aligned} \quad (9)$$

and by integrating over the orientation of $\mathbf{q}$, where θ is the angle between $\mathbf{k}$ and $\mathbf{q}$.

In the higher approximation required, (9) must be replaced by

$$\delta \left\{ \frac{dE}{dk} \left(q \cos \theta + \frac{q^2}{2k} \right) + \frac{1}{2} \left(\frac{d^2 E}{dk^2} - \frac{1}{k} \frac{dE}{dk} \right) q^2 \left(\cos \theta + \frac{q}{2k} \right) \pm \hbar \nu_q \right\} . \quad (10)$$

Now to simplify (10), we use the following theorem: If the two real roots of $ax^2 + bx + c = 0$ are x_1 and x_2 , then

$$\delta(ax^2 + bx + c) = \frac{1}{|a(x_1 - x_2)|} \delta(x - x_1) + \frac{1}{|a(x_1 - x_2)|} \delta(x - x_2) . \quad (11)$$

If the region of integration over x does not include x_2 , the second term of right side of (11) may be omitted. By using (11) and the relation $\hbar \nu_q / q(dE/dk) \ll 1$, (10) may be rewritten as

$$\delta(E_{k+q} - E_k \pm \hbar \nu_q) = \frac{1}{q dE/dk} \left\{ 1 \pm \frac{\frac{d^2 E}{dk^2} - \frac{1}{k} \frac{dE}{dk}}{(dE/dk)^2} \hbar \nu_q \right\} \delta \left(\cos \theta + \frac{q}{2k} \pm \frac{\hbar \nu_q}{q dE/dk} \right) . \quad (12)$$

Then (8) is replaced by

$$\left[\frac{\partial f}{\partial t} \right]_2 = k_z \frac{\partial f_0}{\partial E} \frac{3\pi C^2}{2Mu_0} \left(\frac{dE}{dk} \right)^{-1} \left(\frac{T}{\Theta} \right)^3 \int_{-\Theta/T}^{\Theta/T} \left\{ 1 - \frac{d^2 E}{dk^2} \frac{1}{k} \frac{dE}{dk} \kappa Tz \right\} \\ \times \left[c(\eta) - c(\eta+z) \right] \left\{ 1 + \frac{\kappa Tz}{k dE/dk} - \frac{q_0^2}{2k^2} \left(\frac{T}{\Theta} \right)^2 z^2 \right\} \left[\frac{e^\eta + 1}{e^{\eta+z} + 1} \frac{z^2 dz}{|1 - e^{-z}|} \right]. \quad (13)$$

From (3), (5), (7) and (13), we may write the equation for the steady state of the electron distribution in the form

$$\frac{1}{k} \frac{dE}{dk} \left(eF + T \frac{\partial}{\partial x} \frac{\xi}{T} + \frac{E}{T} \frac{\partial T}{\partial x} \right) = \mathcal{L}(c), \quad (14)$$

where

$$\mathcal{L}(c) = -N_i P (1 + \gamma_1 \kappa T \eta + \dots) k^{-2} \left(\frac{dE}{dk} \right)^{-1} c(\eta) \\ - A^{-1} \left(\frac{dE}{dk} \right)^{-1} \left(\frac{T}{\Theta} \right)^3 \int_{-\Theta/T}^{\Theta/T} \left\{ 1 - \frac{d^2 E}{dk^2} \frac{1}{k} \frac{dE}{dk} \kappa Tz \right\} \\ \times \left[c(\eta) - c(\eta+z) \right] \left\{ 1 + \frac{\kappa Tz}{k dE/dk} - \frac{q^2}{2k^2} \left(\frac{T}{\Theta} \right)^2 z^2 \right\} \left[\frac{e^\eta + 1}{e^{\eta+z} + 1} \frac{z^2 dz}{|1 - e^{-z}|} \right], \quad (15)$$

and A denotes $4Mu_0/(3hC^2)$. To solve Eq. (14), we put

$$c(\eta) = \left(eF + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) c^{(1)}(\eta) + \frac{1}{T} \frac{\partial T}{\partial x} c^{(2)}(\eta), \quad (16)$$

then $c^{(1)}$ and $c^{(2)}$ are the solutions of

$$E^{n-1} \frac{1}{k} \frac{dE}{dk} = \mathcal{L}(c^{(n)}) \quad (n=1, 2). \quad (17)$$

The electric and heat current densities are given by

$$J = K_{11} \left(e^2 F + eT \frac{\partial}{\partial x} \frac{\xi}{T} \right) + K_{12} \frac{e}{T} \frac{\partial T}{\partial x}, \quad (18)$$

$$w = K_{21} \left(-eF - T \frac{\partial}{\partial x} \frac{\xi}{T} \right) - K_{22} \frac{1}{T} \frac{\partial T}{\partial x}, \quad (19)$$

where

$$K_{mn} = \frac{1}{3\pi^2 \hbar} \int_{-\infty}^{\infty} E^{m-1} k^3 c^{(n)}(\eta) \frac{\partial f_0}{\partial \eta} d\eta. \quad (20)$$

2.2. Solution of the Transport Equation

To solve the integral equation (17), we use the variation principle of Kohler⁷⁾. The principle applied to the case of spherical energy band can be stated as follows:

The solution of (17) is such as to make the integral

$$(c^{(n)}, c^{(n)}) = \int_{-\infty}^{\infty} k^4 \left(\frac{dE}{dk} \right)^{-1} c^{(n)} \mathcal{L}(c^{(n)}) \frac{\partial f_0}{\partial \eta} d\eta \quad (21)$$

a maximum, subject to the subsidiary condition

$$\int_{-\infty}^{\infty} k^4 \left(\frac{dE}{dk} \right)^{-1} c^{(n)} \mathcal{L}(c^{(n)}) \frac{\partial f_0}{\partial \eta} d\eta = \int_{-\infty}^{\infty} E^{n-1} k^3 c^{(n)} \frac{\partial f_0}{\partial \eta} d\eta. \quad (22)$$

Now we put $c^{(n)}(\eta)$ in the form

$$c^{(n)}(\eta)=\sum_{r=0}^1c_r^{(n)}\eta^r\,,\tag{23}$$

and put

$$\alpha_r^{(n)}=\int_{-\infty}^{\infty}E^{n-1}k^3\eta^r\frac{\partial f_0}{\partial\eta}\,d\eta\,,\tag{24}$$

$$d_{rs}=(\eta^r,\eta^s)=\int_{-\infty}^{\infty}k^4\left(\frac{dE}{dk}\right)^{-1}\eta^r\mathcal{L}(\eta^s)\frac{\partial f_0}{\partial\eta}\,d\eta\,.\tag{25}$$

Then

$$(c^{(n)},c^{(n)})=\sum_{r=0}^1\sum_{s=0}^1d_{rs}c_r^{(n)}c_s^{(n)}$$

must be a maximum, subject to the condition

$$\sum_{r=0}^1\sum_{s=0}^1d_{rs}c_r^{(n)}c_s^{(n)}-\sum_{r=0}^1\alpha_r^{(n)}c_r^{(n)}=0\,.$$

The current densities are given by (18) and (19), and now (20) becomes

$$K_{mn}=\frac{1}{3\pi^2\hbar}\sum_{r=0}^1\alpha_r^{(m)}c_r^{(n)}\,.$$

By the symmetry relation $d_{01}=d_{10}$, we can easily show the reciprocal relation

$$K_{21}=K_{12}\,.\tag{26}$$

The solutions of the variational problem are easily obtained by the usual method¹⁶⁾, and we obtain the leading terms of the conductivities and thermoelectric power as follows:

$$\begin{aligned}\sigma&=\frac{e^2}{3\pi^2\hbar}\frac{(\alpha_0^{(1)})^2}{d_{00}}\,,\\ \kappa_T&=\frac{1}{3\pi^2\hbar T}\frac{(\alpha_0^{(1)}\alpha_1^{(2)}-\alpha_1^{(1)}\alpha_0^{(2)})^2}{(\alpha_0^{(1)})^2d_{11}}\,,\\ S&=-\frac{\kappa}{e}\frac{\alpha_1^{(1)}\alpha_0^{(1)}d_{11}-\{\alpha_2^{(1)}\alpha_0^{(1)}+(\alpha_1^{(1)})^2\}d_{01}+\alpha_2^{(1)}\alpha_1^{(1)}d_{00}}{(\alpha_0^{(1)})^2d_{11}}\,.\end{aligned}$$

To calculate $\alpha_r^{(n)}$ and d_{rs} , we use the expansion

$$\begin{aligned}k&=k_0\left(1+\frac{1}{\alpha k_0}\kappa T\eta-\cdots\right),\\ \frac{dE}{dk}&=\alpha\left(1+\frac{\beta}{\alpha^2}\kappa T\eta-\cdots\right)\end{aligned}$$

in (24) and (25).

The final results are

$$\frac{1}{\sigma}=\frac{1}{\sigma_i}+\frac{1}{\sigma_0}\,,\tag{27}$$

$$\frac{1}{\sigma_i}=\rho_i=\frac{3\pi^2\hbar}{e^2k_0^4\alpha^2}N_iP\,,\tag{28}$$

$$\frac{1}{\sigma_0} = \rho_0 = \frac{3\pi^2 \hbar q_0^2 A^{-1}}{e^2 k_0^4 \alpha^2} \left(\frac{T}{\Theta} \right)^5 J_5 \left(\frac{\Theta}{T} \right), \quad (29)$$

$$\frac{1}{\kappa_T} = \frac{1}{\kappa_i} + \frac{1}{\kappa_0}, \quad (30)$$

$$\frac{1}{\kappa_i} = \frac{9\hbar N_i P}{\kappa^2 T \alpha^2 k_0^4}, \quad (31)$$

$$\frac{1}{\kappa_0} = \frac{27\hbar A^{-1}}{\pi^2 \kappa^2 k_0^2 \alpha^2} \left(\frac{T}{\Theta} \right)^3 \left[J_5 + \left(\frac{T}{\Theta} \right)^2 \frac{q_0^2}{k_0^2} \left\{ \frac{1}{3} \pi^2 J_5 - \frac{1}{6} J_7 \right\} \right], \quad (32)$$

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \times \frac{\frac{\pi^2 N_i P}{3} \left(\frac{4}{\alpha k_0} + \frac{2\beta}{\alpha^2} - r_1 \right) + \frac{1}{A} \left(\frac{T}{\Theta} \right)^3 \left[\frac{2}{\alpha k_0} k_0^2 J_5 + \left(\frac{T}{\Theta} \right)^2 q_0^2 \left\{ \frac{4}{3} \pi^2 \left(\frac{1}{\alpha k_0} + \frac{\beta}{2\alpha^2} \right) J_5 - \frac{1}{6} \left(\frac{5}{\alpha k_0} - \frac{2\beta}{\alpha^2} \right) J_7 \right\} \right]}{\frac{\pi^2 N_i P}{3} + \frac{1}{A} \left(\frac{T}{\Theta} \right)^3 \left\{ k_0^2 J_5 + \left(\frac{T}{\Theta} \right)^2 q_0^2 \left(\frac{\pi^2}{3} J_5 - \frac{1}{6} J_7 \right) \right\}}, \quad (33)$$

where

$$J_n \left(\frac{\Theta}{T} \right) = \int_0^{\Theta/T} \frac{z^n dz}{(e^z - 1)(1 - e^{-z})},$$

and ρ denotes the electrical resistivity and suffices i and 0 denote residual and ideal parts respectively. Using (28) and (29), Eq. (33) can be rewritten in the form

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \frac{\rho_i \left(\frac{4}{\alpha k_0} + \frac{2\beta}{\alpha^2} - r_1 \right) + \rho_0 \left\{ \left(\frac{4}{\alpha k_0} + \frac{2\beta}{\alpha^2} \right) - \frac{1}{2\pi^2} \left(\frac{5}{\alpha k_0} - \frac{2\beta}{\alpha^2} \right) \frac{J_7}{J_5} + \frac{6}{\pi^2} \frac{k_0^2}{q_0^2} \frac{1}{\alpha k_0} \left(\frac{\Theta}{T} \right)^2 \right\}}{\rho_i + \rho_0 \left\{ 1 - \frac{J_7}{2\pi^2 J_5} + \frac{3}{\pi^2} \frac{k_0^2}{q_0^2} \left(\frac{\Theta}{T} \right)^2 \right\}}. \quad (34)$$

Now, in the case that $\rho_i \gg \rho_0$, the Boltzmann equation can be solved by successive approximation, and then thermoelectric power is obtained as a power series of ρ_0/ρ_i . If we expand (34) in a power series of ρ_0/ρ_i , and retain up to the second term, the coefficient of the term of J_7/J_5 differs from that of the solution obtained by successive approximation. This is due to the fact that we restricted the function $c^{(n)}(\eta)$ to the form such as (23). However the terms of J_7/J_5 give practically negligible contribution to the numerical results, and so we neglect those terms in (34). Then (34) becomes

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \frac{\rho_i \left(\frac{4}{\alpha k_0} + \frac{2\beta}{\alpha^2} - r_1 \right) + \rho_0 \left\{ \frac{4}{\alpha k_0} + \frac{2\beta}{\alpha^2} + \frac{6}{\pi^2} \frac{k_0^2}{q_0^2} \frac{1}{\alpha k_0} \left(\frac{\Theta}{T} \right)^2 \right\}}{\rho_i + \rho_0 \left\{ 1 + \frac{3}{\pi^2} \frac{k_0^2}{q_0^2} \left(\frac{\Theta}{T} \right)^2 \right\}}. \quad (35)$$

2.3. Discussion about the Results of the Simple Theory

Eq. (29) agrees with that obtained by Bloch as an interpolation formula¹³⁾, and (32) agrees with that obtained by Klemens¹³⁾. From Eqs. (27) through (32) we see that the electrical conductivity and the thermal conductivity depend only on α^2 and not on β . These equations will be obtained from corresponding formulae for the quasi-free electrons by re-

placing the effective mass m^* by $\hbar^2 k_0/\alpha$, and vice versa. Therefore our model does not give essentially different results from quasi-free electron model.

On the other hand for the thermoelectric power, we obtain a remarkable result (35) which is not deduced from that of free electron model by the simple replacement of m^* .

For pure metals (35) reduces to

$$S_0 = -\frac{\pi^2}{3e} \left(\frac{4}{\alpha k_0} + \frac{2\beta}{\alpha^2} \right) \kappa^2 T \quad (36)$$

at high temperatures ($T \gg \Theta$), and to

$$S_0 = -\frac{2\pi^2 \kappa^2 T}{3e \alpha k_0}, \quad (37)$$

at low temperatures ($T \ll \Theta$).

For the free electron limit ($\beta = \alpha/k_0$, $\alpha k_0 = 2\zeta$), (36) and (37) reduce to the well known formulae¹⁵⁾. Eq. (37) shows that the sign of the thermoelectric powers of pure metals at low temperatures is always negative contrary to the experimental results for noble metals, Li, Cs and Rb¹⁷⁾. On the other hand, (36) shows that at high temperatures

$$S_0 < 0 \quad \text{if} \quad \beta + 2\alpha/k_0 > 0, \quad (38a)$$

and

$$S_0 > 0 \quad \text{if} \quad \beta + 2\alpha/k_0 < 0. \quad (38b)$$

Experimentally, noble metals and Li have positive thermoelectric powers at high temperatures. Therefore, for these metals the condition (38b) should hold.

Now, near the center of the Brillouin zone (energy minimum point), the energy band shape may well be approximated by the quasi-free electron model and hence $d^2E/dk^2 = 2(dE/dk)/k = \hbar^2/m_1^*$ (> 0). On the other hand near the energy maximum point on the zone boundary, the band shape may well be approximated by the positive hole model with $d^2E/dk^2 = -\hbar^2/m_2^*$ (< 0), and $2(dE/dk)/k \simeq 0$. Here m_1^* and m_2^* are the effective masses in each region. Therefore, if the Fermi surface goes from the center to the boundary of the zone, the value of β changes its sign from positive to negative and then its absolute value becomes larger than $2\alpha/k_0$. In the monovalent metals, the Fermi surface lies rather near the zone boundary, so that it may be reasonable to assume that $\beta < 0$ and $|\beta| > 2\alpha/k_0$ for noble metals.

The fact that noble metals should have larger negative values of β than those of alkali metals (except lithium) may be interpreted by the fact that the distance between the Fermi surface and the zone boundary is smaller for the face centered cubic structure than for the body centered cubic structure.

Our simple model is not appropriate to interpret the thermoelectric power at low temperatures, but it is expected that the thermoelectric power at high temperatures may be

interpreted by our simple model. The reason is as follows.

For the general case of anisotropic energy band, the rate of change of distribution function $f(k)$ by the lattice scattering is written in the form¹⁶⁾,

$$\left[\frac{\partial f}{\partial t} \right]_2 = -\frac{1}{\kappa T} \int V(\mathbf{k}, \mathbf{k}') \{ \Phi(\mathbf{k}) - \Phi(\mathbf{k}') \} d\mathbf{k}', \quad (39)$$

where

$$\Phi = -(f - f_0)/(\partial f_0/\partial E). \quad (40)$$

At low temperatures, the wave numbers of effective phonons are small compared to those of electrons, and so only the states $\mathbf{k}'$ on the Fermi surface near the state $\mathbf{k}$ contribute to the integration of (39). Therefore $(\partial f/\partial t)_2$ depends strongly on the behavior of the energy band near the state $\mathbf{k}$, and hence the anisotropy of band structure gives large effects at low temperatures. On the contrary, at high temperatures, the wave numbers of effective phonons are large, and all states $\mathbf{k}'$ on the Fermi surface contribute to the integration (39), so that $(\partial f/\partial t)_2$ depends on the behavior of the energy band on the whole states near the Fermi surface. Hence the anisotropy may be averaged out to a certain extent. Accordingly the averaged spherical energy model may be a good approximation at high temperatures at least semi quantitatively.

§ 3. Effects of Umklapp Processes

In the preceding section, we neglected the Umklapp processes, but at high temperatures they play important role for the transport of electrons. Therefore we consider the effects at high temperatures in this section. Using the interaction parameters $C^2(q)$ calculated by Bardeen⁸⁾, Ziman⁹⁾ has considered the effects of the U-processes on the electrical and thermal conductivities of monovalent metals. But the effects of U-processes on the thermoelectric powers have never been calculated. Here we will show that the effect of the U-processes on the thermoelectric power is considerably important.

If we use Zieman's method to calculate the time of relaxation of pure metals at high temperatures, we have

$$\frac{1}{\tau(k)} = \frac{4}{4\pi^2 M dE/dk} \int_0^{2k} C^2(q) \frac{\kappa T q}{h} \left\langle \frac{1}{v_p^2} \right\rangle \frac{q^4}{2k^2} dq, \quad (41)$$

where $\mathcal{V}$ is the volume of a unit cell and $\mathbf{q} = \mathbf{k} - \mathbf{k}'$. ν_p is given by

$$\nu_p/\nu_0 \equiv n(u, \psi) \quad \text{for } 0 \leq u \leq u_0 \quad (42a)$$

$$= \begin{cases} u/u_0 & \text{for } 0 \leq u \leq u_0 \\ (u^2 + b^2 - 2ub \cos \phi)^{1/2}/u_0 & \text{for } u_0 < u \leq 1, \end{cases} \quad (42b)$$

where ν_0 is the maximum frequency of lattice wave, $u = q/2k = \sin(\phi/2)$, $u_0 = q_0/2k$, $b = g_1/2k$, $\mathbf{g}_1$ being a reciprocal lattice vector (see Fig. 1), and ϕ and ψ are the angles shown in Fig. 1. For the U-processes ($u_0 < u \leq 1$), $\langle 1/\nu_p^2 \rangle$ means the averaged value of $1/\nu_p^2$ with the orientation of $\mathbf{q}$ relative to the reciprocal lattice:

$$\langle 1/\nu_p^2 \rangle = \int_0^{\psi_0} \frac{1}{\nu_p^2} \sin \psi \, d\psi / \int_0^{\psi_0} \sin \psi \, d\psi.$$

The interaction parameter $C^2(\mathbf{q})$ calculated by Bardeen is written in the form,

$$C^2(\mathbf{q}) = \xi^2 G^2(\bar{u}), \quad (43)$$

Fig. 1. Geometry of the scattering process. (See Ziman's paper⁹.)

where $\bar{u} = q/2k_0 = 2^{-2/3}$, and the function $G^2(\bar{u})$ is identical with $G^2(u)$ given in (27) of Ziman's paper if we replace u by $\bar{u}$. (For the calculation of the electrical and thermal conductivities only, it is not necessary to discriminate u and $\bar{u}$.) Eq. (41) is evaluated in the same manner as Ziman's, and becomes

$$\frac{1}{\tau(\bar{k})} = \frac{1}{\tau_0} k^{-2} \left(\frac{dE}{dk} \right)^{-1} \left(\frac{T}{\Theta} \right)^5 \times \int_0^{\Theta/T} \left\{ G^2 \left(\frac{T}{\Theta} \bar{u}_0 x \right) + \Gamma^2 \left(\frac{T}{\Theta} u_0 x \right) \right\} x^3 dx, \quad (44)$$

where $\bar{u}_0 = q_0/2k_0$,

$$\frac{1}{\tau_0} \equiv \frac{4\xi^2 q_0^6}{8\pi^2 M \nu_0}, \quad (45)$$

and

$$\Gamma^2(y) \equiv \frac{6}{y^4 b} \int_{y-y}^1 u^4 G^2 \left(\frac{k}{k_0} u \right) du. \quad (46)$$

Ziman's expression for the electrical resistivity at high temperatures is easily obtained from (44) by putting $k = k_0$ ($u = u_0$).

For the calculations of the thermoelectric power, Ettingshausen and Ettingshausen-Nernst coefficients, we have to obtain the values of $\{(1/\tau)(d\tau/dE)\}_{E=\zeta}$ which is easily calculated from (44) as follows:

$$\left(\frac{1}{\tau} \frac{d\tau}{dE} \right)_{E=\zeta} = \frac{2}{\alpha k_0} + \frac{\beta}{\alpha^2} - \frac{\lambda}{\alpha k_0}, \quad (47)$$

$$\lambda = \frac{6G^2(1)\bar{b}^{-1} \log \bar{u}_0/(\bar{b}-1)}{\int_0^{\bar{u}_0} \{G^2(y) + \Gamma^2(y)\} y^3 dy}, \quad (48)$$

where $\bar{b} = g_1/2k_0 (=1.138$ for b.c.c. structures). Ziman calculated the numerical values of $G^2(y)$ and $\Gamma^2(y)$ for sodium and showed in Figs. 2 and 5 of his paper. We have graphically evaluated the integral in the denominator of (48) from Ziman's Fig. 5, and have recalculated $G(1)$ in the numerator (since it is difficult to read $G(1)$ from Ziman's Fig. 2). Thus we have obtained the numerical value of λ for sodium,

$$\lambda = 1.8. \quad (49)$$

Bardeen used the quasi-free electron approximation in his calculation of $C(\mathbf{q})$, so that the numerical value of λ given in (49) is not very accurate. Since it is not easy to evaluate the numerical values of λ for all monovalent metals with sufficient accuracy, hereafter we regard λ as a parameter. Considering the value given in (49), we may assume that the numerical values of λ are generally positive and order of magnitude of unity.

§ 4. Thermoelectric Power

The relaxation time τ in the case when both thermal and impurity scatterings exist is given by

$$\frac{1}{\tau} = \frac{1}{\tau_i} + \frac{1}{\tau_0} \quad (50)$$

where τ_0 is the relaxation time due to the lattice scattering obtained in the preceding section (Eq. (44)), and τ_i is that due to the impurity scattering and, from (10), τ_i is given by

$$\frac{1}{\tau_i} = \frac{N_i P}{h} k^{-2} \left(\frac{dE}{dk} \right)^{-1} \{1 + r_1(E - \zeta) + \dots\}. \quad (51)$$

The thermoelectric power at high temperatures is easily obtained from Mott's formula¹¹⁾ as

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \frac{\left\{ \frac{d}{dE} \left(k^2 \frac{dE}{dk} \tau \right) \right\}_{E=\zeta}}{k_0^2 \alpha \tau} = -\frac{\pi^2 \kappa^2 T}{3e} \left(\frac{2}{\alpha k_0} + \frac{\beta}{\alpha^2} + \frac{1}{\tau} \frac{d\tau}{dE} \right). \quad (52)$$

Eq. (52) was also derived by Klemens⁴⁾. From (51) we have

$$\left(\frac{1}{\tau_i} \frac{d\tau_i}{dE} \right)_{E=\zeta} = \frac{2}{\alpha k_0} + \frac{\beta}{\alpha^2} - r_1. \quad (53)$$

Inserting (50) with (47) and (53) into (52), we have

$$S = -\frac{\pi^2 \kappa^2 T}{3e} \frac{\rho_i \left(\frac{4}{\alpha k_0} + \frac{2\beta}{\alpha^2} - r_1 \right) + \rho_0 \left(\frac{4}{\alpha k_0} + \frac{2\beta}{\alpha^2} - \frac{\lambda}{\alpha k_0} \right)}{\rho_i + \rho_0}. \quad (54)$$

If we put $\lambda=0$, (54) reduces to high temperature approximation of (35). Now we will discuss two special cases.

4.1. Pure Metals

From (54) with $\rho_i=0$, we get the thermoelectric power for the pure metals as

$$S_0 = -\frac{\pi^2 \kappa^2 T}{3e} \left(\frac{4-\lambda}{\alpha k_0} + \frac{2\beta}{\alpha^2} \right) \quad (55a)$$

or

$$= -0.0244 T \left(\frac{4-\lambda}{\alpha k_0} + \frac{2\beta}{\alpha^2} \right), \quad (55b)$$

in which S_0 is in $\mu\text{V}/\text{deg.}$ and αk_0 and α^2/β are in electron-volts. About the sign of the thermoelectric powers, from (55), we have

$$S_0 < 0 \quad \text{if} \quad \beta + \frac{\alpha}{k_0} (2-\lambda) > 0, \quad (56a)$$

and

$$S_0 > 0 \quad \text{if} \quad \beta + \frac{\alpha}{k_0} (2-\lambda) < 0. \quad (56b)$$

The condition (56b) for the occurrence of positive thermoelectric power is less stringent than the condition (39b) where the U-processes are neglected.

In (55) the value of αk_0 can be obtained from the data of electronic specific heat. The electronic specific heat C_e per mole of a metal is given by¹⁸⁾

$$C_e = rT = \frac{V}{3} \kappa^2 k_0^2 \alpha^{-1} T, \quad (57)$$

where V is the molar volume. From (57) we easily obtain

$$\alpha k_0 = \pi^2 N_0 \kappa^2 / r,$$

where N_0 is the Avogadro number. Inserting

the numerical values for the constants, we have

$$\alpha k_0 = 1.69 \times 10^{-3} / r, \quad (58)$$

in which αk_0 is in electron-volts and r in cal/mole-deg². But, since (55) includes further two unknown parameters β and λ , we can not determine these parameters from the experiments on the thermoelectric powers only.

If we neglect, tentatively, the U-processes ($\lambda=0$), the value of β/α^2 and β are obtained from (55). Table I shows the results these obtained for noble metals from the measurements of Otters¹⁹⁾ on the thermoelectric power and those of Corak et al.²⁰⁾ on the electronic specific heats. If the U-processes were taken into account, the values of β/α^2 should become larger than those given in Table I. (Absolute values of β/α^2 should become smaller.)

For alkali metals, since the electronic speci-

Table I.

Metals	S_0 at 400°C.	$S_0/0.0244T$	αk_0	β/α^2

fic heats have never been measured except for sodium, we make a crude approximation that αk_0 in (55) may be replaced by $2\zeta \simeq \hbar k_0^2 / m^*$. Using the experimental values²¹⁾ of S_0 at 0°C and the calculated values²²⁾ of m^* , we can obtain a rough estimation of the values of β/α^2 . The results are shown in Table II.

For sodium, if we use the electronic specific heats $rT = 4.3 \times 10^{-4} T$ cal/mole-deg.²³⁾, we ob-

tain $\alpha k_0 = 3.9 \text{ eV}$ and $\beta/\alpha^2 = -0.11 (\text{eV})^{-1}$. It has been believed that the band structures of sodium and potassium are very well approximated by the free electron model. However, a recent calculation on the electronic energy states of potassium²⁴⁾ shows that there are considerable deviations from the free electron model, and therefore it is not surprising that sodium might have a very small or even a negative value of β .*

4.2. Effect of Impurity

Eq. (54) holds for any concentration of impurity atom. But when the valency of impurity atoms differs from unity and the concentration is large, the total number of the conduction electrons changes and so the Fermi level shifts. Therefore the change of the values of α and β must be taken into account. Here we consider only the initial change of the thermoelectric power when the concentration of impurity atoms is small. In this case, the change of the thermoelectric powers is mostly due to the impurity scattering of electrons and the change of the values of α and β may be neglected.

Let p be the fraction of the impurity atoms in a metal. We define the initial increase of the resistivity by

$$\xi_i = \left(\frac{\partial \rho_i}{\partial p} \right)_{p=0},$$

and then from (54) the initial increase of the thermoelectric power by the impurities is obtained as follows,

$$\left(\frac{\partial S}{\partial p} \right)_{p=0} = \xi_i \frac{\pi^2 \kappa^2 T}{3e} \frac{r_1 - \lambda/\alpha k_0}{\rho_0}. \quad (59)$$

Therefore we have

$$\left(\frac{\partial S}{\partial p} \right)_{p=0} > 0, \quad \text{if } r_1 > -\lambda/\alpha k_0 \quad (60a)$$

$$\left(\frac{\partial S}{\partial p} \right)_{p=0} < 0, \quad \text{if } r_1 < -\lambda/\alpha k_0. \quad (60b)$$

The experiments on noble metals show that generally (60b) seems to hold, but in the cases of Mn as the impurity in noble metals and possibly Ti and Cr in Cu, the relation (60a) seems to hold²⁵⁾.

Domenicali and Otter²⁵⁾ calculated the initial increases of the thermoelectric powers of impure metals by using the quasi-free electron model. They expanded the scattering cross section Q in the form

$$Q = Q_0(1 + \alpha_1 \kappa T \eta + \dots). \quad (61)$$

Comparing (61) with (7), we have

$$\alpha_1 = -\frac{2}{\alpha k_0} - \frac{2\beta}{\alpha^2} + r_1. \quad (62)$$

Domenicali and Otter's results (their Eq. (22)) may be written in our notations in the form

$$\left(\frac{\partial S}{\partial p} \right)_{p=0} = \frac{\xi_i}{\rho_0} \left\{ \frac{\pi^2 \kappa^2 T}{3e} \left(\frac{1}{2\zeta} + \alpha_1 \right) - S_0 \right\}. \quad (63)$$

Eq. (59) may also be rewritten in the corresponding form

$$\begin{aligned} \left(\frac{\partial S}{\partial p} \right)_{p=0} &= \frac{\xi_i}{\rho_0} \left\{ \frac{\pi^2 \kappa^2 T}{3e} \left(r_1 - \frac{4}{\alpha k_0} - \frac{2\beta}{\alpha^2} \right) - S_0 \right\} \\ &= \frac{\xi_i}{\rho_0} \left\{ \frac{\pi^2 \kappa^2 T}{3e} \left(\alpha_1 - \frac{2}{\alpha k_0} \right) - S_0 \right\}, \end{aligned} \quad (64)$$

and in the case of quasi-free electrons, (64) reduces to

$$\left(\frac{\partial S}{\partial p} \right)_{p=0} = \frac{\xi_i}{\rho_0} \left\{ \frac{\pi^2 \kappa^2 T}{3e} \left(\alpha_1 - \frac{1}{\zeta} \right) - S_0 \right\}. \quad (65)$$

Eq. (63) does not agree with (65). This is due to the fact that Domenicali and Otter assumed erroneously the number of electrons n_0 to be independent of energy E in their Eq. (3). Using (63), Otter¹⁹⁾ analysed his experimental results on the thermoelectric power and electrical resistivity of dilute alloys of Mn, Pd and Pt in Cu, Ag and Au, and obtained the values of α_1 . Since (63) is not correct, we have recalculated α_1 from (64). If we compare (64) with Eq. (2) of Otter's paper, it is seen that $\alpha_1 - \alpha_0$ of Otter's must be replaced by $\alpha_1 - 2/\alpha k_0 - 3e S_0/\pi^2 \kappa^2 T$. Therefore if we use the values of αk_0 determined from the electronic specific heats and the observed values of S_0/T , we can obtain the correct values of α_1 from the values of α_1 and α_0 given in Table I and Fig. 7 of Otter's paper. Table III (except for the last two rows) shows the results thus obtained.

* Recently L. M. Roberts (Proc. Phys. Soc. B **70** (1957), 744) has measured the electronic specific heats of Li and Na. If we use his values of γ , the values of αk_0 in Table II become 4.06 and 5.15 for Li and Na respectively, and the values of β/α^2 become -1.24 and 0.01 for Li and Na respectively.

Domenicali and Otter²⁵⁾ analysed the thermoelectric powers of Cu-Si alloy and Cu-Zn alloy by using their Eq. (17). Using their values of α_1 and α_0 , we can also obtain the correct values of α_1 . The results are shown on the last two rows of Table III.

If we use Barrie's calculation (6), the theoretical value of α_1 is given by (62), and here γ_1 is easily calculated from (6) as

$$\gamma_1 = \frac{\mu}{\alpha k_0},$$

where

$$\mu = \frac{32k_0^4 r_0^4}{(1 + 4k_0^2 r_0^2)^2 \ln(1 + 4k_0^2 r_0^2) - 4k_0^2 r_0^2 (1 + 4k_0^2 r_0^2)},$$

and the value of μ changes from 4 to 0 when $k_0 r_0$ changes from 0 to infinity. Therefore the values of γ_1 of noble metals should be in the range between 0.4 and 0 (eV)⁻¹ and, if we use the rough estimation of β/α^2 given in Table I, the values of α_1 should be in the range between 0.8 and 0.4 (eV)⁻¹ showing a large discrepancy from the values given in Table III. This discrepancy would show that the Born approximation used by Barrie was not good.

§ 5. Transverse Galvanomagnetic and Thermomagnetic Effects

In our model, the negative value of β does not mean the "hole-conduction." The positive hole model gives the positive Hall coefficients, but our model gives the negative Hall coefficients showing the character of "electronic-conduction" irrespectively of the sign of β .

Both the usual free electron and the positive hole models give the positive Ettingshausen and Ettingshausen-Nernst coefficients at high temperatures, but actually these coefficients of noble metals are negative. Our model can give an interpretation of the negative coefficients of noble metals.

The transverse galvanomagnetic and thermomagnetic effects have been calculated by Sondheimer²⁶⁾ for the two band model composed of the usual free electron band and the inverted band of positive hole. Here we will calculate these effects for the general spherical band model. Since the spherical band model is not good approximation in the case of low temperatures, we consider only the case of high temperatures in which the time of relaxation τ exists.

We consider a metal strip with its surface in the xy -plane, carrying an electric current J_x or a thermal current w_x in the x -direction and subjected to a magnetic field H in the z -direction. The Boltzmann equation is

$$-\frac{e}{\hbar} \left(\mathbf{F} + \frac{1}{c} \mathbf{v} \times \mathbf{H} \right) \cdot \text{grad}_k f + \mathbf{v} \cdot \text{grad}_r f = -\frac{f - f_0}{\tau}, \quad (66)$$

where $\mathbf{F}$ is the electric field, $\mathbf{v}$ the velocity of electron and c the velocity of light. In (66) F is in electrostatic unit and H is in electromagnetic unit. If we put

$$f = f_0 - \mathbf{k} \cdot \mathbf{c}(E) \frac{\partial f_0}{\partial E}, \quad (67)$$

(66) gives²⁷⁾

$$\frac{\hbar k}{\tau dE/dk} \mathbf{c}(E) - \frac{e}{\hbar c} \mathbf{H} \times \mathbf{c}(E) = -e\mathbf{F} - T \operatorname{grad} \left(\frac{\xi}{T} \right) - \frac{E}{T} \operatorname{grad} T. \quad (68)$$

The x and y components of (68) are

$$\left. \begin{aligned} \frac{\hbar}{\tau} k \left(\frac{dE}{dc} \right)^{-1} c_1 + \frac{eH}{\hbar c} c_2 &= -eF_x - T \frac{\partial}{\partial x} \frac{\xi}{T} - \frac{E}{T} \frac{\partial T}{\partial x} \\ -\frac{eH}{\hbar c} c_1 + \frac{\hbar}{\tau} k \left(\frac{dE}{dk} \right)^{-1} c_2 &= -eF_y - T \frac{\partial}{\partial y} \frac{\xi}{T} - \frac{E}{T} \frac{\partial T}{\partial y} \end{aligned} \right\} \quad (69)$$

where c_1 and c_2 are x and y components of $\mathbf{c}$.

The electric and thermal current densities are given by

$$\left. \begin{aligned} J_x &= \frac{e}{3\pi^2 \hbar} \int k^3 c_1 \frac{\partial f_0}{\partial \eta} d\eta, \\ J_y &= \frac{e}{3\pi^2 \hbar} \int k^3 c_2 \frac{\partial f_0}{\partial \eta} d\eta, \\ w_x &= -\frac{1}{3\pi^2 \hbar} \int E k^3 c_1 \frac{\partial f_0}{\partial \eta} d\eta, \\ w_y &= -\frac{1}{3\pi^2 \hbar} \int E k^3 c_2 \frac{\partial f_0}{\partial \eta} d\eta. \end{aligned} \right\} \quad (70)$$

Now we consider only the case of weak field ($H \rightarrow 0$). After a straightforward calculation we find

$$\left. \begin{aligned} J_x &= K_{11} e \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) + K_{12} \frac{e}{T} \frac{\partial T}{\partial x} - K_{13} e \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) - K_{14} \frac{e}{T} \frac{\partial T}{\partial y}, \\ J_y &= K_{13} e \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) + K_{14} \frac{e}{T} \frac{\partial T}{\partial x} + K_{11} e \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) + K_{12} \frac{e}{T} \frac{\partial T}{\partial y}, \\ w_x &= -K_{21} \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) - K_{22} \frac{1}{T} \frac{\partial T}{\partial x} + K_{23} \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) + K_{24} \frac{1}{T} \frac{\partial T}{\partial y}, \\ w_y &= -K_{23} \left(eF_x + T \frac{\partial}{\partial x} \frac{\xi}{T} \right) - K_{24} \frac{1}{T} \frac{\partial T}{\partial x} - K_{21} \left(eF_y + T \frac{\partial}{\partial y} \frac{\xi}{T} \right) - K_{22} \frac{1}{T} \frac{\partial T}{\partial y}, \end{aligned} \right\} \quad (71)$$

where

$$\left. \begin{aligned} K_{11} &= -\frac{1}{3\pi^2 \hbar^2} \int k^2 \frac{dE}{dk} \frac{1}{\tau} \frac{\partial f_0}{\partial \eta} d\eta, \\ K_{12} &= -\frac{1}{3\pi^2 \hbar^2} \int E k^2 \frac{dE}{dk} \frac{1}{\tau} \frac{\partial f_0}{\partial \eta} d\eta = K_{21}, \\ K_{22} &= -\frac{1}{3\pi^2 \hbar^2} \int E^2 k^2 \frac{dE}{dk} \frac{1}{\tau} \frac{\partial f_0}{\partial \eta} d\eta, \\ K_{13} &= -\frac{eH}{3\pi^2 \hbar^4 c} \int k \left(\frac{dE}{dk} \right)^2 \tau^2 dE, \\ K_{14} &= -\frac{eH}{3\pi^2 \hbar^4 c} \int E k \left(\frac{dE}{dk} \right)^2 \tau^2 dE = K_{23}, \\ K_{24} &= -\frac{eH}{3\pi^2 \hbar^4 c} \int E^2 k \left(\frac{dE}{dk} \right)^2 \tau^2 dE. \end{aligned} \right\} \quad (72)$$

From (72), it is seen that K_{mn} 's satisfy Onsager's reciprocal relations.

Putting $\operatorname{grad} T = 0$ and $J_y = 0$ in (71), we find the Hall coefficient R as follows:

$$R = \frac{F_y}{H J_x} = -\frac{K_{13}}{e^2 H K_{11}^2} = -\frac{3\pi^2}{e c k_0^3} = -\frac{1}{n e c}. \quad (73)$$

Eq. (73) shows that the Hall coefficient is al-

ways negative in our model.

Putting $J_y=0$, $w_y=0$, $\partial T/\partial x=0$, we find the Ettingshausen coefficient A_E :

$$A_E = -\frac{\partial T/\partial y}{H J_x} = \frac{T(K_{11}K_{14} - K_{12}K_{13})}{eHK_{11}(K_{11}K_{22} - K_{12}^2)}. \quad (74)$$

Putting (72) into (74), we have

$$A_E = \frac{T}{nc} \left(-\frac{1}{\alpha k_0} + \frac{\beta}{\alpha^2} + \frac{1}{\tau} \frac{d\tau}{dE} \right). \quad (75)$$

Putting $J_x = J_y = \partial T/\partial y = 0$ in (71), we find the isothermal Ettingshausen-Nernst coefficient B_{EN}^i :

$$B_{EN}^i = -\frac{F_y}{H \partial T/\partial x} = \frac{1}{HeT} \frac{K_{11}K_{14} - K_{12}K_{13}}{K_{11}^2}, \quad (76)$$

and putting (72) into (76), we have

$$B_{EN}^i = \frac{\pi^2 \kappa^2 T \alpha \tau}{3c \hbar^2 k_0} \left(-\frac{1}{\alpha k_0} + \frac{\beta}{\alpha^2} + \frac{1}{\tau} \frac{d\tau}{dE} \right). \quad (77)$$

Putting $J_x = J_y = w_x = 0$, we find the Righi-Leduc coefficient B_{RL} :

$$B_{RL} = \frac{\partial T/\partial y}{H \partial T/\partial x} = \frac{K_{11}^2 K_{24} + K_{12}^2 K_{13} - 2K_{11}K_{12}K_{14}}{HK_{11}(K_{12}^2 - K_{11}K_{22})}, \quad (78)$$

and putting (72) into (78), we have

$$B_{RL} = -\frac{e \alpha \tau}{\hbar c k_0}. \quad (79)$$

The electrical and thermal conductivities are given by

$$\sigma = e^2 K_{11} = \frac{e^2}{3\pi^2 \hbar^2} k_0^2 \alpha \tau, \quad (80)$$

$$\kappa_T = \frac{K_{11}K_{22} - K_{12}^2}{TK_{11}}, \quad (81)$$

$$= \frac{\kappa^2 T}{9\hbar^2} k_0^2 \alpha \tau. \quad (82)$$

From (74), (76) and (81), we have

$$A_{EN}^i \equiv \frac{B_{EN}^i}{\kappa_T} = \frac{A_E}{T}. \quad (83)$$

Using the second law of thermodynamics, Bridgman derived²⁸⁾ (83), and Callen²⁹⁾ derived (83) from Onsagers's reciprocal relations.

From (73), (78), (80) and (82) we have

$$R\sigma = B_{RL}, \quad (84)$$

and

$$\frac{RB_{EN}^i}{A_E B_{RL}} = \frac{\pi^2}{3} \left(\frac{\kappa}{e} \right)^2. \quad (95)$$

These relations were also derived by Bridgman by a phenomenological consideration²⁸⁾, and by Sondheimer²⁶⁾ for the free electron

model. It is known that the relations (83), (84) and (85) generally hold for many metals including noble metals²⁸⁾.

Now, from (52) and (75) we can eliminate both unknown parameters β and λ , and we have

$$\frac{1}{T} \left(nc A_E + \frac{3e}{\pi^2 \kappa^2} S \right) = -\frac{3}{\alpha k_0}. \quad (86)$$

5.1. Pure Metals

Putting (47) into (75) and (77), we have

$$A_E = \frac{T}{nc} \left(\frac{1-\lambda}{\alpha k_0} + \frac{2\beta}{\alpha^2} \right), \quad (87)$$

$$B_{EN}^i = \frac{\pi^2 \kappa^2 T}{3c \hbar^2} \left(\frac{1-\lambda}{\alpha k_0} + \frac{2\beta}{\alpha^2} \right) \frac{\tau}{\alpha k_0^2}. \quad (88)$$

Therefore

$$A_E > 0, B_{EN}^i > 0 \quad \text{if} \quad \beta + \frac{\alpha}{2k_0} (1-\lambda) > 0 \quad (89a)$$

and

$$A_E < 0, B_{EN}^i < 0 \quad \text{if} \quad \beta + \frac{\alpha}{2k_0} (1-\lambda) < 0. \quad (89b)$$

Both free electron and positive hole models give negative values of A_E and B_{EN}^i . However, noble metals and many other metals have negative Ettingshausen and Ettingshausen-Nernst coefficients. No model has yet been worked out for which A_E and B_{EN}^i are negative at high temperatures. Now from our simple model, A_E and B_{EN}^i are negative if the condition (89b) holds.

The condition (89b) is less stringent than the condition (56b), so that A_E and B_{EN}^i are negative for the metals which have positive thermoelectric powers. Noble metals are in this case. For alkali metals (except for Li), A_E and B_{EN}^i have not yet been measured. But from the values of S_0/T and αk_0 shown in Table II and Eq. (86), we see that Li and Cs may have negative values of A_E and B_{EN}^i at room temperatures. The measurement on Li³⁰⁾ shows, however, the positive B_{EN}^i and make an unfortunate exception.

Now we will compare (86) with the experiments for pure noble metals. Our theory is applicable for the case of high temperatures ($T \gg \Theta$), but the available experimental data for A_E are only the measurements on noble metals in room temperature region ($T \simeq \Theta$). Therefore we are compelled to use the room

temperature data of A_B and the high temperature data of S_0 , and then we have the results shown Table IV.

Considering that the data of A_B are those at room temperatures, we may conclude that the agreement of the theory with the experiments is fairly good. Owing to a curious exception that A_B/T of Au is not constant with temperatures³²⁾, we have omitted Au from Table IV.

In Table V, we summarized the qualitative results on the sign of the thermoelectric powers and the coefficients of the transverse galvanomagnetic and thermomagnetic effects.

5.2. Effect of Impurity

Putting (50) with (47) and (51) into (75) and (87), we have the expressions of the Ettingshausen and Ettingshausen-Nernst coefficients for case of any impurity concentration. From these expressions, we easily obtain the initial increases as follows,

$$\left(\frac{\partial A_B}{\partial p}\right)_{p=0} = -\frac{\xi_i T}{nc\rho_0} \left(\frac{4-\lambda}{\alpha k_0} + r_1\right), \tag{90}$$

$$\left(\frac{\partial B_{BN}^i}{\partial p}\right)_{p=0} = \xi_i \frac{\pi^2 \kappa^2 T}{3e^2 cn\rho_0^2} \left(\frac{2\lambda-1}{\alpha k_0} - \frac{2\beta}{\alpha^2} - r_1\right). \tag{91}$$

Using (59) and (55a), we can eliminate the parameters λ and β from (90) and (91), and thus we find

$$\frac{3e}{\pi^2 \kappa^2} \left(\frac{\partial S}{\partial p}\right)_{p=0} + nc \left(\frac{\partial A_B}{\partial p}\right)_{p=0} = 0, \tag{92}$$

$$\frac{3e}{\pi^2 \kappa^2 T} \left[-S_0 + \frac{\rho_0}{\xi_i} \left\{ \left(\frac{\partial S}{\partial p}\right)_{p=0} + ecn\rho_0 \left(\frac{\partial B_{BN}^i}{\partial p}\right)_{p=0} \right\} \right] = \frac{3}{\alpha k_0}. \tag{93}$$

From (90), (91) and (87), we have also

$$\frac{A_B}{T} + \frac{\rho_0}{T\xi_i} \left[\frac{3e^2\rho_0}{\pi^2 \kappa^2} \left(\frac{\partial B_{BN}^i}{\partial p}\right)_{p=0} - \left(\frac{\partial A_B}{\partial p}\right)_{p=0} \right] = 0. \tag{94}$$

Since (92), (93) and (94) do not include the parameters β , λ and r_1 , these equations are suitable to test the agreement of the theory with experiments. In many cases $\partial S/\partial p$ is negative, so that we see from (92) that the Ettingshausen coefficients should increase by a small content of impurity atoms. It is unfortunate that the measurements on the effects of impurities on the Ettingshausen and Ettingshausen-Nernst coefficients of noble metals have never been worked out.

Acknowledgement

The author wishes to express his hearty thanks to Prof. T. Okada and Prof. T. Nakamura for their valuable discussions. This study was financed by the Scientific Research Fund of the Ministry of Education.

Appendix

Influence of Exchange and Correlation on Electron Transport in Metals*
Bohm and Pines have developed a new

* In the short note reported previously³³⁾, Eqs. (4) and (7) were invalid, so that we correct the errors in this appendix.

method for treating exchange and correlation effects in an electron gas. By their collective description of electron interaction, one electron energy in a metal is given by³⁴⁾

$$E(\mathbf{k}) = \frac{3.68}{r_s^2} \left(\frac{k}{k_0} \right)^2 \frac{m}{m^*} - \frac{0.611}{r_s} \left[1 - 2\beta + \frac{\beta^2 k_0^2 - k_0^2 + 3k^2}{2kk_0} + \frac{k_0^2 - k^2}{k_0 k} \ln \left(\frac{k_0 + k}{\beta k_0} \right) \right], \quad (\text{A-1})$$

where E is in rydbergs, r_s is the average interelectronic distance in units of Bohr radius, and β is a measure of the screening of the Coulomb interaction ($\beta = 0.353 r_s^{1/2}$). In the course deriving (A-1), it was assumed that, in the Hartree approximation, the one electron energy is given by that of quasi-free electron:

$$E_0(\mathbf{k}) = \frac{3.68}{r_s^2} \frac{m}{m^*} \left(\frac{k}{k_0} \right)^2. \quad (\text{A-2})$$

Blatt³⁵⁾ calculated the change produced in the conductivity and thermoelectric power of metals when one uses Bohm and Pines' $E-k$ curve (A-1) instead of the usual standard curve (A-2). Since there were errors in Blatt's paper, Barrie¹⁰⁾ has corrected these errors and has found that the conductivity changes markedly. But there are also errors in his paper. In this appendix, we correct these errors by using the results obtained in the text.

If we assume the validity of the use of Bohm and Pines' curve (A-1) in the transport equation (14), we have, from (29), (32), (36) and (37),

$$\frac{\sigma}{\sigma_0} = \frac{\kappa}{\kappa_0} = \left(\frac{X_1}{2A} \right)^2, \quad (\text{A-3})$$

$$\frac{S}{S_0} = \begin{cases} \frac{2A(2X_1 + X_2)}{3X_1^2} & \text{at } T \gg \Theta, \\ \frac{2A}{X_1} & \text{at } T \ll \Theta, \end{cases} \quad (\text{A-4})$$

$$\frac{S}{S_0} = \begin{cases} \frac{2A}{X_1} & \text{at } T \ll \Theta, \end{cases} \quad (\text{A-5})$$

where σ , κ and S are electric- and thermal conductivities and thermoelectric power for the modified band (A-1) and σ_0 , κ_0 and S_0 are those for free-electron band (A-2), and

$$A = \frac{3.68}{r_s^2} \frac{m}{m^*},$$

$$X_1 = \left(k \frac{dE}{dk} \right)_{E=\zeta} = 2A + B \left[\frac{1}{2}\beta^2 - 2 + 2 \ln(2/\beta) \right],$$

$$X_2 = \left(k^2 \frac{d^2 E}{dk^2} \right)_{E=\zeta} = 2A + B [3 - \beta^2 - 2 \ln(2/\beta)],$$

$$B = \frac{0.611}{r_s}.$$

The numerical results are shown in Table A-I.

Table A-I.

	Li	Na	K	Rb	Cs
σ/σ_0	1.43	1.23	1.14	1.12	1.08
$S/S_0(T \gg \Theta)$	0.82	0.91	0.97	0.99	1.02
$S/S_0(T \ll \Theta)$	0.84	0.90	0.94	0.95	0.97

If the U-processes are taken into account, the values of S/S_0 shown in Table A-I will be slightly modified.

The values of σ/σ_0 are smaller than those obtained by Barrie. For thermoelectric powers, the influence of exchange and correlation is rather small compared to the effect of the departure of one electron Hartree energy level from that of quasi-free electrons.

Thomas-Fermi Function for Impurity Atom Dissolved in a Matrix Metal

By Kwai UMEDA

Department of Physics, Okayama University, Okayama

and Shigehiro KOBAYASHI

Department of Physics, Kagawa University, Takamatsu

(Received October 26, 1957)

The scale transformation keeping invariant the TF equation for an impurity atom dissolved with infinite dilution in a matrix metal of very large size was established. It enabled us to reduce the double sequence of solutions of the TF equation specified by two parameters to a single sequence of master solutions specified by one parameter only. Starting from the asymptotic expansion of solution derived here anew the inward numerical integration of the TF equation was carried out. The screened Coulomb potential was compared with our numerical solutions to measure its degree of approximation.

§ 1. Introduction

According to Fujiwara's⁴⁾ notation, the electrostatic potential $V(r)$ around a $Z_0 + Z$ -valent impurity atom dissolved with infinite dilution in a Z_0 -valent matrix metal of very large size can be expressed as

$$V(r) = (e/r)\phi(x) \quad (1)$$

by means of the Thomas-Fermi (TF) function $\phi(x)$, i.e. the solution of the modified TF equation

$$\frac{d^2\phi}{dx^2} = \phi'' = \frac{\phi^{3/2}}{x^{1/2}} - A^{3/2}x \quad (2)$$

subject to the initial and boundary condition

$$\phi(x=0) = Z \quad (3)$$

and

$$\phi(x \rightarrow \infty) \rightarrow Ax \quad (4)$$

respectively, where x is the distance from the impurity atom as origin measured in the standard (unit atomic number) TF unit $\mu_0 (= 0.88534 a_H)$

$$x = r/\mu_0 \quad (5)$$

and A is a constant depending on atomic valency Z_0 and atomic radius r_0 of solvent metal

$$A^{3/2} = \left(\frac{3\pi}{4}\right)^3 \left(\frac{Z_0}{2\pi}\right) \left(\frac{a_H}{r_0}\right)^3 \quad (6)$$

Accordingly $V(r)$ has the normalization $V(\infty) = eA/\mu_0$.

Then, $\phi(x)$ is specified by two parameters, Z and A as $\phi(x; Z, A)$. The special natures

of solute and solvent can be taken into account solely through parameters Z and A respectively. The solution of Eq. (2) was given first by Mott¹⁾ in the first order approximation (linearization of Eq. (2)) of the screened Coulomb form which was refined by Friedel²⁾ in the so-called second order approximation and by Sugiyama *et al*³⁾ with use of variational method, and then by Fujiwara⁴⁾ and Alfred-March⁵⁾ using the direct numerical integration which was carried out outwards as usual on starting in accordance with Eq. (3) from the point ($x=0$, $\phi=Z$) by series expansion having the initial slope adjustable to satisfy Eq. (4), as shown schematically in Fig. 1 and accurately in Fujiwara's Fig. 1. This numerical solution is very sensitive to the value of the initial slope and besides it is fairly difficult to discriminate numerically the asymptotic convergence required by Eq. (4). In addition, in order to obtain one correct

Fig. 1. Customary method: outward integration of the TF equation, Eq. (2).

solution we have to calculate a number of trial solutions in vain. This circumstance lets us try to solve Eq. (2) rather by the inward integration which was previously proved by us⁶⁾ to be efficient for the ordinary TF and TFD equation, as then all of calculated solutions can be significant ones.

§ 2. Derivation of Master Solutions

For definiteness we take as a master solvent the one for which A has a definite value C (e.g. in the present work $C=0.182044 \approx A_{Ag}$, $C^{3/2}=0.0776723$ since we took $\lambda=(3/2)^{1/2}C^{1/4}=0.8$ sharp to make the computation of the asymptotic expansion, Eq. (14), easy). Denoting ϕ and x by Φ and X respectively we con-

sider any master solution of the fundamental equation corresponding to Eq. (2)

$$\frac{d^2\Phi}{dX^2} \equiv \ddot{\Phi} = \frac{\Phi^{3/2}}{X^{1/2}} - C^{3/2}X \quad (7)$$

subject to the boundary condition

$$\Phi(X \rightarrow \infty) \rightarrow CX \quad (8)$$

only. Then $\Phi(X)$ will take on the other boundary $X=0$ its proper definite value, i.e. its initial value

$$\Phi(X=0) \equiv \Phi_0 \quad (9)$$

which represents the excess valency Z in this case and specifies the considered master solution.

To investigate the asymptotic behavior of $\Phi(X)$, we put conveniently $\Phi(X)$ for very large values of X in the form

$$\Phi(X) \equiv CX + Y(X) \quad (10)$$

$Y(X)$ vanishing asymptotically.

In the first order approximation, Eq. (7) is simplified to a linear homogeneous equation

$$\ddot{Y} = \lambda^2 Y \quad (11)$$

with

$$\lambda^2 \equiv (3/2)C^{1/2} \quad (12)$$

or

$$C^{3/2} = (8/27)\lambda^6. \quad (12a)$$

The form of the solution of Eq. (11)

$$Y = ae^{-\lambda X} \quad (13)$$

suggests us that, in the higher order approximation, $Y(X)$ should be expressed by a power series of $e^{-\lambda X}$ and followingly the exact asymptotic solution should take the form

$$\Phi = CX + \sum_{k=1}^{\infty} a_k(X) e^{-k\lambda X} \quad (14)$$

$$= \frac{4}{9} \lambda^4 X \left[1 + \sum_{k=1}^{\infty} \frac{9}{4} \frac{a_k(X)}{\lambda^4 X} e^{-k\lambda X} \right]. \quad (14a)$$

Inserting Eqs. (14a) and (12a) into Eq. (7) we obtain the recurrence formulas for the expansion coefficients $a_k(X)$ as follows.

i) In order of $e^{-\lambda X}$:

$$\ddot{a}_1 - 2\lambda \dot{a}_1 = 0, \quad (15)$$

$$\therefore a_1 = \text{const} \equiv a. \quad (16)$$

This reproduces obviously the solution in the first order approximation given above, Eq. (13), which results with $a = \Phi_0$ the Mott potential, Eq. (28).

ii) In order of $e^{-2\lambda X}$:

$$\ddot{a}_2 - 4\lambda \dot{a}_2 + 3\lambda^2 a_2 = \frac{9}{16} \frac{a^2}{\lambda^2 X}, \quad (17)$$

$$\therefore a_2 = \frac{3}{16} \frac{a^2}{\lambda^4 X} \left[1 - \frac{4}{3} \frac{1}{\lambda X} + \frac{26}{9} \frac{1}{(\lambda X)^2} - \frac{80}{9} \frac{1}{(\lambda X)^3} + \dots \right]. \quad (18)$$

iii) In order of $e^{-3\lambda X}$:

$$\ddot{a}_3 - 6\lambda \dot{a}_3 + 8\lambda^2 a_3 = \frac{9}{8} \frac{\dot{a}a^2}{\lambda^2 X} - \frac{27}{128} \frac{a^3}{\lambda^6 X^2}, \quad (19)$$

$$\therefore a_3 = -\frac{9}{256} \frac{a^3}{\lambda^8 X^2} \left[0 + \frac{1}{\lambda X} - \frac{53}{12} \frac{1}{(\lambda X)^2} + \frac{221}{12} \frac{1}{(\lambda X)^3} - \dots \right]. \quad (20)$$

It is peculiar that a_3 is not of $O(1/(\lambda^3 X^2))$ but of $O(1/(\lambda^9 X^3))$.

iv) In order of $e^{-4\lambda X}$:

$$\ddot{a}_4 - 8\lambda \dot{a}_4 + 15\lambda^2 a_4 = \frac{9}{16} \frac{a_2^2 + 2aa_3}{\lambda^2 X} - \frac{81}{128} \frac{a^2 a_2}{\lambda^6 X^2} + \frac{729}{4096} \frac{a^4}{\lambda^{10} X^3}, \quad (21)$$

$$\therefore a_4 = \frac{27}{5120} \frac{a^4}{\lambda^{12} X^3} \left[1 - \frac{23}{30} \frac{1}{\lambda X} + \dots \right]. \quad (22)$$

v) In order of $e^{-5\lambda X}$:

$$\begin{aligned} & a_5 - 10\lambda \dot{a}_5 + 24\lambda^2 a_5 \\ &= \frac{9}{8} \frac{aa_4 + a_2 a_3}{\lambda^2 X} - \frac{81}{128} \frac{aa_2^2 + a^2 a_2}{\lambda^6 X^2} + \frac{729}{1024} \frac{a^3 a_2}{\lambda^{10} X^3} - \frac{6561}{32768} \frac{a^5}{\lambda^{14} X^4}, \end{aligned} \quad (23)$$

$$\therefore a_5 = -\frac{567}{163840} \frac{a^5}{\lambda^{16} X^4} \left[1 - \dots \right]. \quad (24)$$

Thus, we see that a alone is the only parameter specifying any master solution $\Phi(X)$ in such a way that a definite value of a allows to evaluate the values of $\Phi(X)$ for several very large values of X and followingly it

Fig. 2. Present method: inward integration of the master TF equation, Eq. (7).

determines the entire curve of $\Phi(X)$ which will meet finally the Φ -axis at a finite point Φ_0 , Eq. (9), as shown in Fig. 2. The finite slope at this point $\dot{\Phi}_0$ makes possible to determine Φ_0 very accurately. In this way we have obtained for a sequence of values of a the corresponding sequence of master solutions

Fig. 3. Relations of Φ_0 and $A^{3/2}/Z^2$ versus a , cf. Eqs. (9), (27) and (16) respectively.

$\Phi(X)$ and particularly the corresponding sequence of values of Φ_0 and $\dot{\Phi}_0$ as columned in Table I. The basic relation of Φ_0 versus a is illustrated in Fig. 3. The full table of values of $\Phi(X)$ over the whole range of X will be published in the Memoirs of the Faculty of Liberal Arts & Education, Kagawa University, Japan.

Table I. Values of Φ_0 and $\dot{\Phi}_0$ of the master solutions specified by a and values of $A^{3/2}/Z^2$ for the cases (Z, A) reducible to the master solutions.

3.25	8.3153	-26.713	11233
3.50	9.4714	-31.787	0386584
3.75	10.7256	-37.528	67519
4.00	12.0852	-44.010	53181

$$\left. \begin{aligned} \phi &\rightarrow (1/c)\phi, \\ x &\rightarrow c^{1/3}x, \\ A^{3/2} &\rightarrow (1/c)^2 A^{3/2}, \\ Z &\rightarrow (1/c)Z. \end{aligned} \right\} \quad (25)$$

Based on this, the master solution $\Phi(X)$ specified by a value of a or by the corresponding value of Φ_0 deduced from the Φ_0 - a -relation (Table I and Fig. 3), i.e. the solution for the case $(Z=\Phi_0, A=C)$ can afford immediately the correct solution for the case (Z, A) satisfying Eqs. (2) to (4) by the following scale transformation with $c=\Phi_0/Z$

$$\left. \begin{aligned} (Z/\Phi_0)\Phi &= \phi, \\ (\Phi_0/Z)^{1/3}X &= x, \\ (Z/\Phi_0)^2 C^{3/2} &= A^{3/2}, \\ (Z/\Phi_0)\Phi_0 &= Z. \end{aligned} \right\} \quad (26)$$

Inversely, the correct solution $\phi(x; Z, A)$ for an arbitrary case (Z, A) can be derived in turn from the master solution $\Phi(X; \Phi_0, C)$ specified by the initial value

$$\Phi_0 = Z(C/A)^{3/4} = (Z^2/A^{3/2})^{1/2} C^{3/4} \quad (27)$$

or by the value of a associated to this value of Φ_0 due to the Φ_0 - a -relation (Table I and Fig. 3). The needed master solution should be obtained by interpolation. The dependence of ϕ on x is given by the first two equations of Eq. (26), the scale factor Φ_0/Z being conveniently replaced by $(C/A)^{3/4}$.

It should be noted that all cases with identical value of $A^{3/2}/Z^2$, i.e. ratio of parameter of the TF equation to squared excess valency of impurity atom, can be reduced to the same master solution specified by the definite value of Φ_0 (or equivalently a) given by Eq. (27). Thus, a double sequence with two parameters Z and A can be simplified to a single sequence with one parameter Φ_0 (or equivalently a) only.

The values of $A^{3/2}/Z^2$ for general case (Z, A) (i.e. the value of $A^{3/2}$ of matrix metal for $Z=1$) reducible to each of master solutions obtained above are given in Table I. The dependence of $A^{3/2}/Z^2$ (or $A^{3/2}(Z=1)$) on a is illustrated in Fig. 3.

The practical need for existing metallic elements ($A^{3/2}=0.01\sim 0.29$ and $Z=1\sim 4$) can be sufficiently covered by such ranges of the values of Φ_0 and a as given in Table I and Fig. 3 ($\Phi_0=0\sim 12$ and $a=0\sim 4$).

Fig. 4. Variation of the screening parameter $q(\Phi_0, C)(X)$ of the screened Coulomb potential fitted to the master solutions by Eq. (29a). The full lines are the curves Eq. (29a) and the broken line is the definition curve $q_{\text{eff}} \cdot r = 1$. The crossing points determine $q_{\text{eff}}(\Phi_0)$.

§ 3. Reduction of the TF Function for General Case to One of Master Solutions

Eqs. (2) to (4) are obviously invariant for the following scale transformation with a scale factor c

§ 4. Comparison of the Screened Coulomb Potential with the Master Solution

As Alfred-March⁵⁾ (their Fig. 1) as well as Fujiwara⁴⁾ (his Fig. 2) pointed out, the screened Coulomb potential (Mott¹⁾ potential) normalized to $V(\infty)=0$

$$V(r) = (Ze/r)e^{qr} \quad (28)$$

or correspondingly

$$\phi(x) = Ax + Ze^{-a\mu_0 x} \quad (28a)$$

cannot fit over whole range the exact solution. It is also clear from that $Y(X)$, Eqs. (10) and (14), cannot be represented by single exponential term. The degree of approximation of Eq. (28) would be measured by the dependence of the shielding parameter q on x defined by Eq. (28a), $\phi(x)$ being regarded as the exact solution obtained numerically. Then, inserting Eq. (26) into Eq. (28a) we can reduce the general case (Z, A) to the master case (Φ_0, C) as

$$q_{(Z,A)}(x) = q_{(\Phi_0,C)}(X) \cdot (A/C)^{1/4} \quad (29)$$

with

$$q_{(\Phi_0,C)}(X) = [\ln \Phi_0 - \ln(\Phi - CX)] / \mu_0 X. \quad (29a)$$

Therefore it is sufficient if we investigate the dependence of $q_{(\Phi_0,C)}$ on X as given in Fig. 4. With Eq. (13), $q_{(\Phi_0,C)}$ converges asymptotically as

$$q_{(\Phi_0,C)}(X \rightarrow \infty) \approx \frac{1}{\mu_0} \left(\lambda + \frac{\ln(\Phi_0/a)}{X} \right) \rightarrow \frac{\lambda}{\mu_0} \quad (30)$$

which establishes that $q_{(\Phi_0,C)}$ increases monotonically with excess valency Φ_0 because Φ_0/a increases monotonically with Φ_0 as seen from Fig. 3. From Fig. 4 the constant shielding parameter seems to be valid only in the range distant enough from the impurity atom.

Alfred-March⁵⁾ used rather the effective shielding parameter q_{eff} which corresponds to the crossing point of the curve Eq. (29a) given

above and the definition curve $q_{\text{eff}} \cdot r = 1$. It is noticeable that

$$q_{\text{eff}} > q(\infty) (= \lambda/\mu_0) \quad (31)$$

and q_{eff} increases with excess valency Φ_0 in accordance with the $q_{\text{eff}}-Z$ -curve for copper given in Alfred-March's Fig. 2. The values $q_{\text{eff}}(\Phi_0)$ determined from Fig. 4 were ascertained to lie just on their $q_{\text{eff}}-Z$ -curve for copper, $q_{\text{eff}}(\Phi_0)$ and Φ_0 being multiplied with $(A_{\text{Cu}}/C)^{1/4}$ and $(A_{\text{Cu}}/C)^{3/4}$ respectively. Conversely, their $q_{\text{eff}}-Z$ -curve for copper can be transformed into the one for matrix metal A , the ordinate $q_{\text{eff,Cu}}$ and the abscissa Z being multiplied in turn with $(A/A_{\text{Cu}})^{1/4}$ and $(A/A_{\text{Cu}})^{3/4}$ respectively.

Defects in Ionic Crystals

I. Improvement of the Method of Mott and Littleton and its Applications to Simple Defects

By Tatsumi KUROSAWA

The Institute for Solid State Physics, University of Tokyo

(Received October 30, 1957)

An improvement of the method of Mott and Littleton is proposed, and its applications to simple defects are treated. The formation energies of Schottky defects in LiF, NaCl, NaBr, KCl, KBr, RbBr and AgCl crystals, and that of a Frenkel defect in AgCl crystal are calculated. More complicated defects will be treated in forthcoming papers.

§ 1. Introduction

Hitherto, the calculations of the formation energy of defects in ionic crystals have been carried out by the method of Mott and Littleton¹⁾. Although this method is very ingenious, it is not such a formulation that considers the total energy of the lattice to be a function of the displacements and the electronic polarizations of ions. If such a formulation were developed, it might have two merits. (1) Since the total energy takes its minimum value when the displacements and the electronic polarizations of ions are in equilibrium, the calculated energy may be a good approximation even when the values of the displacements or the polarizations are not exact. This fact would prove of particular value in the case of complicated defects. (2) While the method of Mott and Littleton is applicable only when the lattice around defect is in equilibrium, such a limitation does not exist in the above mentioned formulation.

Such an attempt may have also practical importance, because knowledge about the interionic potentials and the dielectric properties of ionic crystals has been increased, and experimental data on the formation energy of defects have also accumulated, since the work of Mott and Littleton.

In this paper, we attempt to develop such a formulation, that is, to express the energy approximately as a function of displacements and electronic polarizations of the ions. Here we apply the method to evaluate the formation energy of simple defects. More complicated defects in equilibrium, and such cases as the lattice around a defect not being in

equilibrium, will be treated in forthcoming papers.

§ 2. The Improvement of the Method of Mott and Littleton

We try to express the energy as a function of the displacements and the electronic polarizations of ions around a defect. The exact description of the energy for an arbitrary configuration of ions is prohibitively complicated, so that we are obliged to introduce an approximate expression. For this purpose, we divide the crystal into two regions, i.e., (I) the region near the defect, and (II) the outer region. We write the displacements and the polarizations of the ions in the region (I) symbolically as $X_1, X_2, \dots, X_j, \dots$, and those in the region (II) as $x_1, x_2, \dots, x_\mu, \dots$. We frequently write them X and x for simplicity. We take as the origins of X and x the state in which the ions form an undeformed lattice and the electronic polarizations are zero.

When the defect is absent, the energy change due to the deformation of the lattice and the ions is formally

$$E(X, x) = A(X) + \sum_{\mu} f_{\mu}(X)x_{\mu} + \frac{1}{2} \sum_{\mu, \nu} a_{\mu\nu} x_{\mu} x_{\nu}, \quad (2.1)$$

where we assume that x_{μ} 's are all small and only the terms of the lowest order are retained. When the defect is present, the following terms must be added

$$\phi_0 + \sum_{\mu} \phi_{\mu} x_{\mu} + \Phi(X). \quad (2.2)$$

These terms represent the energy necessary to create a defect with the fixed configuration (X, x) . For instance, this is the negative of

the interaction energy between an ion which is to be removed from the lattice to infinity and its surrounding ions. The first two terms come from the region (II), and the last term from (I). If the forces between ions are the two-body type, ϕ_μ is independent of X ; we make this assumption. Now, the total energy is

$$W(X, x) = \frac{1}{2} \sum_{\mu, \nu} a_{\mu\nu} x_\mu x_\nu + \sum_{\mu} f_\mu(X) x_\mu + A(X) + \phi_0 + \sum_{\mu} \phi_\mu x_\mu + \mathcal{O}(X). \quad (2.3)$$

Since it is prohibitively difficult to compute the energy for an arbitrarily given value of X and x , we substitute for this expression the following approximation.

Let us consider the equilibrium state of the defect, which is given by the following Eqs.:

$$\left(\frac{\partial W}{\partial x_\mu} \right)_{X=X^0, x=x^0} = \sum_{\nu} a_{\mu\nu} x_\nu^0 + \phi_\mu + f_\mu(X^0) = 0 \quad (\text{for all } \mu), \quad (2.4)$$

and

$$\left(\frac{\partial W}{\partial X_j} \right)_{X=X^0, x=x^0} = 0 \quad (\text{for all } j). \quad (2.5)$$

If we put x^0 into Eq. (2.3), in virtue of Eq. (2.4), we have

$$W(X, x^0) = \phi_0 + \sum_{\mu} \left\{ f_\mu(X) - \frac{1}{2} f_\mu(X^0) + \frac{1}{2} \phi_\mu \right\} x_\mu^0 + A(X) + \mathcal{O}(X). \quad (2.6)$$

If we take the region (I) sufficiently large, x_μ^0 's may rapidly approach the values which are determined by the continuous model of Mott and Littleton. Practically we have to choose the region (I), such that the values determined by the continuous model are a comparatively good approximation of x^0 and the calculation of $f_\mu(X)$, $A(X)$ and $\mathcal{O}(X)$ of Eq. (2.6) for a given value of X is not too cumbersome. If we minimize $W(X, x^0)$ with respect to X , we obtain the energy of the defect in the equilibrium state, so far as x_μ^0 's are exactly given.

On the other hand, when the defect is complex and the values of X^0 and x^0 are known only approximately, we are obliged to substitute these approximate values $\bar{X}^0 = X^0 + \delta X$ and $\bar{x}^0 = x^0 + \delta x$ for X, X^0 and x^0 in Eq. (2.6). This procedure is equivalent to substituting $\bar{X}^0$ and $\bar{x}^0$ in the following expression:

$$\bar{W}(X, x) = \phi_0 + \frac{1}{2} \sum_{\mu} \{ \phi_\mu + f_\mu(X) \} x_\mu + A(X) + \mathcal{O}(X). \quad (2.7)$$

And the result of this substitution is:

$$\begin{aligned} \bar{W}(\bar{X}^0, x^0) &= W(X^0, x^0) + \frac{1}{2} \sum_{\mu} \{ f_\mu(X^0) + \phi_\mu \} \delta x_\mu \\ &\quad - \frac{1}{2} \sum_{\mu, j} \frac{\partial f_\mu(X^0)}{\partial X_j} x_\mu^0 \delta X_j \\ &\quad + (\text{the second order terms of } \delta x \text{ and } \delta X), \end{aligned} \quad (2.8)$$

where we used Eq. (2.5). The linear terms of δx and δX can be transformed into

$$\frac{1}{2} \sum_{\mu} \{ f_\mu(X^0) + \phi_\mu \} \left[\delta x_\mu - \sum_j \left\{ \frac{\partial x_\mu(X)}{\partial X_j} \right\}_{X=X^0} \delta X_j \right], \quad (2.9)$$

where $x_\mu(X)$ is given by

$$\sum_{\nu} a_{\mu\nu} x_\nu(X) + f_\mu(X) + \phi_\mu = 0, \quad (2.10)$$

that is, the equilibrium value of x_μ for an X . Compared with the present technique, the method of Mott and Littleton is nearly equivalent to using the following expression instead of $\bar{W}(X, x)$:

$$\begin{aligned} \bar{W}_{ML}(X, x) &= \phi_0 + \mathcal{O}(0) \\ &\quad + \frac{1}{2} \sum_{\mu} \phi_\mu x_\mu + \frac{1}{2} \{ \mathcal{O}(X) - \mathcal{O}(0) \}. \end{aligned} \quad (2.11)$$

And the result of the substitution, $\bar{X}^0$ for X and $\bar{x}^0$ for x , is

$$\begin{aligned} \bar{W}_{ML}(\bar{X}^0, \bar{x}^0) &\simeq W(X^0, x^0) \\ &\quad + \frac{1}{2} \sum_{\mu} \phi_\mu \delta x_\mu + \frac{1}{2} \sum_j \left(\frac{\partial \mathcal{O}}{\partial X_j} \right)_{X=X^0} \delta X_j \\ &\quad + (\text{the second order terms of } \delta x \text{ and } \delta X). \end{aligned} \quad (2.12)^*$$

The main error comes from the term $(\partial \mathcal{O} / \partial X) \delta X$, since both $\partial \mathcal{O} / \partial X$ and δX are large. On the other hand, we can expect that the coefficient of δX in the expression (2.9) may be much smaller than $\partial \mathcal{O} / \partial X$ comparing their physical meanings, especially when the region (I) is large. For this reason, we use $\bar{W}(X, x)$ for $\bar{W}_{ML}(X, x)$. In the case of the complicated defects for which the exact determination of X^0 is cumbersome, our method may be useful.

* As the simplest example, we calculate the energy of a point charge e located on a lattice point (000) of a fictitious crystal; simple cubic lattice, κ (dielectric constant) = 4 and the atoms being fixed at their equilibrium posi-

* Generally $\bar{W}_{ML}(X^0, x^0) \neq W(X^0, x^0)$ by the reason which is explained at the end of this chapter.

tions. This example was treated by Mott and Littleton in detail. We consider the six (100) ions as the region (I), and the others as (II). In this case x_{μ}^0 means the dipole moment of the μ th atom. According to Mott and Littleton, we take x_{μ}^0 as $(ea^3/4\pi r^2)(1-1/\kappa)$, where r is the distance of the μ th atom from the origin and a is the lattice constant. Then, $\sum_{\mu} \phi_{\mu} x_{\mu}^0$ is the potential at the origin created by these dipoles:

$$\frac{1}{2} \sum_{\mu} \phi_{\mu} x_{\mu}^0 = -\frac{1}{2} \sum_{r>(100)} \frac{a^4}{r^4} = -5,266, \tag{2.13}$$

where the unit of energy is $(e^2/4\pi a)(1-1/\kappa)$. $\Phi(0)$ and ϕ_0 are trivial and we neglect them. $\sum_{\mu} f_{\mu}(X) x_{\mu}^0$ is the interaction energy between the electric field at (100) created by the dipoles in the region (II) and the dipoles on the (100) atoms. The former is: $-(2.353e/4\pi a^2) \times (1-1/\kappa)$, and the latter is; $m=(ea/4\pi) \times (1-1/\kappa)X$. Thus we have:

$$\sum_{\mu} f_{\mu}(X) x_{\mu}^0 - \frac{1}{2} \sum_{\mu} f_{\mu}(X^0) x_{\mu}^0 = 0.843X - 0.421X^0. \tag{2.14}$$

Next, $A(X)$ is the sum of the polarization energy of the (100) atoms and the interaction energy between the dipoles on (100), that is, $6(m^2/2\alpha + 2.371m^2/2a^3)$, where α is the polarizability; or in the above unit it becomes:

$$A(X) = 1.500X^2 + 0.425X^2. \tag{2.15}$$

Finally, $\Phi(X) - \Phi(0)$ is the interaction energy between the extra point charge at (000) and the (100) dipoles

$$\Phi(X) - \Phi(0) = -6X. \tag{2.16}$$

Then, we have:

$$W(X, x^0) = 1.925X^2 - 5.157X - 5.266 - 0.421X^0. \tag{2.17}$$

If we determine X^0 from the condition

$$\left\{ \frac{\partial W(X, x^0)}{\partial X} \right\}_{X=X^0} = 3.850X^0 - 5.157 = 0, \tag{2.18}$$

we obtain

$$X^0 = 1.340.$$

Substituting this value into Eq. (2.17), we obtain

$$W(X^0, x^0) = -9.29.$$

This procedure gives exactly the same value as that of the Mott-Littleton's first approximation.

Next, if we regard X^0 as unity, which cor-

responds to the Mott-Littleton's 0th approximation, and substitute this into $\bar{W}(X, x^0)$, we have

$$\bar{W}(1, x^0) = -8.92.$$

The 0th approximation of Mott and Littleton gives, however, -8.27 , and the most exact value (the fourth approximation of their computation) is -9.25 . In Fig. 1, we show

Fig. 1. $\bar{W}(X, x^0)$ and $\bar{W}_{ML}(X, x^0)$.

$\bar{W}(X, x^0)$ (in the solid line) and $\bar{W}_{ML}(X, x^0) = -3X - 5.266$ (in the broken line), for the values of X near X^0 . Evidently our formulation gives much better values as compared with the energy form due to Mott and Littleton, when X^0 is not exact.

Moreover, if $A(X)$ has terms higher than X^2 , or $f_{\mu}(X)$ and $\Phi(X)$ have those higher than X , and in fact this is the real case, the method of Mott and Littleton is not very accurate, that is, such a simple procedure in which we

Table I. Comparison of the present method and the method of Mott and Littleton using the same repulsive energy and polarizabilities.

	Mott-Littleton	From Eq. (2.6)

regard the deformation energy of the surrounding medium as one half of the potential energy at the center due to the surrounding polarization, is rather crude. For instance, we recalculated the energy of the Schottky defect in NaCl by Eq. (2.6) with the same repulsive energy and polarizabilities as Mott and Littleton had used. The results are given in Table I. The differences come from the above mentioned reason, but are rather small in this simple example.

§3. The Formation Energy of a Schottky Defect

The interionic potentials, the polarizabilities and the short range effects of the electronic polarizations are given in the Appendix. We take the six (100) ions as the region (I), and write the displacements of these ions $a\xi$ and the electronic polarizations $ea\eta$. Each term of Eq. (2.6) for NaCl type crystal with lattice constant a is as follows

$$A(X) = 3\left(\frac{1}{2} + 2\sqrt{2} + \frac{1}{2+2\xi} + \frac{2\sqrt{2}}{1+\xi} - \frac{2}{2+\xi} - \frac{8}{\sqrt{2+2\xi+\xi^2}}\right)\frac{e^2}{a} + 6\eta f(\xi)\frac{e^2}{a} + \frac{7.113}{(1+\xi)^3}\eta^2\frac{e^2}{a} + 3\eta^2\left(\frac{a^3}{\alpha}\right)\frac{e^2}{a} + 6[u(a+a\xi) + u(a-a\xi) + 4u(a\sqrt{1+\xi^2}) - 6u(a)] - 21.5\xi^4\frac{e^2}{a} \pm 6ea\eta A_{\mp} e^{-a/\rho}(e^{(a/\rho)\xi} - e^{-(a/\rho)\xi} - 4\xi), \quad (3.1)$$

and

$$f(\xi) = 4\left\{\frac{1+\xi}{(2+2\xi+\xi^2)^{3/2}} - \frac{1}{2\sqrt{2}(1+\xi)^2}\right\} + \left\{\frac{1}{(2+\xi)^3} - \frac{1}{(2+2\xi)^2}\right\}, \quad (3.2)$$

where the first three terms in Eq. (3.1) represent the change in the coulomb interaction energy due to the displacements and the polarizations of the (100) ions, the fourth term is the deformation energy of the ions, α is the polarizability of the (100) ion. The fifth is the change in the short range potential, $u(r)$ being the short range potential between different ions and we have neglected those between ions of like sign. The sixth term comes from the crystalline field. The last term represents the short range effect of electronic polarizations, which is explained in the

Appendix, where $+A_-$ stands for the case that the (100) ions are negative and vice versa.

The energy required to remove a (000) ion from the lattice to infinity with the fixed configuration $X=(\xi, \eta)$ and $x=0$, is given by

$$\phi_0 + \phi(X) = \frac{\alpha_M e^2}{a} - \frac{6\xi}{1+\xi} \frac{e^2}{a} - \frac{6\eta}{(1+\xi)^2} \frac{e^2}{a} - 6u(a+a\xi) \pm 6ea\eta A_{\mp} e^{-(a/\rho)(1+\xi)}, \quad (3.3)$$

where the first three terms are the coulomb energy (and α_M is the Medelung constant).

Finally,

$$\sum_{\mu} \left\{ \frac{1}{2} \phi_{\mu} + f_{\mu}(X) - \frac{1}{2} f_{\mu}(X^0) \right\} x_{\mu}^0 = -\frac{1}{2}(4.198M_{+} + 6.335M_{-}) \frac{e^2}{a} + 6(0.388M_{+} + 1.965M_{-}) \left(\xi + \eta - \frac{\xi_0}{2} - \frac{\eta_0}{2} \right) \frac{e^2}{a} + 6M_a a \left[\frac{u'(a) - u'(a-a\xi)}{4} + \sqrt{2} \left\{ u'(a) - \frac{1-\xi}{\sqrt{1+\xi^2}} u'(a\sqrt{1+\xi^2}) \right\} \right] - 3M_a a \left[\frac{u'(a) - u'(a-a\xi_0)}{4} + \sqrt{2} \left\{ u'(a) - \frac{1-\xi_0}{\sqrt{1+\xi_0^2}} u'(a\sqrt{1+\xi_0^2}) \right\} \right], \quad (3.4)$$

where M_+ , M_- and M_a have been introduced by Mott and Littleton, and are explained in the Appendix. When the (100) ions are negative, we take the upper part of the double suffix, and vice versa. The first term comes from the polarization in the region (II), and the last three terms are due to the interaction between the region (I) and (II). The notations ξ_0 and η_0 mean the equilibrium values of ξ and η respectively. We have neglected in Eq. (3.4) the terms which involve A_+ or A_- , because they are very small.

We sum up these three Eqs. (3.1), (3.3) and (3.4), differentiate with respect to ξ and η , and put the results equal to 0:

$$\frac{\partial W(\xi, \eta)}{\partial \xi} = \frac{\partial W(\xi, \eta)}{\partial \eta} = 0. \quad (3.5)$$

These equations give ξ_0 and η_0 , and this procedure is formally equivalent to that of Mott and Littleton. The values of ξ_0 and η_0 are given in Table II.

If we substitute these ξ_0 and η_0 into Eq. (2.6), we obtain the energy required to remove

an ion from the lattice to the infinity. The values are listed in Table III, and the formation energy of the Schottky defect in several

crystals is also shown. For the purpose of comparison, we show the experimental values, the computed values due to Mott and Littleton (denoted by M.L.) and in our previous paper²⁾ (denoted by A). Generally, the present values are larger than those of Mott and Littleton, mainly because of the presence of A_+ and A_- . For the positive (negative) ion vacancy, $A_-(A_+)$ works to decrease (increase) ξ_0 and η_0 and to increase (decrease) $W_+(W_-)$, and the effect of A_- is generally larger than that of A_+ . It may be expected that our values are somewhat better than those of M.L. and A, because of the more careful determination of interionic interactions and of the more exact formulation of the energy. The adoption of the ionic model, however, will limit the accuracy.

§ 4. The Formation Energy of a Frenkel Defect in AgCl

The formation energy of the Frenkel defect in AgCl crystal has been calculated in paper A. The main differences between the present calculation and the previous one are the taking account of A_+ and A_- , and the adoption of a new formulation for the energy. Moreover, because of the importance of the van der Waals potential Dr^{-6} between the Ag^+ ions, we calculate the energy for three values of D , that is

$Da^{-6}=0, -0.100$ and -0.200×10^{-12} erg .

On the other hand, according to Mayer's estimation,

$Da^{-6}=-0.145\times10^{-12}$ erg .

As $\bar{W}(X)$ is only slightly dependent on X near X^0 , we calculated the energy for three values of D with the same X^0 , which is the equilibrium position of ions when Da^{-6} is -0.100×10^{-12} erg.

The results are in Table IV. The recalcu-

lated energy is again larger than that of A. It is to be noted, that the Ag^+-Ag^+ potential has little effect on the properties of the perfect crystal, and then does not affect the determination of the short range potential treated in the Appendix, but has a large effect on the energy of a Frenkel defect.

The observed value of the formation energy of lattice defects in AgCl seems to be 1.0~1.3ev. In the case of the alkali halides the calculated formation energies of Schottky defects are reasonable, so that we may expect the same to hold true for AgCl. On the other hand, for the Frenkel defect, the calculated energy may have large error. That is, our interaction energies which are determined in the Appendix may not be reliable for such

small distances as we meet in the case of the Frenkel defect, and the Ag^+-Ag^+ potential can not be determined either empirically or theoretically with reliable precision. Moreover the energy difference between the 5s level of the interstitial Ag^+ ion and the 3p level of the nearest Cl^- ion is small and a sort of covalency may be expected. So that we may conclude that the predominant lattice defect in AgCl at low temperatures should be of the Frenkel type as concluded in A.

The author is greatly indebted to Professor J. Yamashita for his helpful discussions.

Appendix The Determination of the Interionic Potentials and others

For the determination of the interionic potentials, the polarizabilities of ions and the short range effects of the electronic polarizations, we use the data which have been analysed in § 5 and § 6 of A. In this analysis, we have assumed the energy change of a polarized crystal as follows

$$\Delta E = a_+ p_+^2 + a_- p_-^2 + c p_x^2 - \frac{1}{2} \frac{4\pi}{3v} (p_+ + p_- + p_x)^2 + a_+ p_+ p_- + b_+ p_+ p_x + b_- p_- p_x, \quad (\text{per ion pair}) \quad (\text{A.1})$$

where p_x is the polarization due to the displacement of ions, being equal to ex , and x is the relative displacement of ions. p_+ and p_- is the electronic polarization of a positive ion and a negative ion respectively and v is $2a^3$. The fourth term is the so-called Lorentz correction term, and the last three terms are due to the short range interaction between the polarizations.

From the experimental data, i.e., high frequency dielectric constant κ_0 , static dielectric constant κ and infra-red absorption frequency ω_i , we have estimated the above coefficients. Using these results, we determine the values necessary for the calculations in § 3 and § 4 in the following manner.

a) Electronic polarizability

In paper A, we have suggested that it is reasonable to take $a_+ \simeq 0$, and a_+ and a_- are only dependent on the ion itself but independent on its partner. This is apparently equivalent to the additivity rule of the crystal polarizability, which had been suggested by Shockley and others⁷⁾. The polarizability α of an ion is given by

$$\alpha_+ = \frac{1}{2a_+} \quad \text{and} \quad \alpha_- = \frac{1}{2a_-}, \quad (\text{A.2})$$

and the values of α 's are listed in Table V.

Table V. Polarizability (10^{-24} cm^3).

Ions	α	Ions	α
Li^+	0.05	Ag^+	2.14
Na^+	0.28	F^-	0.86
K^+	1.13	Cl^-	2.92
Rb^+	1.79	Br^-	4.12

b) Interionic potentials

The procedure used to determine these potentials is similar to that in § 7 of A. We neglect the short range interaction between ions of like sign. We assume the interaction form as

$$u(r) = A e^{-r/\rho} \quad \text{for Alkali Halides,} \quad (\text{A.3})$$

and

$$u(r) = A e^{-r/\rho} + C r^{-6} \quad \text{for AgCl.} \quad (\text{A.4})$$

For the determination of A , ρ and C , we have four data; lattice energy W_L , lattice constant a , compressibility χ and c in Eq. (A.1). Assuming appropriate probable errors for these data, we determine A and ρ by the least square method. For AgCl , we have assumed three values of C , i.e., $C a^{-6} = -0.14$, -0.18 and $-0.27 \times 10^{-12} \text{ erg}$, and determined A and ρ for each case. The sum of two terms is almost the same in three cases for $0.8a \leq r \leq 1.1a$, although each term differs case by case. Thus, as pointed out in paper A, the separation of the interionic potential into the repulsive energy and the van der Waals energy has no definite meaning, at least empirically. In the practical calculation, we used the last C . In Table VI, we listed A , ρ and C determined in such a way, and the data which are used (denoted by Exp.) and are calculated using the above-determined potential (denoted by Cal.) too. We can determine two parameters A and ρ from four data consistently, although the consistency is somewhat poor for AgCl . This fact seems to be an indirect confirmation of our assumptions.

c) The short range effects of the electronic polarization

Let us take a pair of ions, the interaction energy between them is $-e^2/r + u(r)$, when the polarization is absent. When the ions polarize, the interaction energy changes, and

* Estimated from the recent data on the affinity by Pritchard⁸⁾, $83,5 \pm 2$ Kcal/mole.

the change consists of that of the coulomb energy and of the short range energy. The latter may be written generally in the following form:

$$p_+ \cos \vartheta_+ B_+(r) + p_- \cos \vartheta_- B_-(r),$$

where $\vartheta_+(\vartheta_-)$ is the angle between $\vec{p}_+(\vec{p}_-)$ and the vector from the positive (negative) ion to the negative (positive) ion. Since $B_+(r)$ and $B_-(r)$ result from the overlap between ions, we may assume a form

$$B_+(r) = -A_+ e^{-r/\rho} \quad (\text{A.5})$$

and

$$B_-(r) = -A_- e^{-r/\rho}, \quad (\text{A.6})$$

and the same ρ as in $u(r)$. From these, we can derive

$$eb_+ = -A_+ e^{-1/\rho} \left(\frac{2}{\rho} - \frac{4}{a} \right)$$

and

$$eb_- = A_- e^{-a/\rho} \left(\frac{2}{\rho} - \frac{4}{a} \right). \quad (\text{A.7})$$

Moreover, we have suggested the following relations in A,

$$b_+ \simeq -0.3c \quad b_- \simeq 0.9c. \quad (\text{A.8})$$

We can determine A_+ and A_- , from Eqs. (A.7) and (A.8).

d) M_+ , M_- and M_a

The polarization P and the electric field F are connected by a relation

$$P = \frac{1}{4\pi} (\kappa - 1) F. \quad (\text{A.9})$$

The dipole moment per ion pair is

$$p = vP = \frac{1}{4\pi} (\kappa - 1) vF, \quad (\text{A.10})$$

p consists of three parts: the electronic dipole moment of the negative ion p_- , that of the positive ion p_+ and the dipole moment due to the displacement p_x . According to paper A, they are given by

$$p_x = \frac{3}{4\pi} \frac{\kappa - \kappa_0}{\kappa_0 + 2} \frac{e}{e^*(0)} vF, \quad (\text{A.11})$$

$$p_+ = \left\{ \frac{v}{4\pi} (\kappa - 1) F - p_x \right\} \frac{\alpha_+}{\alpha_+ + \alpha_-} - \frac{b_+ - b_-}{2(a_+ + a_-)} p_x \quad (\text{A.12})$$

and

$$p_- = \left\{ \frac{v}{4\pi} (\kappa - 1) F - p_x \right\} \frac{\alpha_-}{\alpha_+ + \alpha_-} + \frac{b_+ - b_-}{2(a_+ + a_-)} p_x, \quad (\text{A.13})$$

where

$$e^*(0)^2 = \frac{3v}{4\pi} \frac{3\mu\omega_i^2}{(\kappa_0 + 2)^2} (\kappa - \kappa_0), \quad (\text{A.14})$$

and μ is the reduced mass of ions.

Due to the definition of Mott and Littleton, M_+ , M_- and M_a are given by

$$M_{\pm} = \frac{1}{2\pi} \left(1 - \frac{1}{\kappa} \right) \frac{p_{\pm} + \frac{p_x}{2}}{p_+ + p_- + p_x} \quad (\text{A.15})$$

and

$$M_a = \frac{1}{4\pi} \left(1 - \frac{1}{\kappa} \right) \frac{p_x}{p_+ + p_- + p_x}. \quad (\text{A.16})$$

The values of M_+ , M_- and M_a are shown in Table VI.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 2, FEBRUARY, 1958

On Solvent Effects in Dipole Moment Determinations*

By Kisaburo SHOGENJI**

Faculty of Engineering, Nagoya University, Nagoya

(Received November 6, 1957)

A new theory of the solvent effects is presented in this paper, in which the solute molecule is assumed to have a spheroidal form and have an electric dipole moment directed in the axis of rotation at its centre. The cavity field and the reaction field, etc. are calculated as the functions of the shape of the solute molecule and the dielectric constant of the solvent, and the molecular polarization is also calculated. Theoretical curve, expressing the molecular polarization *vs.* the dielectric constant of the solvent, obtained from this theory shows a fairly good agreement with the experimental results. The curve shows that the molecular polarization has a maximum value for a small dielectric constant of the solvent and its value decreases for larger dielectric constants.

§ 1. Introduction

In measuring the dipole moment of a molecule by using its solution, the solvent effects must be taken into consideration. There are many theories for the solvent effects. Higasi calculated an additive moment, which was due to the polarization of the medium surrounding the molecule: this polarization was induced by the dipolar field of the molecule. Ross and Sack,²⁾ on the other hand, calculated in detail the effects of the electric field acting on the molecule, which depended upon the shape of the molecule and the dielectric constant of the solvent. In these theories the shape of the molecule and the dielectric constant of the solvent determine the magnitude of the solvent effects.

Here we consider carefully the effects of the induced moment and of the electric fields acting on the molecule. As for the electric fields we calculate cavity field, reaction field, etc. for a spheroidal molecule as Onsager³⁾ did for a spherical molecule, and we adopt Higasi's calculation¹⁾ for the induced moment. After the calculation of the interaction energy between the dipole and the fields, the molecular polarization is obtained. Thus the solvent effects are calculated as the functions of the shape of the dipolar molecule and of the dielectric constant of the solvent.

The assumptions, on the basis of which this calculation is made, are as follows: (i) The dissolved dipolar molecule is of spheroidal shape, whose semi-axes are a and b respectively, the former being the axis of revolution. (ii) The molecule has a point dipole moment at the centre of it, and the direction of the dipole is the same as the axis of revolu-

* This paper was published in Japanese: *Busseiron Kenkyu* No. 70 (1954), 1.

** Present address: Hitachi Central Research Laboratory, Kokubunji, Tokyo.

tion and the magnitude of the moment in vacuum is μ . (iii) The molecule can be considered as a continuous medium with the dielectric constant n^2 , where n is the refractive index. (iv) The solvent can be thought as a continuous medium with the dielectric constant ϵ , and it surrounds the dissolved molecule tightly. (v) The solution is sufficiently dilute so that the mutual interaction between dissolved molecules can be considered as negligible. On the basis of the above assumptions the potentials inside and outside the molecule are calculated electrostatically by using the spherical functions in §2. The approximate expressions for the fields derived from the above potentials are given in §3. These expressions have convenient forms common to both prolate and oblate, while the exact formulae have different forms for two spheroids. The expressions contain, as a special case, the well-known expressions for the sphere obtained by Onsager³⁾. Using the results obtained and Higasi's theory¹⁾, we calculate the polarization of molecule in a given direction relative to the external field, then obtain the molecular polarization in §4. This result is compared with the experiments in §5. The experimental values used in the comparison are those of chlorobenzene and tert-butyl chloride.

§2. Calculation of Potentials

The electrostatic potentials, Ψ 's, in space free from charges are expressed as the solutions of Laplace's equation, aside from constant

$$1/d = 1/c \left[\sum_{n=0}^{\infty} (2n+1)(\pm 1)^n \kappa^{2n+1} P_n(\kappa \xi_1) P_n(\eta_1) Q_n(\kappa \xi) P_n(\eta) \right. \\ \left. + 2 \sum_{n=1}^{\infty} (2n+1) \sum_{m=1}^n (-1)^m (\pm 1)^{n-m} \kappa^{2m+1} \left\{ \frac{(n-m)!}{(n+m)!} \right\}^2 P_n^m(\kappa \xi_1) P_n^m(\eta_1) Q_n^m(\kappa \xi) P_n^m(\eta) \cos m(\varphi_1 - \varphi) \right], \quad (2.5)$$

as given by Neumann and Heine⁷⁾.

When there is a dipole at point r_1 , the magnitude of whose moment is μ and the direction of whose axis is z -direction, the potential at point r is, in general, given by $(\partial/\partial z_1)(1/d)$. Therefore assuming that there is a dipole μ at the origin r_1 pointing to z -direction, the potential Ψ_a due to the dipole is obtained by differentiating Eq. (2.5). Thus

$$\Psi_a = (\mu/c^2) \sum_{n=0}^{\infty} (\pm 1)^n \kappa^{2(n+1)} (2n+1) \dot{P}_n(0) Q_n(\kappa \xi) P_n(\eta), \quad (2.6)$$

$\dot{P}_n(0)$ expressing the value of first derivative of P_n at 0. Differentiations used here are $(1/c)(\partial/\partial \eta_1)(1/d)$ at $\xi_1=1$ and $\eta=0$ for prolate and $(1/c)(\partial/\partial \xi_1)(1/d)$ at $\xi_1=0$ and $\eta_1=1$ for oblate. It is clear that Eq. (2.6) is a solution

factors, as follows:—

$$\Psi = LMN, \quad (2.1)$$

where

$$L = \begin{cases} (\pm \kappa)^{n-m} P_n^m(\kappa \xi) \\ \kappa^{n+m+1} Q_n^m(\kappa \xi) \end{cases}, \quad M = \begin{cases} P_n^m(\eta) \\ Q_n^m(\eta) \end{cases}, \\ N = \begin{cases} \cos m\varphi \\ \sin m\varphi \end{cases}, \quad (2.2)$$

and

$$x = c\sqrt{\xi^2 \mp 1} \sqrt{1 - \eta^2} \cos \varphi, \\ y = c\sqrt{\xi^2 \mp 1} \sqrt{1 - \eta^2} \sin \varphi, \quad z = c\xi \eta, \quad (2.3)$$

$$c^2 = \pm(a^2 - b^2) \quad (2.4)$$

ξ , η and φ being spheroidal coordinates, x , y and z ordinary rectangular coordinates. For brevity's sake, notation κ is used, which we make to express unity for prolate and imaginary unit for oblate, namely,

$$\kappa = \begin{cases} 1 & \text{for prolate} \\ i & \text{for oblate} \end{cases},$$

and the upper sign (+ or —) in the above equations refers to prolate and the lower one to oblate. These notation and convention are used hereafter.

Extensions of Onsager's theory³⁾ to spheroidal molecule have already been done by several authors, e.g. Fujishiro⁴⁾, Abbott and Bolton⁵⁾ and Buckingham⁶⁾. Also a similar attempt is made in this section.

(a) *Potential due to dipole.* Let the distance between two points $r_1(\xi_1, \eta_1, \varphi_1)$ and $r(\xi, \eta, \varphi)$ be d , the former being nearer than the latter to the origin of the coordinate. Then

of Laplace's equation by referring to Eq. (2.2).

(b) *Potentials inside and outside spheroid.*

(i) We assume that dissolved molecule is of spheroid and the ratio of its two semi-axes is $k=a/b$ and the dielectric con-

tant inside the spheroid is n^2 and that of solvent outside is ϵ . If there exists an electric field E in z -direction, which is the direction of revolution of spheroid, the potential is $-zE$ at a large distance from the spheroid. Let the potentials outside and inside the spheroid be Ψ_{01} and Ψ_{i1} , respectively. Then we may put

$$\Psi_{01} = \mp \kappa c E_z P_1(\kappa \xi) \pm B_{11} Q_1(\kappa \xi) P_1(\eta), \quad (2.7)$$

$$\Psi_{i1} = \pm \kappa C_{11} P_1(\kappa \xi) P_1(\eta). \quad (2.8)$$

Using

$$(\Psi_0)_{z=a/c} = (\Psi_i)_{z=a/c}, \quad (2.9)$$

and

$$-\epsilon(\partial\Psi_0/\partial\xi)_{z=a/c} = -n^2(\partial\Psi_i/\partial\xi)_{z=a/c}, \quad (2.10)$$

as boundary conditions, we get

$$B_{11} = \frac{\kappa(\epsilon - n^2)P_1\dot{P}_1 c E_z}{\epsilon P_1\dot{Q}_1 - n^2\dot{P}_1 Q_1}, \quad (2.11)$$

$$C_{11} = \frac{-\kappa(P_1\dot{Q}_1 - \dot{P}_1 Q_1)\epsilon c E_z}{\epsilon P_1\dot{Q}_1 - n^2\dot{P}_1 Q_1}, \quad (2.12)$$

where P_1 , Q_1 and $\dot{P}_1$ etc. represent the values of spherical functions and its first derivatives at a/c or ia/c .

(ii) When the electric field is directed in x -direction, being perpendicular to the axis of revolution, we get the potentials in a similar way as made in (i) as follows:—

$$\Psi_{02} = \mp \kappa c E_x P_1^1(\kappa \xi) \pm \kappa B_{21} Q_1^1(\kappa \xi) P_1^1(\eta) \cos \varphi, \quad (2.13)$$

$$\Psi_{i2} = C_{21} P_1^1(\kappa \xi) P_1^1(\eta) \cos \varphi. \quad (2.14)$$

From the boundary conditions

$$B_{21} = \frac{\kappa(\epsilon - n^2)P_1^1\dot{P}_1^1 c E_x}{\epsilon P_1^1\dot{Q}_1^1 - n^2\dot{P}_1^1 Q_1^1}, \quad (2.15)$$

$$C_{21} = \frac{-\kappa(P_1^1\dot{Q}_1^1 - \dot{P}_1^1 Q_1^1)c E_x}{\epsilon P_1^1\dot{Q}_1^1 - n^2\dot{P}_1^1 Q_1^1}, \quad (2.16)$$

(iii) When there exists a dipole at the centre of the spheroid pointing to z -direction, we may put

$$\Psi_{03} = \sum_{n=0}^{\infty} \kappa^{n+1} B_{3n} Q_n(\kappa \xi) P_n(\eta), \quad (2.17)$$

$$\Psi_{i3} = \sum_{n=0}^{\infty} \{(\pm \kappa) C_{3n} P_n(\kappa \xi) + \kappa^{n+1} D_{3n} Q_n(\kappa \xi) P_n(\eta)\}. \quad (2.18)$$

From Eq. (2.6) we can see

$$D_{3n} = \frac{(2n+1)\mu(\pm 1)^n \kappa^{n+1} \dot{P}_n(0)}{n^2 c^2},$$

$$D_{30} = 0, \quad D_{31} = \frac{3\mu}{n^2 c^2}, \quad D_{32} = 0, \quad (2.19)$$

$$D_{33} = -\frac{21\mu}{2n^2 c^2}.$$

Using the boundary conditions mentioned above we get

$$B_{3n} = \frac{n^2(P_n\dot{Q}_n - \dot{P}_n Q_n)D_{3n}}{\epsilon P_n\dot{Q}_n - n^2\dot{P}_n Q_n}, \quad (2.20)$$

$$C_{3n} = \frac{\pm \kappa(\epsilon - n^2)Q_n\dot{Q}_n D_{3n}}{\epsilon P_n\dot{Q}_n - n^2\dot{P}_n Q_n}. \quad (2.21)$$

§ 3. Approximate Formulae Expressing Fields

In this section we get approximate expressions for the results of the preceding section. These approximate expressions are simpler than the preceding results, and from them we may easily derive those of fields. Using these approximate formulae, we calculate cavity field, self field and reaction field, whose expressions include, as a special case, the well-known formulae for sphere³⁾.

(a) *Approximate expressions for results of the preceding section.* If we expand the spherical functions in the formulae of the preceding section in the series and keep the main terms only, neglecting others, we obtain approximate expressions for the potentials by using Eq. (2.4) and the ratio k of semi-axes as follows:—

$$\Psi_{01} = -zE_z - \frac{(\epsilon - n^2)a^3 E_z \cos \theta}{\{(3k^2 - 1)\epsilon + n^2\}r^2}, \quad (3.1)$$

$$\Psi_{i1} = -\frac{3k^2 E_z z}{(3k^2 - 1)\epsilon + n^2}, \quad (3.2)$$

corresponding to Eqs. (2.7) and (2.8), and

$$\Psi_{02} = -xE_x - \frac{2(\epsilon - n^2)a^3 E_x \cos \theta'}{\{(3k^2 + 1)\epsilon + (3k^2 - 1)n^2\}r^2}, \quad (3.3)$$

$$\Psi_{i2} = -\frac{6k^2 \epsilon E_x x}{(3k^2 + 1)\epsilon + (3k^2 - 1)n^2}, \quad (3.4)$$

$$\Psi_{03} = -\frac{3k^2 \mu \cos \theta}{\{(3k^2 - 1)\epsilon + n^2\}r^2}, \quad (3.5)$$

$$\Psi_{i3} = -\frac{(\epsilon - n^2)(3k^2 - 1)\mu z}{\{(3k^2 - 1)\epsilon + n^2\}n^2 a^3} + \frac{\mu z}{n^2 r^2}. \quad (3.6)$$

In the above equations r expresses the distance from the origin, θ the angle between z -axis and the line connecting the point under consideration to the origin, and θ' the angle

between x -axis and the line. These approximate equations have the same expressions for both prolate and oblate, provided that is k greater than $1/\sqrt{2}$. For the values of k smaller than $1/\sqrt{2}$, the approximate expressions, which are obtained by expanding the spherical functions in the series, are different from those for the values of k greater than $1/\sqrt{2}$, so that the above approximate expressions are not applicable.

(b) *Cavity field.* (i) When we put $n^2=1$ in Eq. (2.8) or (3.2), we get cavity field F_{zo} in z -direction since no self field and no reaction field act inside the spheroid, there being no dielectric. Its approximate form is as follows:—

$$F_{zo} \equiv \gamma_z E_z \simeq \frac{3k^2 \epsilon E_z}{(3k^2 - 1)\epsilon + 1} \quad (3.7)$$

(ii) For x -direction we get similarly

$$F_{xo} \equiv \gamma_x E_x \simeq \frac{6k^2 \epsilon E_x}{(3k^2 + 1)\epsilon + 3k^2 - 1} \quad (3.8)$$

(c) *Self field.* (i) When there is no dielectric outside the spheroid and no permanent dipole inside, and the external field is E , then the field inside the spheroid, which we denote E_{zi}' , is obtained from Eq. (2.8) or (3.2) by putting $\epsilon=1$. In this case the cavity field is obtained from the same equation by putting $\epsilon=1$ and $n^2=1$, then this becomes in accordance with the external field. Thus self field F_{zs} is considered as the difference between the above two fields, because the reaction field does not act in this case. This field and its approximate form are as follows:—

$$\begin{aligned} F_{zo} &= E_{zi}' - E_z = \frac{(n^2 - 1) \dot{P}_1 Q_1 E_z}{P_1 \dot{Q}_1 - n^2 \dot{P}_1 Q_1} \\ &\simeq - \frac{(n^2 - 1) E_z}{3k^2 - 1 + n^2} \end{aligned} \quad (3.9)$$

On the other hand the polarization P_z inside the spheroid is

$$P_z = \frac{(n^2 - 1) E_{zi}'}{4\pi} \quad (3.10)$$

Therefore

$$F_{zs} = \frac{4\pi \dot{P}_1 Q_1 P_z}{P_1 \dot{Q}_1 - \dot{P}_1 Q_1} \simeq - \frac{4\pi P_z}{3k^2} \quad (3.11)$$

(ii) For x -direction we get similarly

$$\begin{aligned} F_{xs} &= E_{xi}' - E_x = \frac{(n^2 - 1) \dot{P}_1 Q_1 E_x}{P_1 \dot{Q}_1 - n^2 \dot{P}_1 Q_1} \\ &\simeq - \frac{(3k^2 - 1)(n^2 - 1) E_x}{3k^2 + 1 + (3k^2 - 1)n^2} \end{aligned} \quad (3.12)$$

$$F_{xs} = \frac{4\pi \dot{P}_1 Q_1 P_x}{P_1 \dot{Q}_1 - \dot{P}_1 Q_1} \simeq - \frac{4\pi (3k^2 - 1) P_x}{6k^2} \quad (3.13)$$

(d) *Reaction field.* (i) When the molecule has a dipole, the reaction field acts on the molecule, which is due to the polarization of the surrounding dielectric induced by the original dipole.

At first the reaction field, when a molecule has a dipole due to homogeneous polarization P_z in z -direction, is calculated. As the field derived from Eq. (2.8) can be considered as consists of the cavity, self and reaction fields, the reaction field F_{xr} is obtained by subtracting the cavity and self fields from the field mentioned above. Thus we get

$$\begin{aligned} E_{xr} &\equiv g_z m_z = E_{xi} - F_{zs} - F_{zo} \\ &= - \frac{4\pi P_1 Q_1 \dot{P}_1 \dot{Q}_1 (\epsilon - 1) P_z}{(P_1 \dot{Q}_1 - \dot{P}_1 Q_1)(\epsilon P_1 \dot{Q}_1 - \dot{P}_1 Q_1)} \end{aligned} \quad (3.14)$$

using Eqs. (3.10) and (3.11), where m_z is the dipole moment. An approximate expression is

$$F_{xr} \simeq \frac{(3k^2 - 1)(\epsilon - 1) m_z}{\{(3k^2 - 1)\epsilon + 1\} a^3} \quad (3.15)$$

where

$$m_z = V P_z = \frac{4\pi a^3 P_z}{3k^2} \quad (3.16)$$

V being the volume of the spheroid.

(ii) For x -direction we get

$$\begin{aligned} F_{xr} &\equiv g_x m_x = E_{xi} - F_{xs} - F_{xo} \\ &= - \frac{4\pi P_1 Q_1 \dot{P}_1 \dot{Q}_1 (\epsilon - 1) P_x}{(P_1 \dot{Q}_1 - \dot{P}_1 Q_1)(\epsilon \dot{P}_1 \dot{Q}_1 - \dot{P}_1 Q_1)} \\ &\simeq \frac{(3k^2 + 1)(3k^2 - 1)(\epsilon - 1) m_x}{2\{(3k^2 + 1)\epsilon + 3k^2 - 1\} a^3} \end{aligned} \quad (3.17)$$

(iii) When a dipole μ exists at the centre of the spheroid and points to z -direction, the reaction field is obtained from the first term of Eq. (2.18) putting $n^2=1$. The approximate expression for the reaction field, which is obtained from Eq. (3.6) by putting $n^2=1$, is the same as Eq. (3.15), although the first term of the series expressed in Eq. (2.18) alone is not rigorously the same as Eq. (3.14).

§ 4. Molecular Polarization

The molecular polarization is calculated in this section. At first the polarizability of molecule is calculated, using the approximate expressions of the preceding section, and this is easily seen to be in accord with that of sphere in the case of $k=1$ ³⁾. Next we cite the results of Higasi's theory briefly, as it is needed for the following calculation. Then the statistical mean of the component parallel to the external field of permanent and induced dipole moment is obtained. The value of this is easily, though not very simply, calculated numerically, and is to be compared with experimental values.

(a) *Polarizability.* The polarizability of molecule may be gotten from equation

$$m = \alpha F, \quad (4.1)$$

where m is the dipole moment induced by the field F acting on the molecule, and α the polarizability of the molecule, which is calculated in this section for the cases where F is directed in z - and x -directions respectively. When no permanent dipole exists, the field acting on the molecule is given by

$$F = \gamma E + g m, \quad (4.2)$$

E being the external field. With Eqs. (4.1) and (4.2) we obtain

$$m = \frac{\alpha \gamma E}{1 - \alpha g}. \quad (4.3)$$

(i) For z -direction, using Eqs. (3.10), (3.16), (4.3) and the approximate expressions for γ_z and g_z , we get

$$\alpha_z = \frac{(n^2 - 1)a^3}{3k^2 - 1 + n^2}. \quad (4.4)$$

(ii) For x -direction we obtain similarly

Fig. 1. Polarizability calculated by Eq. (4-4) and (4-5).

$$\alpha_x = \frac{2(n^2 - 1)a^3}{(3k^2 + 1) + (3k^2 - 1)n^2}. \quad (4.5)$$

Fig. 1 shows the polarizability as a function of k .

(b) *Higasi's theory*¹⁾. According to Higasi the reason that the apparent moment of molecule in the solvent differs from the moment in vacuum is as follows: When a dipolar molecule is put into solvent, the surrounding solvent gets polarization due to the field of the diople. If the molecule has a spherical form, this polarization has no effect on measuring the dipole moment. In other cases, this polarization between the molecule and the sphere circumscribing it affects the dipole moment determination as if the induced moment of this polarization were a part of the original dipole moment. Thus the apparent moment in the solvent depends not only on the original moment but also on the shape of the molecule and the dielectric constant of the solvent. The additive moment due to the solvent for the spheroidal molecule is

$$\mu_{ad} = \{(\epsilon - 1)/(\epsilon + 1)\} \mu \left\{ \frac{A}{A'} \right\}, \quad (4.6)$$

$$A = -\frac{3}{k^2 - 1} \left\{ 1 - \frac{k}{\sqrt{k^2 - 1}} \ln |k + \sqrt{k^2 - 1}| \right\} - 1, \quad (4.7)$$

$$A' = \frac{3k'^2}{k'^2 - 1} \left\{ 1 - \frac{1}{\sqrt{k'^2 - 1}} \sin^{-1} \frac{\sqrt{k'^2 - 1}}{k'} \right\} - 1, \quad (4.8)$$

$k' = 1/k$

where A is for prolate and A' for oblated.

(c) *Statistical mean of dipole moment.* In order to obtain the molecular polarization, the statistical mean of the dipole moment parallel to the external field should be calculated, because the dipoles point to various directions even under the external field.

The component of the dipole in z -direction is given by

$$m_z = \mu + \alpha_z F_z. \quad (4.9)$$

Combining Eqs. (4.2) and (4.9) m_z may be solved as

$$m_z = \frac{\mu + \alpha_z \gamma_z E_z}{1 - \alpha_z g_z}. \quad (4.10)$$

And also we get

$$m_x = \frac{\alpha_x \gamma_x E_x}{1 - \alpha_x g_x}. \quad (4.11)$$

If the axis of revolution of the spheroid makes an angle θ with respect to the

external field E , then the components of the external field are $E_z = E \cos \theta$ and $E_x = E \sin \theta$ respectively. Substituting these and Eqs. (4.10) and (4.11) into Eq. (4.2) we obtain

$$F_z = \frac{\mu g_z + \gamma_z E \cos \theta}{1 - \alpha_z g_z}, \quad (4.12)$$

$$F_x = \frac{\gamma_x E \sin \theta}{1 - \alpha_x g_x}. \quad (4.13)$$

The torque acting on the molecule is given by the vector product of F and m . By integrating it with respect to the angle, the potential energy $w(\theta)$ may be obtained as a function of θ . It is, however, necessary that the torque to the additive moment calculated in § 4 (b) should be included in the total torque. It will not introduce any serious error if the field acting on it is assumed to be a Lorentz field. Then the torque is $\{(\epsilon-1)/3\} A \mu E \sin \theta$. By integrating the total torque, the above term being included, we get

$$w(\theta) = \frac{1}{(1 - \alpha_z g_z)(1 - \alpha_x g_x)} \{ (\alpha_z g_z - 1) \gamma_z \mu E \cos \theta + (\alpha_x - \alpha_z) \gamma_x \gamma_z E^2 \cos^2 \theta \} + \frac{\epsilon-1}{3} A \mu E \cos \theta. \quad (4.14)$$

When the angle between the axis of revolution and the external field is θ , the component of dipole moment parallel to the external field, including the additive moment calculated above, is given by

$$m_B(\theta) = \frac{\{1 + (\epsilon-1)A/(\epsilon+2)\} \mu + \alpha_z \gamma_z E \cos \theta}{1 - \alpha_z g_z} \cos \theta + \frac{\alpha_x \gamma_x E}{1 - \alpha_x g_x} \sin^2 \theta. \quad (4.15)$$

The statistical mean of it is obtained from

$$\bar{m}_B = \frac{\int_0^\pi m_B(\theta) \exp(-w/kT) \sin \theta d\theta}{\int_0^\pi \exp(-w/kT) \sin \theta d\theta}. \quad (4.16)$$

This calculation is rather complicated, but in ordinary conditions the terms of higher order with respect to E can be neglected. The procedures employed in the calculation of the numerator are as follows: after integration by parts, $\exp(-w/kT)$ contained in the resultant is expanded in a series and then the terms proportional to E are only picked up, the others being neglected, and they are rearranged. For the denominator the first term alone is also kept. Then

$$\bar{m}_B = \left[\frac{\{1 + (\epsilon-1)A/(\epsilon+2)\} \mu^2}{3kT(1 - \alpha_z g_z)} \frac{(1 - \alpha_x g_x) \gamma_x}{(1 - \alpha_z g_z)(1 - \alpha_x g_x)} + \frac{\epsilon-1}{3} A + \frac{1}{3} \left(\frac{\alpha_z \gamma_z}{1 - \alpha_z g_z} + \frac{2\alpha_x \gamma_x}{1 - \alpha_x g_x} \right) \right] E. \quad (4.17)$$

Of course this becomes accord with the formula for the sphere³⁾, when α , γ and g are taken for sphere and A is put equal to zero. That the first term in Eq. (4.17) is more complicated than that for the sphere is mainly due to the fact that the magnitude and direction of dipole and the field vary in a complicated way as the functions of k and ϵ . The factors A in Eq. (4.17) is caused by the additive moment and the consequent torque. The molecular polarization P_m is given by

$$P_m = \frac{4\pi \bar{m}_B L}{(\epsilon+2)E}, \quad (4.18)$$

where L is Avogadro's number.

§ 5. Comparison with Experiments

The experimental values for chlorobenzene and tert-butyl chloride are shown in Figs. 2 and 3, respectively. The values used in the

Fig. 2. Comparison between theoretical and experimental values P_m of molecular polarization of chlorobenzene.

calculations are as follows: $T=300^\circ\text{K}$; $\mu=1.70$ for chlorobenzene and $\mu=2.13$ for tert-butyl chloride in Debye unit; $n^2=2.34$ for chlorobenzene and $n^2=1.91$ for tert-butyl chloride. The lengths a 's of semi-axis of revolution used here are shown in Fig 4, which are

Fig. 3. Comparison between theoretical and experimental values P_m of molecular polarization of tert-butyl chloride.

Fig. 4. The value of semi-axis used in calculation molecular polarizability.

determined so as to make the theoretical value of P_m calculated from Eq. (4.18) with $\epsilon=1$ and μ mentioned above equal to the experimental value at $\epsilon=1$.

The features of these theoretical curves are as follows: As the dielectric constant of solvent increases from unity, the molecular polarization generally increases at first and reaches its maximum and then decreases. The

slope of this decreasing curve is steeper than that of Higasi's theory so that agreement with experiments becomes better. In general the smaller the ratio k becomes, the larger the maximum of the curve becomes and the larger the value of dielectric constant of solvent becomes, at which the curve reaches its maximum. Thus the apparent moment in the solvent can be larger than the true moment for small dielectric constant of solvent even for prolate. On the other hand for larger dielectric constant of solvent the apparent moment becomes smaller even for oblate. These features seem to represent the experimental characteristics.

It should be noted that Eq. (4.17) is only approximate formula. And the more k differs from unity, the worse the approximation becomes. That the calculation given here is made on the basis of the assumptions given at first should be noticed also. In spite of these approximation and simplifying assumptions, this calculation can show a fairly good agreement with experiments.

The writer should express his sincere thanks to Professor K. Higasi, Hokkaido University, for his kind guidance and encouragement, without which this work might have been left unfinished. He was also encouraged by interest shown to this work by Dr. J. W. Smith, University of London.

Study on the Ordered Alloy Ag_3Mg

By Kunio FUJIWARA[†], Makoto HIRABAYASHI, Denjiro WATANABE
and Shiro OGAWA

*The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan*

(Received November 11, 1957)

One-dimensional anti-phase domain structure of the ordered alloy Ag_3Mg has been confirmed by X-ray diffraction study using a single crystal as well as polycrystals and by electron diffraction study with evaporated thin films. The measurements of specific heat and electrical resistivity have also been done, and these results have been qualitatively discussed in connection with the structure of this alloy.

§ 1. Introduction

The existence of the superlattice Ag_3Mg in the face-centred cubic α phase of silver-magnesium alloy system was first suggested by Clarebrough and Nicholas¹⁾ and confirmed by Kachi's investigation²⁾ mainly from the electrochemical properties of this alloy. As to the atomic arrangement of this superstructure, however, nothing was known. In 1954, from the results of the X-ray diffraction study, Schubert, Kiefer, Wilkens and Haufier³⁾ concluded that the ordered alloy Ag_3Mg has a one-dimensional anti-phase domain structure like Cu_3Au in the partially ordered state. They came to this conclusion

only by using powder specimens. It seemed, therefore, to be desirable that this result was examined with a single crystal. In the present work, the anti-phase domain structure of Ag_3Mg has clearly been confirmed by X-ray diffraction study using a single crystal as well as polycrystals and also by electron diffraction study with evaporated single-crystal-like films. Measurements of electrical resistivity and a series of calorimetries on the alloys in the α phase and the $\alpha+\beta$ two phase region (see Fig. 1) were also carried out, in order to elucidate the relation between these physical properties and the peculiarities of the structure. No quantitative conclusion, however, has been obtained in the present work.

§ 2. The Model of Superstructure of the Present Alloy.

As mentioned above, Schubert and his collaborators adopted the concept of a one-dimensional anti-phase domain structure in order to explain the result of their X-ray diffraction study with powder specimens.

Fig. 2. Illustration of a one-dimensional anti-phase domain structure ($M=2$).

Fig. 2 illustrates such a structure. The fundamental lattice of this structure is considered to be a face-centred tetragonal lattice

with the atomic arrangement similar to that in perfectly ordered Cu_3Au . An out-of-step vector in atomic arrangement, $(\vec{a}_2 + \vec{a}_3)/2$, however, exists at every M cells along the x direction, where $\vec{a}_1$, $\vec{a}_2$ and $\vec{a}_3$ represent three fundamental vectors of face-centred tetragonal lattice, the tetragonal axis being $\vec{a}_1$. Nothing particular occurs in the atomic arrangements along the y and z axes, and so a unit cell of this structure must be taken as outlined by the thick lines in the figure. The intensity distribution in reciprocal space corresponding to such a structure is illustrated in Fig. 3-(a), where the splittings of the superlattice reflections having odd $k+l$ are shown. The indices of these split spots are $(h+1/2M, k, l)$ and $(h-1/2M, k, l)$ in terms of the fundamental face-centred tetragonal lattice. In the actual crystal, however, the tetragonal axis will distribute not only along x but also along y and z directions, and the superposed intensity distribution is illustrated in Fig. 3-(b).

(b) corresponding to the superposition of three orientations, where tetragonality is neglected, since $c/a \sim 1$ in Ag_3Mg .

§ 3. X-ray Diffraction Study

a) Experimental Methods

A single crystal specimen was prepared by sawing out a relatively large grain from a specimen for calorimetry. The powder specimens whose compositions range from 9 to

33 per cent* were prepared by sucking up the melt into silica capillaries. It is disadvantageous for annealing that the vapour pressure of magnesium is considerably high. In all annealing process, therefore, specimens were enclosed in small glass tubes filled with argon. This procedure was effective to prevent the evaporation of magnesium to a large extent. After annealing the specimens were always etched in nitric acid in order to remove the surface layers from which some quantity of magnesium might have been lost by evaporation, and then their compositions were determined. The method of chemical analysis was inexpedient, as it required the consumption of considerably large amount of specimen in order to obtain high accuracy in composition determination, and so it was applied only to several specimens in the $\alpha + \beta$ two phase region. The compositions of the alloys in the α phase were determined by measuring the lattice constants in disordered state quenched from 500°C and comparing with the standard curve illustrated in Fig. 4.

Fig. 4. Variations of lattice constants with composition.

The preparation of this standard curve was made by using the specimens for calorimetry, and the details will be described in § 5-(a).

A 7 cm oscillation camera and an 11.46 cm

* In the present paper, mere 'per cent' will be used in place of 'atomic per cent of magnesium'.

powder camera were used for the single crystal specimen and the powder specimens respectively. All photographs were taken with copper radiation on the Fuji industrial high speed films. The lattice parameters were determined from Debye-Scherrer photographs by means of the graphical-extrapolation method.

b) Experimental Results

The lattice variation caused by ordering were first noticed. The results obtained from powder photographs are summarized in Fig. 4. In this figure, the full curve depicts the disordered state quenched from 500°C into water, while the dotted curves depict the almost completely ordered state induced by slow cooling from 400°C to 250°C in 22 days. For the ordered specimens containing magnesium

Fig. 5. Volume ratio of ordered to disordered state.

Fig. 6. (a) A portion of oscillation photograph of 25 per cent single crystal, [001] being vertical. (b) Intensity distribution in reciprocal space corresponding to (a).

less than about 23 per cent the lattice remains in the face-centred cubic form, although the lattice constant contracts a little. The transformation to the face-centred tetragonal form** accompanies ordering, however, in the alloys containing magnesium more than about 23 per cent. The tetragonality, c/a , increases monotonously with composition until the boundary between the α -phase and the $\alpha+\beta$ two phase region is reached, where it has the maximum value 1.006. The corresponding volume change is illustrated in Fig. 5 in terms of the volume ratio of ordered and disordered state.

The single crystal specimen containing 25 per cent magnesium was slowly cooled from 390°C to 250°C in 14 days. Fig. 6-(a) shows a portion of an oscillation photograph. Unfiltered copper radiation was used, [001] being vertical and oscillation angle being 15°. The cross-like splits of three superlattice reflections, (231), (230) and $(23\bar{1})$ ***, are clearly shown. The observed intensity distribution in reciprocal space corresponding to Fig. 6-(a) is illustrated in Fig. 6-(b), and accords well with Fig. 3-(b), the existence of a one-dimensional anti-phase domain structure being confirmed. Besides the primary split spots, $(h \pm 1/2M, k, l)$ and so on, the faint secondary splittings, e.g. $(h \pm 3/2M, k, l)$, are also observed in Fig. 6. The value of the period of out-of-steps, M , can be calculated from the separation of split spots, and is 1.77 in this specimen. In Fig. 7, the values of M observ-

ed mainly from powder patterns are plotted against composition.

§ 4. Electron Diffraction Study

a) Experimental Method

The specimens were prepared in the following way. Single-crystal-like films of silver were first formed by evaporation *in vacuo* onto cleavage surfaces of rocksalt heated at 180~210°C, and then they were detached from the substrata in water and mounted on nickel supporters. Magnesium was evaporated *in vacuo* onto these silver films at room temperature, and then the films were quickly heated up to 300°C and slowly cooled in the apparatus for homogenization. High vapour pressure of magnesium, however, hindered the formation of the alloy films having expected composition. The amount of magnesium to be evaporated was, therefore, always increased by a few times as much as that corresponding to the desired composition. The thickness of the alloy films estimated from the evaporated quantities was 600~700Å.

Fig. 8. (a) Electron diffraction pattern from a film containing about 25 per cent Mg.

Fig. 8. (b) Intensity distribution in reciprocal space corresponding to (a). The difference in size between (a) and (b) should be noticed.

Fig. 7. Period of out-of-step, M , versus composition.

** It should be noticed, however, that the face-centred tetragonal cell can no longer be a unit cell in the ordered lattice.

*** Miller's indices of the superlattice reflection are used in terms of the fundamental face-centred tetragonal lattice, as described in § 2.

Since a precise determination of the lattice constants such as in the X-ray study was not expected in the electron diffraction study, the compositions of films were estimated by comparing the observed values of the period of out-of-step with the X-ray data as shown in Fig. 7, although such procedure is undesirable from the view point of structure analysis. Annealing of specimens was carried out in flow of argon, and this attempt brought fairly good results to avoid the evaporation and oxidation of magnesium during annealing.

A diffraction camera made by the Hitachi Co. was used, the applied voltage being about 50 KV. All diffraction photographs were taken at the normal incidence.

b) Experimental Results

Alloy films which were not completely homogenized before annealing exhibited unknown complex spot patterns as well as body-centred cubic rings due to the β phase, besides face-centred cubic spots with split superlattice reflections. As the annealings of specimens advanced, however, the extra spots and rings disappeared gradually. On the other hand, the superlattice reflections due to the α phase grew more intense. Fig. 8-(a) shows a diffraction photograph of a specimen annealed at 150°C for 18 hours, and Fig. 8-(b) shows the corresponding intensity distribution in reciprocal space in terms of the fundamental face-centred tetragonal lattice. Cross-like splittings of superlattice reflections can be clearly observed, and thus the one-dimensional anti-phase domain structure of Ag_3Mg is confirmed also by electron diffraction method. The composition of this film is estimated to be about 25 per cent from the observed value of M , 1.79. Further annealing of this specimen did not bring any essential change to the diffraction pattern, though the background intensity increased perhaps by contamination of the specimen.

§ 5. Calorimetric Study

a) Experimental Methods

An adiabatic calorimeter of the Nagasaki-Takagi type⁴⁾ was used to measure the specific heat. The specimens were made of ingots which had been homogenized by annealing at 750°C . Each of the specimens has three holes, one of which is for heating coil and

the other two are for thermocouples, and its mass is about 30 gr on the average. In annealing processes the specimens were enclosed in glass tubes filled with argon, and all measurements were carried out under one atmospheric pressure of argon. The rate of heating of specimens was about 2°C per min. in the region of normal specific heat. The compositions of specimens in the α phase were calculated by using the measured values of their specific gravities and lattice constants in disordered state quenched from 500°C into water. The effects of vacancy, other lattice defects and grain boundaries were all neglected in this calculation. The results were plotted in Fig. 4 and used as the standard curve for the specimens for X-ray diffraction study, as already described. For the specimens in the $\alpha+\beta$ two phase region, the chemical analyses were employed.

b) Experimental Results

A series of calorimetric experiments was carried out on the alloys whose compositions

Fig. 9. Specific heat versus temperature curve of 25.4 per cent alloy. (I)

Fig. 10. Configurational energy versus temperature curve corresponding to Fig. 9.

range from 15.6 to 33.0 per cent. Figs. 9, 10 and 11 depict the results on the 25.4 per cent alloy as an example. The full curve in

Fig. 11. Specific heat versus temperature curve of 25.4 per cent alloy. (II)

Fig. 9 illustrates the specific heat versus temperature curve. In this case the specimen was initially in a highly ordered state by slow cooling from 400°C to room temperature in 24 days. A typical λ -type transformation with anomalous residual specific heat above the critical temperature can be seen in this figure. The corresponding energy versus temperature curve is drawn in Fig. 10. Latent heat is observed at 393°C between two arrows in the figure, and it amounts to about 150 cal/mol. Fig. 11 depicts another specific heat versus temperature curve of the same specimen, the initial state in this case being a disordered state attained by quenching from 500°C into water. The decrease of specific heat due to the development of order begins at about 100°C, and the most highly ordered state of this alloy in the course of this measurement is realized at about 320°C, where the specific heat comes back onto the normal value indicated by the dotted line. The endothermic value in the disordering process was a little higher than the calorific value in the preceding, ordering process. This fact suggests that a perfectly disordered state of the specimen was not obtained by quenching. Latent heat at the critical temperature could not be observed in this measurement. The variations of the critical temperature and the configurational energy with composition are summarized in Figs. 12 and 13, respectively. Here, the data obtained from 15.6 and 18.1 per cent specimens have

Fig. 12. Critical temperature versus composition.

Fig. 13. Configurational energy just above T_c versus composition.

relatively low accuracy, as they showed only broad peaks in the specific heat measurements.

§ 6. Measurement of Electrical Resistivity

A wire of 24.8 per cent alloy was used as a specimen, whose dimensions were 8.5 cm in length and 0.8 mm in diameter. This specimen was initially quenched from 500°C into water, and then the variation of electrical resistivity with temperature was measured at the heating rate of about 100°C per hour under one atmospheric pressure of argon gas. Fig. 14 depicts the result. It should be noticed that the anomalous increase of re-

Fig. 14. Electrical resistivity versus temperature curve of 24.8 per cent alloy.

sistivity can be detected between 100°C and 260°C prior to the decrease in 260~400°C. This fact will be discussed in the next paragraph in comparison with the specific heat versus temperature curve.

§ 7. Discussions

a) Discussions on the Diffraction Experiments

Recently, Hill and Axon⁵⁾ measured the lattice spacings of the α solid solution of silver-magnesium alloy system. The present result on the lattice spacings of the disordered α phase, as shown in Fig. 4, agrees well with their results within the experimental error. On the other hand, the values reported by Letner and Sidhu⁶⁾, who failed to discover the superlattice Ag_3Mg , are considerably smaller than those of the present work, probably owing to the formation of order to a certain extent in their specimens. As to the lattice spacings in the ordered state, the results of Schubert *et al.* are in good qualitative agreement with those of the present work shown in Fig. 4. The slight difference in composition is, however, found between these two works, but the origin is not clear at the present stage.

The X-ray oscillation photograph of a single crystal specimen and the electron diffraction pattern of an evaporated thin film, as shown in Fig. 6 and Fig. 8 respectively, can well be explained by the one-dimensional anti-phase domain structure model. Thus, the result of Schubert *et al.* has been confirmed. The values of the period of out-of-step, M , decreases gradually from 2.0 to 1.7 as the concentration of magnesium increases (Fig. 7). Such a result is also in accord with that of Schubert *et al.* qualitatively. An attention should be paid, however, to the fact that the

observed values of M are generally not integral in spite of the sharpness of split superlattice reflections. This fractional property of M has already been discussed by one of the present authors (K.F.)⁷⁾. That is to say, the fractional value of M can be interpreted by considering a model in which a few, different periods of anti-phase domain are mixed uniformly but probably with some irregularity. For details reference may be made to the original paper.

Schubert *et al.* reported that several, faint, additional lines were found in their powder photographs of the alloy containing magnesium more than 26 per cent. In the present work, however, no additional pattern could be observed. In the electron diffraction patterns of CuAu II ⁸⁾, Cu_3Pd ⁹⁾ and Au_3Mn ¹⁰⁾, which have also anti-phase domain structures, the strange satellites flanking normal spots have been observed. The appearance of such satellites may be expected in the case of Ag_3Mg , too. They were, however, not observed even in the highly ordered specimen which had been annealed at 150°C for 106 hours.

b) Discussions on the Calorimetries and the Measurement of Electrical Resistivity

The values of the critical temperature determined by calorimetries agree quite well with those of Clarebrough and Nicholas¹⁾ and of Kachi²⁾ deduced with different experimental methods. The present work has, however, failed to reveal the quantitative relationship between configurational energy and period of out-of-steps owing to the complexity of the phenomena and the relatively low accuracies of experiments. The peak of configurational energy versus composition curve, as shown in Fig. 13, seems not to lie just in 25 per cent but to shift to a little higher concentration of magnesium. This slight shift is not thought to relate to the value of M which decreases monotonously as the concentration of magnesium increases. Such a phenomenon may be considered in connection with the degree of volume contraction in ordering process which increases with composition as shown in Fig. 5.

It is unfortunate for the results of the present calorimetries that all extant theories can tell nothing about the anti-phase domain structure. Nevertheless, some comparisons

between theories and experiments were made in Table I, where $E(Tc+)$, $\phi(Tc+)$ and Q represent the configurational energy and

Table I. Comparison between theories and the data of calorimetry.

	Experiment (25.4% alloy)	Theories (A_3B -type)	
		Bragg-Williams	Peierls
T_c	666°K	—	—
$E(Tc+)$	560 ± 25 cal/mol	—	—
$\phi(Tc+)$	0.94 ± 0.05 cal/deg. mol	—	—
Q	150 ± 10 cal/mol	—	—
$RT_c/E(Tc+)$	2.37 ± 0.11	2.19	2.38
$\phi(Tc+)/R$	0.47 ± 0.03	0.562	0.46
Q/RT_c	0.11 ± 0.01	0.100	0.27

entropy just above the critical temperature and the latent heat, respectively. Fairly good coincidence exists between them, and thus no singularity due to the existence of anti-phase domains could be detected.

It is interesting to compare the specific heat versus temperature curve of 25.4 per cent alloy, as shown in Fig. 11, with the electrical resistivity versus temperature curve of 24.8 per cent alloy, as shown in Fig. 14. Both specimens were initially quenched from 500°C into water, and then they were heated up at the almost similar rates. Owing to the development of order, the decrease of specific heat appears at about 100°C, while the electrical resistivity begins, on the contrary, to increase anomalously at the similar temperature, and then turns to decrease at about 260°C. Such an anomalous increase of electrical resistivity in the initial process of ordering can be seen also in the data of Clarebrough and Nicholas¹⁾, though they did not point it out. Similar phenomena have been observed in other superlattice alloys such as Cu_3Au ¹¹⁾ and Cu_3Pd ¹²⁾, and they seem to relate to the anti-phase domain structure in the follow-

ing way. The development of order in a domain may induce the decrease of electrical resistivity, while the formation of anti-phase domain boundaries may, on the other hand, induce the increase. If the latter effect is thought to overcome the former at the early stage of ordering, such a curious phenomenon may be expected.

Acknowledgements

The authors wish to express their sincere thanks to Dr. S. Kachi for the kind dispensation of his own specimens and for the useful discussions and also to Mr. S. Ikeda for his kind offices on the chemical analyses of several specimens.

The present investigation has partly been supported by the fund of the Ministry of Education in Aid of Scientific Researches.

The Paramagnetic Susceptibility of Some Nickel Salts

By Taiichiro HASEDA and Muneyuki DATE

*The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan*

(Received November 15 1957)

Paramagnetic susceptibilities of some nickel salts were measured in the temperature range between 1.40°K and 290°K. The flat behavior of the susceptibility *vs* temperature curve in the lowest temperature region was especially prominent in $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$. The paramagnetic susceptibility of a powdered specimen of the nickel salt was calculated with the low field approximation. The characteristic behavior of a nickel ion in various salts was explained as due to the Stark splitting of the lowest spin triplet. The measured values of susceptibility were analysed and consistent results were obtained. Especially in $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, the crystalline field was expected to be much deformed from cubic symmetry and this is consistent with the fact that the paramagnetic resonance could not be detected at 9800 and 18000 Mc/sec in this salt.

§ 1. Introduction

The development of the microwave technique makes it facilitate to determine the energy splitting of the paramagnetic ions in crystalline field. Numerous investigations have been made on various salts. However, there are also a number of salts in which the paramagnetic resonance is not detected. The reason for the failure to detect the resonance is attributed to too short spin-lattice relaxation times in some cases or to too large energy splittings in some cases. Thus, in these salts, an alternative procedure is necessary to determine the energy levels of the salts; the determination of the parameters in the energy splitting expression by comparing the calculated susceptibility with the experimental values in a wide temperature range, is yet a very useful method now.

Some measurements have been made on the susceptibility or on the magnetic anisotropy of hydrated nickel salts in the temperature range mostly from 14°K to 290°K,¹⁾ and these results have been interpreted using Schlapp and Penney's theory²⁾ or more carefully in some cases.³⁾ As is well known, the orbital levels of divalent nickel ions in a cubic field split like those of trivalent chromium, leaving an orbital singlet lowest. So, a rather long spin-lattice relaxation time is expected. In fact, paramagnetic resonance has been detected in many nickel salts at room temperature. If the crystal structure is also known, a theoretical analysis can be

made in detail. However, there are also some nickel salts of which the crystal structure are not known exactly in addition to the failure of paramagnetic resonance data. The analysis of susceptibility data in these cases give only ambiguous results. Notwithstanding these unfavourable conditions, it may still be worthwhile to get a qualitative information about energy levels in these cases. From this point of view, the expression of susceptibility of a nickel salt in powdered form especially at very low temperatures is given in this paper. It is intended to account for the nature of the susceptibility of $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ under the hypothesis of considerable distortion of the crystalline field from cubic symmetry.

§ 2. Experimental

Susceptibilities of powdered samples of $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$, $\text{NiK}_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ and $\text{NiSiF}_6 \cdot 6\text{H}_2\text{O}$ were measured in the temperature range from 1.40°K to 290°K. The method used was a usual a.c. bridge method. The frequency used was 90 c/s. The effective measuring field was about two or three gauss.

The experimental results are given in Table I and Fig. 1. Susceptibility of NiNH_4 Tutton salt was measured by Jackson down to liquid hydrogen temperatures, and the Weiss constant was given to be about -4°K .⁴⁾ However, as can easily be seen from Table I, the Weiss constant is almost zero in two

Table I. Molar Susceptibility of Nickel Salts

- × NiSiF₆·6H₂O

Tutton salts and in fluosilicate. The reason for so large θ can not be found out theoretically even if the exchange interaction is taken into account.

A characteristic feature is distinct in NiCl₂·6H₂O at very low temperatures. χ_M is quite flat below about 5°K. Measurement on paramagnetic resonance was undertaken at 9800 and 18000 Mc/sec, but any resonance line was not observed. This will be accounted for naturally from the discussions described in the following section.

In Fig. 2, susceptibilities of the former three salts at liquid helium temperatures are shown. It is evident that the characteristics to be flat at the lowest temperature are com-

Fig. 2. Reciprocal of molar susceptibility of nickel salts at very low temperatures.

- NiK₂(SO₄)₂·6H₂O
- Ni(NH₄)₂(SO₄)₂·6H₂O
- × NiSiF₆·6H₂O

mon in two Tutton salts. Fluosilicate, as is well known, has a trigonal crystalline field and there remains spin degeneracy at the lowest temperature. Values obtained do not show any tendency to be flat at the lowest temperature. These facts are consistent, indeed, with the consideration mentioned below.

§ 3. Calculation of the Paramagnetic Susceptibilities

As is described in the preceeding section, the deviation of the susceptibilities of NiCl₂·6H₂O from the Curie law is remarkable at low temperatures. This deviation of Ni⁺⁺ ion was investigated by Schlapp and Penney²⁾ who pointed out the importance of temperature independent part which is called high frequency term. This is important for the analysis of the susceptibilities at high tempe-

atures because the susceptibility following the Curie law is small at high temperatures. However, Schlapp-Penney's calculation is not so important in the low temperature region and our experimental result cannot be explained by their theory. In this section, it is shown that this low temperature anomaly can be explained by the crystalline Stark separation of the lowest spin triplet. We used the spin Hamiltonian which is familiar in the analysis of the paramagnetic resonance. As Schlapp-Penney's term is not so important at low temperatures as described before, we will neglect it except the analysis of the experimental data at high temperatures observed in our experiments.

As is well known, the ground state of N^{++} ion is ^3F and the degeneracy of ^3F is removed by the cubic crystalline field. Under these conditions, the lowest state is spin triplet that is perfectly degenerate. In most crystals, however, the crystalline electric field have lower symmetries such as trigonal, tetragonal or rhombic. In general, this can be described by the following spin Hamiltonian:⁵⁾⁶⁾

$$H = DS_z^2 + E(S_z^2 - S_y^2) + g\beta H S, \quad (1)$$

where D and E are axial and rhombic crystalline field constant, respectively, and the last term represents the Zeeman energy. The solution of Eq. (1) can be represented as follows:

$$\begin{aligned} -W^3 + 2DW^2 + (E^2 - D^2 + g^2\beta^2 H^2)W \\ - g^2\beta^2 H^2 \{D(l^2 - m^2) - E(l^2 - m^2)\} = 0, \end{aligned} \quad (2)$$

where, l , m , n represent the direction cosine of the angle between magnetic field H and principal axis. Eq. (2) can easily be solved when H is parallel to the principal axes,

(a) $H \parallel x$

$$\left. \begin{aligned} W_1 &= \frac{D+E}{2} - \sqrt{\left(\frac{D+E}{2}\right)^2 + g^2\beta^2 H^2}, \\ W_2 &= D - E, \\ W_3 &= \frac{D+E}{2} + \sqrt{\left(\frac{D+E}{2}\right)^2 + g^2\beta^2 H^2}, \end{aligned} \right\} \quad (3)$$

(b) $H \parallel y$

$$\left. \begin{aligned} W_1 &= D + E, \\ W_2 &= \frac{D-E}{2} - \sqrt{\left(\frac{D-E}{2}\right)^2 + g^2\beta^2 H^2}, \\ W_3 &= \frac{D-E}{2} + \sqrt{\left(\frac{D-E}{2}\right)^2 + g^2\beta^2 H^2}, \end{aligned} \right\} \quad (4)$$

(c) $H \parallel z$

$$\left. \begin{aligned} W_1 &= D - \sqrt{E^2 + g^2\beta^2 H^2}, \\ W_2 &= D + \sqrt{E^2 + g^2\beta^2 H^2}, \\ W_3 &= 0. \end{aligned} \right\} \quad (5)$$

These results are illustrated in Fig. 3.

Fig. 3. Energy level splitting of Ni^{+2} ion (not to scale).

As is well known, the general formula of the magnetic susceptibility is

$$\chi = -\frac{NkT}{H} \frac{\partial}{\partial H} \log Z, \quad (6)$$

where Z is the partition function and N is the number of magnetic ions.

Forming the partition function from Eqs. (3), (4) and (5), and using the relation (6), we can get the principal susceptibilities as follows:

$$\chi_x = \frac{2Ng^2\beta^2}{\frac{D+E}{2}} \frac{\sinh \frac{D+E}{2kT}}{\exp\left(\frac{3E-D}{2kT}\right) + 2 \cosh \frac{D+E}{2kT}}, \quad (7)$$

$$\chi_y = \frac{2Ng^2\beta^2}{\frac{D-E}{2}} \frac{\sinh \frac{D-E}{2kT}}{\exp\left(-\frac{3E+D}{2kT}\right) + 2 \cosh \frac{D+E}{2kT}}, \quad (8)$$

$$\chi_z = \frac{2Ng^2\beta^2}{E} \frac{\sinh \frac{E}{kT}}{\exp\left(\frac{D}{kT}\right) + 2 \cosh \frac{E}{kT}}. \quad (9)$$

To get the equation (7)~(9), the low field approximation is used. The results in the case of $NiNH_4$ Tutton salt are shown in Fig. 4.

The energy levels can also be obtained for the arbitrary directions with the low field approximation. The results are as follows:

Fig. 4. Molar susceptibility of nickel salts. χ_{curie} shows the susceptibility of $D=E=0$, $g=2.25$.

$$\chi_p = \frac{2Ng^2\beta^2}{3(D^2-E^2)} \frac{2D - \left\{ \frac{3E^2-D^2}{E} \sinh \frac{E}{kT} + 2D \cosh \frac{E}{kT} \right\} \exp\left(-\frac{D}{kT}\right)}{1 + 2 \exp\left(-\frac{D}{kT}\right) \cosh \frac{E}{kT}} \quad (11)$$

At $T=0$, Eq. (11) becomes

$$\chi_{p, T \rightarrow 0} = 2Ng^2\beta^2 \frac{-(D+3E)}{6E(D+E)} \quad (12)$$

It must be noticed that the powder susceptibility becomes temperature independent at sufficiently low temperatures and the example is illustrated in Fig. 4 in the case of $\text{Ni}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ which has been investigated by means of paramagnetic resonance^{3), 5)} and D , E and g are well known ($D=-2.24$, $E=-0.39$, $g=2.25$). Though the deviation from Curie's law is small, the theoretical results show a satisfactory coincidence with experimental ones. Then let us consider the anomaly of $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$. This can be explained if we assume D and E , about twenty times greater than that of NiNH_4 Tutton salts. This means the presence of a large deformed electric field on Ni^{++} ion in the crystal. The precise results may be obtained by paramagnetic resonance which could not be observed in the usual microwave region. Submillimeter wave may be necessary for this purpose. It must also be noticed that, D and E are assumed to be large

$$\left. \begin{aligned} W_1 &= D - E - \frac{g^2\beta^2 H^2}{2E} \\ &\quad + \frac{g^2\beta^2 H^2}{2E(D-E)} \{D(l^2+m^2) - E(l^2-m^2)\}, \\ W_2 &= D + E + \frac{g^2\beta^2 H^2}{2E} \\ &\quad - \frac{g^2\beta^2 H^2}{2E(D+E)} \{D(l^2+m^2) - E(l^2-m^2)\}, \\ W_3 &= -\frac{g^2\beta^2 H^2}{D^2-E^2} \{D(l^2+m^2) - E(l^2-m^2)\}, \end{aligned} \right\} \quad (10)$$

Then, using Eq. (6) and averaging for all directions, we get the susceptibility for powdered samples,

compared to the Zeeman energy and therefore our results are not used in the case of $\text{NiSiF}_6 \cdot 6\text{H}_2\text{O}$ in which Ni^{++} ion is subjected to a crystalline field of trigonal symmetry and $E=0$.

It may also be interesting to investigate the effect of the exchange interaction, especially on $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, concerning the above mentioned behaviour.

X-ray Studies on the Structures of Solid Solutions NaCl-CaCl₂

III. Influence of Heat Treatments on the Diffuse Reflexions of X-rays due to {111} and {310} Plate-Zones

By Kazuo SUZUKI

Tokyo Institute of Technology, Oh-Okayama, Meguro, Tokyo

(Received October 30, 1957)

As reported in previous papers (J. Phys. Soc. Japan, **9** (1954) 702; *ibid.* **10** (1955) 794), single crystals of solid solutions NaCl-CaCl₂ contain two kinds of plate-zones extending parallel to {111} and {310} planes of the matrix. The present study concerns with the change of these plate-zones by heat treatments at various temperatures. Single crystals of solid solutions NaCl-CaCl₂ containing 10 mole per cent CaCl₂, which have been made uniform solid solutions by pre-heating at 400°C (being slightly above the solid-solubility limit of the phase diagram of NaCl-CaCl₂ system), were aged at room temperature or heated at higher temperatures. It is found that the {310} plate-zone is stable only at low temperatures, while the {111} plate-zone is more stable at higher temperatures. As the heating temperature is raised, the {111} plate-zone gradually tends from a coherent structure to an incoherent structure. Rotating-crystal X-ray photographs for the crystal heat-treated at 300°C (being slightly below the solid-solubility limit of the phase diagram) reveal that the final products of the precipitation have the crystal structure of CaCl₂, with an orientation favouring the structure model of the {111} plate-zones proposed in Part II.

§ 1. Introduction

In previous papers,^{1), 2), 3)} it was reported that single crystals of the solid solutions of NaCl with a few mole per cent of CaCl₂ give the characteristic diffuse reflexions of X-rays corresponding to a rod-like distribution of the intensity around reciprocal-lattice points for the matrix. These diffuse reflexions were interpreted as being due to precipitation of small plate-like structures (called the *plate-zones*), parallel to {111} or {310} planes of the matrix lattice. In order to explain the fact that the rods in reciprocal space appear only at the normal reciprocal-lattice points of the matrix but not at any super-reciprocal-lattice points, it was assumed that each of the plate-zones was composed of smaller regions (called *platelets*), which possess a quasi-crystalline structure with super-lattice periods and are clustered together rather compactly with anti-phase relations among themselves (Part I).

In Part II of the paper, the structure of the platelets were proposed by anticipating that the arrangement of ions around a Ca⁺⁺ ion in each platelet is somewhat similar to the crystal structure of CaCl₂, and a good agreement was obtained between calculated

and observed intensities of the rods, especially for the $\langle 111 \rangle_r$ rods.

In the present paper, the influence of the heat treatments of samples on the diffuse scattering is reported in more detail than that briefly described in Part II. It was confirmed, in particular, that at higher temperatures the patterns due to the $\langle 111 \rangle_r$ rods change to spotty patterns due to the crystallites of CaCl₂ with orientations favouring the proposed structure model in Part II for the {111} platelets.

§ 2. Experimental

Single crystals of solid solutions of NaCl containing 10 per cent CaCl₂* are used for the specimen, because these can give intense diffuse reflexions. The procedure of heat treatment of the samples is as follows. The crystal suitably shaped by cutting and etching according to the processes described in Part I is put in a small vessel made of thin nickel plate (0.07 mm thick), and heated in an electric furnace kept at a desired temperature. After heating for about 1 hour, the vessel is quickly

* As to the implication of the percentage of CaCl₂, cf. Part I § 2 a).

cooled by placing it on a copper plate kept at room temperature (about 15°C). Because of small heat capacity of the vessel as well as of the specimen, it is conceived that the high temperature states can be quenched sufficiently well to the room temperature by the above procedure.

The specimens heat-treated as above were studied at the room temperature by the stationary-crystal or the rotating-crystal X-ray methods, using Ni-filtered Cu radiation. The distance from specimen to film were 4 cm.

§ 3. Influence of Heat Treatments on the $\langle 111 \rangle_r$ and $\langle 310 \rangle_r$ Rods

The present study on the influence of heat treatment was made by starting from the crystals which were pre-heated at 400°C for 1 hour followed by quenching to a room temperature. As seen in Fig. 1a, the diffraction photograph taken with this crystal shows almost no extra reflexions, indicating that Ca^{++} ions and vacancies are almost uniformly distributed at the atomic sites of NaCl crystal.** It is supposed that the heating at 400°C for the crystal used corresponds to the point "A" in the phase diagram, and it is brought to the point "B" by the quenching (Fig. 2).

The specimens thus treated were subjected to two kinds of treatments; i.e., i) the aging

Fig. 2. Part of the phase diagram for NaCl- CaCl_2 system at lower CaCl_2 compositions.

** The patterns contain no diffuse reflexions except a faint diffuse reflexion located at $(\frac{1}{2}, \frac{1}{2})$. This reflexion suggests a new type of imperfection to exist in the matrix lattice at this stage (cf. Part I § 3 a)).

at room temperature, and ii) the heating at higher temperatures.

i) Room-temperature aging

Fig. 1b shows the diffraction photograph taken when the preheated specimen was kept for 3 days at room temperature. The photograph was taken with the $[001]$ axis vertical and $\varphi = 23^\circ$. φ is the angle between the incident beam and the horizontal $[0\bar{1}0]$ axis. In this photograph the diffuse reflexions due to $\langle 310 \rangle_r$ rods can already be seen around the (200) point of the matrix. The diffuse reflexions due to $\langle 111 \rangle_r$ rods are, however, not yet appearing. Fig. 1c corresponds to the specimen kept for a month, in which we can see that the diffuse spots due to the $\langle 310 \rangle_r$ rods grew intense still further, and at the same time, those due to the $\langle 111 \rangle_r$ rods began to appear.

ii) High-temperature treatments

The influence of heat treatments was studied in the following way. A pre-heated crystal was heated at first at a temperature, say 50°C, and quenched to room temperature and then examined by X-rays. The same sample was next heated at a higher temperature, say 100°C, and quenched to room temperature and again examined by X-rays; and so on. The pre-heat treatment of the specimen was not applied at the stage between two successive heat treatments, because the crystal became imperfect when the specimen was subjected to many cycles of heat treatments across the solid-solubility limit of the phase diagram.

Figs. 3a~f show examples of the stationary-crystal photographs. The orientation of the crystal with respect to the incident X-ray beam is nearly the same as in the case of Fig. 1. By the heating at 50°C, there occurred no appreciable changes as compared with the case of Fig. 1a. When heated at 100°C (Fig. 3b), both the $\langle 111 \rangle_r$ and $\langle 310 \rangle_r$ rods began to appear. Diffuse spots due to the $\langle 310 \rangle_r$ rods were, however, considerably weaker than those due to the $\langle 111 \rangle_r$ rods. When heated at 150°C, diffuse spots due to the $\langle 111 \rangle_r$ rods became very strong, although the length of the rods became short; on the other hand, those due to the $\langle 310 \rangle_r$ rods were completely disappeared (Fig. 3c).

In the same photograph there appear many sharp and strong extra spots, and also streaks

Fig. 1. Stationary-crystal X-ray photographs for the single crystal of NaCl-CaCl_2 solid solution containing 10 % CaCl_2 at several stages of aging at room temperature after being pre-heated at 400°C and quenched to a room temperature. $[001]$ axis vertical, $\varphi=23^\circ$. Filtered Cu radiation, 40 kV, 10 mA, 8 h. Flat films. (a) Immediately after the heat treatment; (b) 3 days after the heat treatment; (c) 4 weeks after the heat treatment.

which are either passing through or lying between the spots. Though it appears at first sight that some of the spots due to the $\langle 111 \rangle_r$ rods (indicated by arrows) are stronger than the rest of the spots due to the same rods, these are overlapped by weak extra reflexions. When the temperature of heat treatment is raised, the reflexions overlapping at the $\langle 111 \rangle_r$

rods increase their intensities and sharpness, and are gradually separating from the $\langle 111 \rangle_r$ rods. At the same time, the streaks change gradually to sharp spots as seen in Figs. 3c~e.

At 300°C (Fig. 3f), the reflexions due to the $\langle 111 \rangle_r$ rods and also all the streaks were perfectly changed to sharp spots. The arrangement of these spots is rather complex

Fig. 3. Stationary-crystal X-ray photographs for the pre-heated single crystal of NaCl- CaCl_2 solid solution containing 10 % CaCl_2 at several stages of heat treatments. but symmetric with respect to the Laue diffraction pattern due to the matrix lattice, indicating preferred orientations of a certain kind of precipitated particles in the matrix. By taking rotating-crystal X-ray photographs as described in the next section, these precipitates are found to be CaCl₂ crystallites.

§ 4. Crystal Structure of Precipitates and their Arrangement relative to the Matrix Lattice

a) Rotating-crystal X-ray photographs

Rotating-crystal photographs were taken for the specimen heat-treated at 300°C, which gave the Laue diffraction pattern of the type as shown in Fig. 3f. The crystal was rotated around either [001] or [101] axis of the crystal. On Fig. 4 corresponding to the [001] axis rotation there appear weak but sharp reflexions superposed on the strong reflexions due to the matrix lattice. The weak reflexions are grouping on several rings of different spacings. In the first column of Table I, the

spacings corresponding to the observed spots are given. The spacings of lattice planes of CaCl₂ crystals⁴⁾ are also tabulated for comparison. We see that the lattice spacings of the precipitates coincide with those of CaCl₂.

b) Orientation of CaCl₂ particles

In analysing the rotating-crystal photographs,

it is convenient to use the cylindrical co-ordinates ξ , ζ and ω for representing the positions of the reciprocal-lattice points (Fig. 5). For the photograph shown in Fig. 4, the ζ -axis is taken parallel to the [001]_r axis of the matrix, while the ξ -axis is lying in the (001)_r plane. When the crystal is rotated around [001]_r, each reciprocal-lattice point moves on a circle with the radius ξ . The crossing points of these rings with the sphere of reflexion determine the conditions for the Bragg reflexions. In the case of the flat-film method, ξ and ζ are given by

$$\left. \begin{aligned} \xi &= \left\{ 1 + \frac{D^2 + x^2}{D^2 + r^2} - \frac{2D}{\sqrt{D^2 + r^2}} \right\}^{1/2}, \\ \zeta &= \frac{y}{\sqrt{D^2 + r^2}}, \end{aligned} \right\} \quad (1)$$

where x and y are the co-ordinate values of each reflexion spot measured on the film, re-

Fig. 5. Cylindrical co-ordinates for a reciprocal-lattice point P .

Fig. 6. (ξ, ζ) -diagram corresponding to weak reflexions in Fig. 4. Crosses which are enclosed by circles show the reflexions explained by Fig. 8; those not enclosed show the reflexions explained by Fig. 10.

spectively parallel and perpendicular to the equator line; D is the distance between the crystal and the film, and $r = (x^2 + y^2)^{1/2}$.

Fig. 6 shows the (ξ, ζ) -diagram for the weak reflexions appearing in Fig. 4. After some trials, we could find that at least some of the reflexions in Fig. 6 are explained by assuming that the precipitated crystallites of CaCl_2 structure (C) take relative orientations with respect to the matrix (M) as follows:

$$\left. \begin{aligned} (100)_C \text{ or } (010)_C // [\bar{1}11]_M, \\ [001]_C // \langle 110 \rangle_M. \end{aligned} \right\} \quad (2)$$

Fig. 7 shows the projection of reciprocal-lattice space for CaCl_2 crystal and that for the matrix related by the condition (2); the plane of projection is $(110)_{M,r}$ which is parallel to $(001)_{C,r}$. The $(hk0)$ points of CaCl_2 ($l=0$) lies on the plane of the projection, whereas

Fig. 7. Projection of reciprocal space for CaCl_2 crystal to the $(110)_{M,r}$ plane of the matrix which are related by the condition (2). Open circles correspond to reciprocal-lattice points of CaCl_2 which is oriented according to the relation $[010]_C // [\bar{1}11]_{M,r}$; filled circles correspond to those of CaCl_2 which is oriented according to the relation $[100]_C // [\bar{1}11]_{M,r}$. Indices are referred to open circles. Reciprocal space for the matrix is represented by solid lines; its reciprocal-lattice points are indicated by "M".

* $(hkl)_{M,r}$ and $[hkl]_{M,r}$ denote the lattice planes and lattice rows in reciprocal space of the matrix respectively, and $(hkl)_{C,r}$ and $[hkl]_{C,r}$ denote those in reciprocal space of CaCl_2 . Cf. Part I, p. 705.

the points with $l \neq 0$ are aligned on the line perpendicular to the plane of the projection

Fig. 8. (ξ, ζ) -diagram of the reflexion spots corresponding to the rotation of the reciprocal lattice of Fig. 7 around $[001]_{M,r}$.

passing through the corresponding $(hk0)$ point. The open and filled circles correspond respectively to the two alternative cases of the first relation in (2). Because of the smallness of the difference of the length of a - and b -axis of the CaCl_2 structure ($a=6.24 \text{ \AA}$, $b=6.43 \text{ \AA}$), the two kinds of points are almost overlapping except for higher indices.

The (ξ, ζ) -diagram of the reflexion spots corresponding to the rotation of the reciprocal lattice of Fig. 7 around $[001]_{M,r}$ is shown in Fig. 8. The spots explained by Fig. 8 are enclosed by circles in Fig. 6. The spots remain unexplained can be interpreted as follows. Though we have considered so far only the case where $[001]_C$ is parallel to $[110]_M$, it is possible to occur the cases in which $[001]_C$ is parallel to $[101]_M$ or $[011]_M$. We can equally construct the (ξ, ζ) -diagram for the latter cases, although the process of construction is

rather complex and some elementary geometrical considerations are needed because the axis of the rotation, $[001]_{M,r}$, is not contained in the $(101)_{M,r}$ or $(011)_{M,r}$ plane (Fig. 9). Fig. 10 shows the result of the construction.

We can see that all of the observed spots indicated in Fig. 6 are explained in this way.

As seen in Fig. 4, some of the reflexion spots due to the precipitates are broad and some are sharp. Moreover, some of the spots

in Fig. 4.

§ 5. Discussion

As was stated in Part I of the paper, the diffraction patterns due to the single crystals of solid solutions NaCl-CaCl₂ which are characterized by the rod-like distributions of the intensity weight in reciprocal space have analogous features with those due to many age-hardening alloys such as Al-Cu, Al-Ag, etc. Moreover, many analogous features with the case of the alloys can be found also with respect to the change of pattern with the heat treatments as described in § 3. These analogous features are expected to take place because of similar thermodynamical conditions on the phase diagram of the solid solutions NaCl-CaCl₂ and of the age-hardening alloys.

Since the crystals were pre-heated at 400°C and then quenched to the room temperature, each crystal was initially in a state of unstable super-saturation at the room temperature. Thus the precipitations of the {111} and {310} plate-zones took place by the aging at this temperature. Rate of precipitation of both kinds of plate-zones are, however, different. When the crystal was kept for 3 days at room temperature, precipitations were composed of {310} plate-zones only, and the {111} plate-zones scarcely appeared after a month. This fact suggests that at room temperature the activation energy for the formation of the {310} plate-zones is lower than for the {111} plate-zones.

As seen in the series of photographs in Fig. 3, the rate of precipitation of the both types of the plate-zones is considerably promoted by heating the crystal at higher temperatures. When the crystal was heated at 150°C, however, the $\langle 310 \rangle_r$ rods which had appeared by the heating at 100°C were perfectly disappeared, while the $\langle 111 \rangle_r$ rods became very strong. This fact suggests that the {310} plate-zone is stable only at relatively low temperatures, and the {111} plate-zone is more stable at higher temperatures, although as mentioned above the activation energy for the formation of the latter seems to be higher than that for the {310} plate-zone.

At 150°C, the extra spots also began to appear superposing on some of the $\langle 111 \rangle_r$ rods, and these became gradually strong and sharp as the heating temperature was elevated (Figs. 3b~d). We can infer from this fact

Fig. 9. Reciprocal space of the matrix showing two kinds of orientational relationship between the $[001]_{M,r}$ axis and the $\{110\}_{M,r}$ planes. $(011)_{M,r}$ plane is not shown since this is equivalent to $(101)_{M,r}$.

Fig. 10. (ξ, ζ) -diagram of the reflexion spots corresponding to the $[001]_{M,r}$ axis rotation of the reciprocal lattice of CaCl₂ being in the relation $(001)_{C,r} // (101)_{M,r}$ with respect to the matrix.

are long and some are short. These features are explained as follows. As seen in the Fig. 8 or 10, each reciprocal-lattice point is composed of two kinds of crystallites represented by open and filled circles, orienting according to the relation $(010)_{C,r} // \{111\}_M$ and $(100)_{C,r} // \{111\}_M$, respectively. Some of such pairs of the reciprocal-lattice points are closer, and some are apart. Besides, some of the reciprocal-lattice points in Fig. 8 are situated at positions very close to those in Fig. 10. Superposing the both figures results in the various features of individual reflexion spot observed

that at 150°C the {111} plate-zone, which has been coherent with the matrix when it was formed by the heat treatment at lower temperatures, have considerably grown up, and are now tending to an incoherent structure. Though the degree of incoherency seems to be still quite small at this stage, it is conceived that the incoherency becomes larger as the heating temperature is elevated further, and finally, to the extent that the particles of CaCl_2 crystals are deposited in the matrix.

Summarizing the above observations it is concluded that the features of the change of the diffraction patterns at relatively low temperatures are characterized by the existence of unstable plate-like regions or the plate-zones. Such unstable regions are well known in the case of age-hardening alloys by the name of Guinier-Preston zones.

In the case of the age-hardening alloys, the coagulation of vacancies in the quench-annealed alloys is considered to be an important factor for the formation of the Guinier-Preston zones.⁵⁾ As was stated in Part I, when CaCl_2 is dissolved in NaCl at higher temperatures, a Na^+ ion at a lattice site of NaCl is replaced by a Ca^{++} ion, and at the same time, another Na^+ ion is removed from the crystal to satisfy

the requirement of the neutrality of electric charge, leaving a positive ion vacancy. So that at least as many positive ion vacancies as the number of the Ca^{++} ions dissolved are frozen-in in the matrix lattice of the NaCl- CaCl_2 solid solutions. The fact that the plate-zones are formed at room temperature suggests that such vacancies can migrate in the interior of the matrix at this temperature, and they aggregate so as to form planar layers. Therefore, it is likely that in the case of NaCl- CaCl_2 solid solutions also the vacancies play an important role in the formation of the {111} and {310} plate-zones.

In conclusion, the author wishes to express his hearty thanks to Professor S. Miyake for his valuable discussions and helpful advices.

Collective Electron Ferromagnetism, III. Relative Magnetization of Ferromagnetic Alloys*

By HIROSHI WATANABE

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received August 20, 1957)

Here is studied the relative magnetization (ζ_0) at absolute zero of temperature of ferromagnetic alloys composed of the first transition metals (except manganese). Based on Stoner's representation of the reduced inverse susceptibility *vs* reduced temperature curves, ζ_0 values are found from the measured values of saturation magnetization at absolute zero (σ_0), of the Curie temperature (θ) and of the mass susceptibilities above the Curie temperature (χ). With the estimated values of ζ_0 , the number of carriers of ferromagnetism is plotted against the number of outer electrons. It is found from experiments on some body-centered cubic alloys of iron that ζ_0 is not much less than unity for these alloys, and hence it is concluded that for body-centered cubic alloys the lower half of the d band is not responsible for ferromagnetism. A similar analysis for face-centered cubic alloys shows that ζ_0 values of face-centered cubic cobalt-iron and nickel-iron alloys decrease gradually as the iron content increases, and the number of carriers of ferromagnetism becomes greater than 2 per atom near the composition of the body- and face-centered cubic boundary. Some other examinations are also made on the band theory of ferromagnetism in relation to the neutron diffraction experiments made by Shull and Wilkinson.

§ 1. Introduction

Collective electron theory of ferromagnetism has been successfully applied to some of the cobalt alloys¹⁾ as well as to quite a number of nickel alloys.²⁾³⁾ And it has also been emphasized that it is much more difficult to interpret the experimental data on iron alloys with the theory.⁴⁾ There are many theories concerning the ferromagnetism of iron and its alloys with other elements, both on the side of the localized electron and on the side of the band picture, but none of them seems to have been accepted as being preferable to the others.

As for the band picture, there are two categories: one of them which has been suggested by Coles and Hume-Rothery⁵⁾⁶⁾ assumes a fairly low value of ζ_0 of 0.76 for iron, assigning + spins for 4.65 d -electrons per atom and—spins for 2.45 d -electrons per atom (n_d , the total number of d -electrons, being assumed to be 7.1 per atom). The magnitude of the exchange energy of the electrons has been regarded as insufficient to align all the spins

in one direction. And further, they attribute the departure of ζ_0 from unity to the broadening of d band, which would be expected to occur along the series nickel→cobalt→iron. The other, put forward by Pauling,⁷⁾ assumes two types of d -functions, one responsible for ferromagnetism, the other for cohesive energy. With this picture the value of ζ_0 should be close to unity for iron provided that the electrons of the latter type are excluded from the carriers of ferromagnetism.

The primary purpose of this paper is to get experimental informations concerning ζ_0 from the measurements of paramagnetic susceptibilities above the Curie temperature, and of the saturation magnetization at absolute zero of temperature (σ_0) for body-centered cubic iron alloys, as well as for face-centered cubic alloys, and to interpret the magnetic properties of alloys composed of the first transition elements on a unified basis.

§ 2. Experimental Procedure and Results

As is well known, alloys rich in iron crystallize in body-centered cubic structure, but, in general, they are apt to be transformed into face-centered cubic structure at high tempera-

tures, the susceptibility undergoing thereby an abrupt change. In order to avoid this transformation we have added a few percent (approximately 5%) vanadium to all of the samples studied in order to suppress this transformation.

Experimental results are shown in Figs. 1 and 2. In Figs. 1a and b, inverse mass susceptibilities of iron-cobalt-vanadium and iron-chromium-vanadium alloys, respectively, are plotted against temperature. The susceptibilities were measured with a pendulum magnetometer and an electromagnet. The samples were put in a small vessel, and were evacuated and sealed off. The measurements

showed no thermal hysteresis for the samples studied here (cobalt content less than 20% for iron-cobalt-banadium alloys, and chromium content less than 30% for iron-chromium-vanadium alloys).

In Fig. 2a and b, the saturation magnetization at absolute zero and the ferromagnetic Curie temperature of both of the alloy systems, respectively, are plotted against composition. For comparison, data of vanadium-free alloys are taken from other author's measurements and are also shown in the figures by the dotted lines (the saturation magnetization of the iron-cobalt alloys are due to Weiss and Forrer,⁸⁾ that of the iron-chro-

and iron-vanadium alloys.

In Fig. 3a, we have given a few computational results of reduced inverse susceptibility against reduced temperature. Curve A is the original Stoner curve¹¹⁾, obtained by assuming a single parabolic band. Other curves will be explained in the next section. We have summarized our data in Figs. 4a and 4b in a similar representation. The comparison of points in these figures with curve A in Fig.

3 readily gives an estimation of ζ_0 values of the measured alloys. Then we find that the values of ζ_0 of these alloys are within the range of values between 0.95 and 1.

We should have extended our measurements to the alloys containing chromium more than 30 percent if there had been no complications as to the phase diagram¹²⁾¹³⁾, but it was given

§ 3. Criticism of the Estimation of the Relative Magnetization

The procedure of the estimation of ζ_0 value from Stoner's curve is based on a single parabolic band model, while the band structure of actual alloys, of course, can by no means be described by such a simplified picture. So there remains a question that the estimated value of ζ_0 would not be a good approximation to the actual alloys. Probably, we should take into account the band overlap effect, and also more general form of the relevant bands. The former effect can be treated analytically with a few assumptions which may be regarded as reasonable. Such a calculation has been made by Wohlfarth for nickel and nickel-copper alloys²⁾ and revealed that the value of ζ_0 is changed only slightly from that derived from the single band model. We made a similar calculation in the case of iron, assuming the degree of overlapping of the s band to be roughly equal to that in the case of nickel, and taking the exchange transfer effect* of electrons from d to s band into account. The result of the calculation is shown by curve B^{**} in Fig. 3a, and it is seen that ζ_0 value to be obtained by referring to curve B is not changed by over 2% from that to be obtained from curve A . Further, the result does not change materially if we take a model in which the carriers of ferromagnetism are not holes but electrons. Curve C^{**}

in Fig. 3a is the result of a calculation based on such a model, again with the assumption of overlapping s and d bands.

To summarize, the effect of band overlapping is not of primary significance for the evaluation of ζ_0 value.

It is more difficult to solve the problem of the band shape. It is almost impossible to manage the general case of band structure in an analytical form. Some calculations have been made for several cases other than that where the band form is parabolic or rectangular by Elcock *et al*¹⁶⁾, but their studies are restricted to paramagnetics, and it is not easy to see how the results would come out in the case of ferromagnetics. At least, however,

Fig. 5. (a)-(e): Some representative curves of band structure discussed qualitatively in 3. (f): The detail of case (e). The shaded regions are occupied levels.

* Cf. Appendix I.

** Cf. Appendix II.

we may say that in our case the estimated values of ζ_0 would not be changed appreciably if the band form does not differ considerably from the standard one. For instance, if we take the band form to be rectangular, the result is $\zeta_0=1$ wherever ($0 < \zeta_0 < 1$ being inhibited in this case), and the conclusion is substantially unchanged. A further qualitative discussion can be made with the help of our previous work on the condition of the occurrence of ferromagnetism⁴⁾. Some representative cases were treated there: In the first case where the state density *vs* energy curve is a decreasing function of energy near the Fermi level (Fig. 5(a)), the minimum exchange energy required for ζ_0 to be unity should be an increasing function of the electron concentration. If in the actual case of ferromagnetic elements, ζ_0 takes the value 1 for nickel or cobalt, while it takes a value less than 1 for iron, the exchange energy should be definitely smaller for iron than for nickel or cobalt. This case corresponds to a slight generalization of the standard band form (the case of curve A in Fig. 3a), and we may expect a smaller slope of the reduced inverse susceptibility *vs* reduced temperature curve for iron than for nickel or cobalt, which is contradictory to the experiment. This conclusion may not be changed appreciably if the band is closed on the low energy side (Fig. 5(b)). The second case is that shown in Fig. 5(c), in which the band has a low state density range in the middle. If the position of the Fermi level of iron were like what is given in the figure, and ζ_0 for iron were appreciably smaller than unity, then ferromagnetism would be observed for elements of lower electron concentrations, say for chromium or vanadium, as far as the band form and the exchange energy are regarded not to change appreciably with concentration. This does not seem likely to be true. The third case is one that represented in Fig. 5(d), in which the state density curve is an increasing function of energy at the Fermi level (Fig. 1 of reference 4). In this case the slope of the state density curve is essential for the slope of the equi-exchange interaction curve as given in that figure; in order to explain the slope of the saturation magnetization *vs* electron concentration curve for iron-chromium alloys on the assumption of constant exchange interaction, the slope of

the state density curve around the Fermi level of iron should be taken to be fairly steep that the state density in the region of non-ferromagnetic alloys is very small. This is what we have assumed in calculating curve B in the previous section. The remaining possibility that our estimation on ζ_0 would fail is one shown in Fig. 5(e), where the band has a long tail in the low energy part. In this case, the relative movement of the + and - spin bands would be such as is indicated in Fig. 5(f), unless the exchange integral takes an extremely high value in the region of low state density. Then ζ_0 would be less than unity while the reduced inverse susceptibility *vs* reduced temperature relation is not altered essentially from the case (d). The difference between cases (d) and (e), however, may be trivial as far as ferromagnetism is concerned, since we are not inquiring as to whether the electron spins in the low energy part of *d* band have positive or negative interaction. We shall call that part of the *d* band is not responsible for ferromagnetism.

§ 4. Discussion

Based on the experiments described in 2 and on the considerations sketched in 3, we may make some inquiries on the band structure of body-centered cubic ferromagnetic alloys. We can also make similar inquiries if we utilize the experimental results of other authors of face-centered cubic or hexagonal alloys. Such a discussion will be given below. In Fig. 6 are summarized the necessary data of the saturation magnetization at absolute zero, and the number of carriers of ferromagnetism deduced from the estimated value of ζ_0 .

(1) Body-centered cubic alloys.

As stated above, ζ_0 value is not much less than unity as far as the experimentally investigated alloys are concerned. We assume this is also true of other alloys. Then there are two cases which fit this fact according as the carriers of ferromagnetism are considered to be holes or electrons. The one is that the number of *d* electrons is equal to 10 minus the observed magnetic moment per atom (for iron, for instance, $n_a=10-2.2=7.8$, $n_s=8-7.8=0.2$); this possibility does not seem to be probable, since, for alloys with total number of outer electrons less than 7.9 per atom, we

would have negative values of n_s .

The other is that the maximum number of carriers of ferromagnetism of body-centered cubic alloy is roughly equal to 2.5 per atom, since this is the maximum observed value of saturation magnetization at absolute zero in Bohr magnetons for body-centered cubic alloys. From this standpoint, the number of energy levels of the band responsible for ferromagnetism should be equal to $2.5 \times 2 = 5$, which leads to a separation of d band into two halves:

$$d = d_1 + d_2,$$

where d_1 and d_2 are sub-bands not responsible and responsible for ferromagnetism, respectively, each sub-band accommodating 5 electrons per atom.*

Now let us compare our result with the picture of Coles and Hume-Rothery referred to in the introduction. In view of our measurements and of the discussion given in the preceding section, the only case where ζ_0 becomes appreciably less than unity should be that indicated in the diagram (e) of Fig. 5; the small value of ζ_0 , however, is not caused by the broadening of the band width with the decrease of electron concentration as they imagine, but is caused by the increasing significance of the low-state-density part of the d band.**

(2) Face-centered cubic and hexagonal alloys.

Nickel and its alloys with copper are the most fully investigated ones of this group.

* This conclusion is the same as that given by Bader *et al.*¹⁷⁾, though the agreement is merely accidental.

** A part of Coles' earlier concept presented in the discussion of electronic structure of titanium alloys is rather closer to our picture.

According to Wohlfarth's analysis²⁾ of the experimental data of them, ζ_0 value for nickel is just equal to unity, whereas it decreases with addition of copper at first slightly but more rapidly as the copper concentration becomes appreciable, falling to zero at about 60 at % copper. Although no detailed analysis has been given for nickel-zinc alloys, we may expect a similar situation for them.

Nickel-cobalt alloys have also been analysed by Wohlfarth¹⁸⁾ with the conclusion that ζ_0 is close to unity over the whole concentration range. According to a recent measurement of susceptibilities up to the melting point of cobalt made by Nakagawa¹⁶⁾, the value of ζ_0 is 0.95.

If we look at the range from cobalt to iron, the data of saturation magnetization due to Weiss and Forrer⁸⁾ and those of susceptibility due to Nakagawa¹⁶⁾ are available. Nakagawa measured the high temperature susceptibilities of cobalt-iron (3:1 at.) alloy. This alloy lies near the composition of the boundary between body- and face-centered cubic phases at room

temperature, and Weiss and Forrer's data for face-centered cubic alloys can easily be extrapolated to this composition, giving the moment of 2.0 Bohr magnetons per atom. Analysing these data, we find that $\zeta_0=0.89$ for this alloy. The number of carriers of ferromagnetism is then estimated to be approximately 2.3 per atom.

Other data giving informations concerning the face- and body-centered cubic phase boundary are those of nickel-iron alloys. This system has been studied in great detail by Peschard,¹⁹⁾ and we can take out necessary data from his measurements.* The result of the analysis for this alloy system in the face-centered cubic range is that ζ_0 is still less than that in the system of face-centered cubic cobalt-iron alloys. At the phase boundary, which lies at the composition of 34.1 at % nickel, $\zeta_0=0.72$, and the estimated number of carriers of ferromagnetism is approximately equal to 2.5 per atom.**

The author believes that the mechanism proposed by Coles and Hume-Rothery for body-centered cubic iron alloys should be really called for to explain the fall of ζ_0 value with increase of iron content in face-centered cubic iron alloys.

(3) Chromium or vanadium added to face-centered cubic alloys.

The saturation magnetization of nickel-chromium and nickel-vanadium alloys deviate from the so-called Slater-Pauling curve^{7)***}. To explain this deviation, it has been proposed by Carr²¹⁾, in connection with the Zener theory of antiferromagnetic coupling between d electrons of adjacent atoms²²⁾, that the moments of chromium or vanadium align antiparallel to those of solvent atoms. His proposition is, however, doubtful, since the neutron diffraction experiment of cobalt-chromium by Shull and Wilkinson²³⁾ does not support such a spin configuration.

* Y. Nakagawa²⁰⁾ has also reported the susceptibility data of this system up to 1600°C, which are in good agreement with Peschard's in the solid state.

** This value is apparently greater than the maximum number of carriers of ferromagnetism predicted by Bader *et al.*, *viz.* 2 per atom.

*** Cf., for instance, R. M. Bozorth, *Ferro-magnetism* (D. van Nostrand Company, Inc., New York 1951) p. 441.

A model much more consistent with the neutron diffraction data can be obtained by assuming that the outer electrons of chromium enter the unoccupied levels of nickel or cobalt, leaving no appreciable moment on chromium atoms. Such an idea has long been proposed by Hirone²⁴⁾ and Wohlfarth²⁵⁾ for nickel alloys, and by the author¹⁾ for cobalt alloys. The neutron diffraction data give two possible configurations of spins, and no one can decide which is the correct one. In the case of cobalt-chromium, one gives small absolute values of chromium moment, while the other gives moment of 1.5-2 Bohr magnetons per atom which is parallel to the cobalt moments. Either configuration gives for cobalt atoms a decreasing moment with increasing chromium content. The above picture is compatible with the former configuration. We do not know, however, the precise number of electrons per chromium atom which enter into the d band of nickel, *viz.* the valency of chromium in this case. We have drawn the diagram in Fig. 7 on a somewhat arbitrary assumption

Fig. 7. Saturation magnetization (black points) in Bohr magnetons and number of carriers of ferromagnetism (open points) per atom of

● and ○ CO-Cr,

▲ and △ Ni-Cr,

against the number of outer electrons per atom. Here a Cr atom is assumed to throw all of its outer electrons to the d holes of Co or Ni.

that all of the $3d$ and $4s$ electrons of chromium enter into the d band of nickel or cobalt (Saturation magnetization data of cobalt alloys are due to Farcas,²⁶⁾ and susceptibility data due to our previous work¹⁾). The points do not lie on a clearly defined straight line, but

the discrepancy may partly be due to the ambiguity mentioned above of the valency of chromium, and partly to the change of band structure with addition of chromium.

(4) Number of s electrons, n_s .

As can be expected from the general grounds, the s electrons of nickel have the tendency to be transferred to the d levels to fill them up. Naturally this tendency is counteracted by another effect which is common to transition elements *i.e.*, that some of the s levels lie lower than the d levels. The actual feature of electronic structure will be dependent on the relative magnitude of these competing factors. If we go from nickel to cobalt, and from cobalt to iron, it is expected that the former effect should be weakened, and hence, that overlapping of s and d bands should be strengthened. The increase of n_s along this series indicated in Fig. 8 (n_s being

Fig. 8. n_s , the number of s electrons per atom against the number of outer electrons per atom. The symbols are the same as those in Fig. 6.

calculated from the estimated number of carriers of ferromagnetism) is in agreement with the expectation from the above consideration.

§ 5. Conclusion

By analysing the experimental results of susceptibility and saturation magnetization of ferromagnetic alloys, we have observed a definite distinction between the band structures of body- and face-centered cubic alloys. Among the current views on the electronic structure of such alloys, the Pauling picture is the best approach to the experimental results as far as body-centered cubic alloys are concerned. On the contrary, we encounter very low values of relative magnetization in some face-centered

cubic alloys, which is caused by the effective smallness of the exchange integral or of the density of energy states.

Finally a brief discussion will be made of the collective electron theory in the light of the results of neutron diffraction experiment obtained by Shull and Wilkinson.²⁸⁾ The collective electron theory, in its original form, does not distinguish between moments of different kind in an alloy, which is not consistent with the result offered by the neutron diffraction experiment that atoms of different kind have, in general, different moments. It may be noted, however, that the moments of constituent atoms are comprehensible by the theory.

A possible revision of the theory which takes account of the above situation may be made by considering the bands of constituent atoms separately,* an electron in one band is subjected not only to the molecular field due to the magnetization of the band to which it belongs but also to that due to the magnetization of the other band. In dilute alloys, the effect of the solute atom is determined primarily by the interaction between solvent and solute bands. In the case of face-centered cubic nickel-iron alloys, the interaction between nickel and iron bands may be estimated from the initial rate of increase of the Curie temperature with increasing iron content, while the decrease of the Curie temperature at higher iron concentrations may be attributed

to the broadening of the iron band and to a consequent decrease of ζ_0 in the same band. In the case of face-centered cobalt-iron alloys, the interaction between electrons in cobalt and iron bands is expected to be weaker than that between electrons in the cobalt band, as is indicated by the initial decrease of the Curie temperature with addition of iron to cobalt. The data for γ -iron itself are rather less conclusive; Wilkinson and Shull²⁷⁾ studied coherent and incoherent magnetic scattering in iron at high temperatures and found magnetic diffuse scattering corresponding to ferro-

* A similar picture has been proposed by Coles²⁹⁾ for the interpretation of the properties of copper rich nickel-copper alloys.

magnetic short range order in γ -iron, while Weiss have suggested that γ -iron is antiferromagnetic by extrapolating the neutron diffraction data on iron-manganese alloys²⁸⁾ to γ -iron. The disagreement may be reconciled by considering that the lattice expansion due to heating changes the antiferromagnetic coupling into a ferromagnetic one, but further experimental studies will be necessary before the problem is settled.

Acknowledgements

The author wishes to express his hearty thanks to Dr. E. P. Wohlfarth who has kindly given him valuable advices concerning the exchange transfer effect, and also to Dr. C. G. Shull, who has notified him of some of the details of the neutron diffraction data on γ -iron and body-centered iron-cobalt. Thanks are also due to Mr. K. Ito for his assistance in the experiments.

APPENDIX I

The Exchange Transfer Effect

When there are two overlapping electronic bands, and the exchange integral in each of the bands is different in magnitude from each other, the electron distribution among these bands may be different in general from the case where no such difference exists. We shall call this effect the exchange transfer effect. We shall evaluate the magnitude of this effect in the simple case of overlapping d and s bands, both assumed to be parabolic, in which it is assumed that s electrons have no exchange integral with one another. An additional assumption will also be made, which is not really justifiable in the strict sense, that the total exchange energy of d electrons is proportional to the square of the net moment.* This case has been treated mathematically by Wohlfarth²⁾ and the result of the analysis has been applied to the interpretation of magnetic properties of nickel-copper alloys by the same author, without including this effect in his calculation.

It can easily be shown from the considera-

* One may carry through the calculation with a better approximation by omitting this assumption. It is doubtful, however, if the result so obtained would be really improved in describing actual state of affairs, since there are many other factors which should be taken into account to this approximation.

tion of energy relation at absolute zero that the quantities related to the Fermi level of each band in Fig. 9 are connected by the following relationship:

$$\frac{1}{2}(\varepsilon_a^- + \varepsilon_a^+) = E - \varepsilon_s,$$

with

$$E = \varepsilon_{a_0} + \varepsilon_{s_0},$$

where ε_{a_0} and ε_{s_0} are ε values corresponding

Fig. 9. Relative movement of d and s bands in an overlapping band model.

to the case with no exchange integral in the d band. With the same assumptions as Wohlfarth's of the value of $r_0 = \varepsilon_{s_0}/\varepsilon_{a_0}$, and the interaction constant θ' satisfying the relation $k\theta'/\varepsilon_{a_0} = 2^{-\frac{1}{2}}$ for nickel, we may ask how his results would be modified.

The main feature of the modification is summarized in the following two points for the nickel-copper series of alloys. One is that the critical composition at which the d band is filled (and θ' falls to zero) is shifted to a slightly lower concentration of copper, *viz.* $C_{\text{crit}} = 0.6728$, from the value $C_{\text{crit}} = 0.6922$ given by Wohlfarth.** The other is that the number of s electrons at absolute zero is increased by the exchange transfer effect, since the additional kinetic energy will be more than offset by the gain in exchange energy due to the

** The composition at which ferromagnetism vanishes has been considered to be approximately 60 at % copper, from the measurement of saturation magnetization due to Alder,²⁹⁾ Marian, &c.³⁰⁾ A recent report by Ahern and Sucksmith³¹⁾ suggests, however, a slightly steeper slope of the saturation magnetization *vs* composition curve. This might be due to the general trend of the relative movement of s and d bands. Since the above analysis neglects this effect, a more detailed discussion of C_{crit} would be superfluous.

increased number of d holes. This effect is the more significant the lower the copper concentration. In the analysis, we fix the number of d holes at absolute zero N_{d_0} at 0.6 per atom for nickel, so that, as the temperature is raised from absolute zero, the exchange transfer effect will decrease, and this will have an effect to reduce the value of N_d . If the temperature is raised further, the normal transfer effect as treated by Wohlfarth becomes predominant. Fig. 10 is a

Fig. 10. Increase in the number of d holes as the temperature is raised from absolute zero to $T = \frac{(\varepsilon_{d0})_{Ni}}{2k}$, against copper concentration. Dotted line: Wohlfarth's calculation.²⁾ Solid line: Present calculation including the exchange transfer effect.

manifestation of such a modification plotting $N_d - N_{d_0}$ against concentration of copper, where N_d is the value at the temperature $T = \frac{(\varepsilon_{d0})_{Ni}}{2}$ ($=773^\circ\text{K}$ in our analysis). As can be seen from the figure, the modification as a whole is not serious in this case. The same can be said for the susceptibilities, and the qualitative aspects of Wohlfarth's results are not in error.

APPENDIX II

Specification of Models in Figs. 3a and 3b.

As for curve A of the single parabolic band model, the reader is referred to Stoner's original papers¹¹⁾ and also to Wohlfarth's.²⁾ The calculation for curves B and C of overlapping band models was made for iron with the assumption that the ratio $r_0 = \varepsilon_{s0}/\varepsilon_{d0}$, which is a measure of the degree of overlapping of the two bands, is equal to 2. This value was chosen because this gives for case B approximately the same degree of overlapping as adopted for nickel by Wohlfarth. This can

easily be seen from the relations:

$$N_d = \frac{4}{3} a_d \varepsilon_d^{\frac{3}{2}} \quad \text{and} \quad N_s = \frac{4}{3} a_s \varepsilon_s^{\frac{3}{2}}$$

The following formula may be obtained provided a_d and a_s are the same for nickel and for iron:

$$(\gamma_0)_{Fe} = (\gamma_0)_{Ni} \left(\frac{N_d}{N_s} \right)_{Ni}^{\frac{2}{3}} \left/ \left(\frac{N_d}{N_s} \right)_{Fe}^{\frac{2}{3}} \right.$$

If we put the values $(\gamma_0)_{Ni} = 10$, $\left(\frac{N_d}{N_s} \right)_{Ni} = \frac{0.6}{0.6} = 1$ and $\left(\frac{N_d}{N_s} \right)_{Fe}^{\frac{2}{3}} = \left(\frac{2.22}{0.22} \right)^{\frac{2}{3}} = 4.67$, we obtain $(\gamma_0)_{Fe} = 2.14$, which was substituted by the round number 2. For the analysis of case C, the same value of a_d/a_s as in B has been adopted, since we have no information of its accurate value. N_d and N_s for the calculation of the case of $\xi_0 = 1$ were chosen to be equal to 2.22 and 0.78, respectively, in accordance with the postulation suggested in the text of dividing the d band into two halves.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 2, FEBRUARY, 1958

On the Effect of High Energy Radiation to Polymers

I. Cross-linking and Degradation

By Osamu SAITO

Faculty of Engineering, Chuo University, Tokyo

(Received October 28, 1957)

Integro-differential equations are obtained, which describe the variation of molecular weight distributions in a polymer substance caused by irradiation. The solutions of these equations give the gel point and the average molecular weights. In the case of cross-linking without cyclization, the results agree with those obtained by other authors. The problems involving cyclization and branching are also solved, showing that the gel formation is retarded by cyclization and that the weight average branching number diverges at the gel point, while the number average branching number does not. As for degradation, the molecular weight distributions for an arbitrary radiation dose are obtained, and it is shown that for any initial distribution the final molecular weight distribution becomes Poisson-like. The problem which deals with the case where cross-linking and degradation coexist is also discussed, and it is shown that for any initial distribution the gel formation occurs only when the ratio of the two probabilities concerning degradation and cross-linking is smaller than 4.

§ 1. Introduction

It is well known that when long chain polymers are irradiated by high energy radiation, new chemical bindings between molecules and also molecular scissions are produced. These effects are classified into cross-linking, degradation and end-linking. Cross-linking is the chemical binding by which two molecules are combined at their side bonds. Degradation results from the scission of molecular main chains. When the molecular ends new-

ly produced by scission are active, they may combine with other molecules at the side bonds. This type of linking is called end-linking. On the other hand, when links are formed between monomers which belong to the same molecule, they are called cyclization. For larger radiation doses, the links become numerous resulting in the formation of gel part which is insoluble in any solvent. This part is composed of macromolecules and the instance when the gel part appears first is

called gel point. Theories of the cross-linking without cyclization were given by Flory¹⁻⁴⁾, Stockmayer^{5,6)}, and Charlesby⁷⁻⁹⁾. Flory obtained the gel point and the average molecular weights for uniform initial distribution and Stockmayer obtained those for arbitrary initial distribution. These theories are concerned with the polymers before the gel point. On the contrary, Charlesby's theory deals with the polymers after the gel formation, giving the gel point and the sol fraction. Charlesby^{10,11)} also developed similar theories about degradation and end-linking, in which cyclization was likewise neglected.

The author develops a new theory concerning the variation of molecular weight distribution induced by cross-linking and obtains the gel point and the average molecular weights, which are the same as those already published by other authors. A similar equation is given in the appendix of Stockmayer's paper, in which he uses discrete degree of polymerization and obtains only the solution for the most probable distribution, not for an arbitrary initial distribution. The theory in this paper is concerned with the most general cases and gives solutions for arbitrary initial distributions. Moreover, this theory can be extended to cases including cyclization and branching, which have not yet been treated. When degradation occurs, the distribution of polymerization is given by a formula in a closed form. The case where cross-linking and degradation coexist is also discussed.

The variation of viscosity of irradiated polymers have been measured by many researchers. However, no sufficient use of these results has been made to understand the behaviours of irradiated polymers, because there has been no exact theory concerning the variation of viscosity of irradiated polymers. The theory given in this paper gives a direct method to obtain the viscosity average molecular weight, so that experimental results are compared with it and interesting results are obtained, which will be described in later papers.

It is known that many irradiated polymers suffer at the same time two or all of the effects of cross-linking, degradation and end-linking. However, the details are not well established. To accomplish this each effect must be separately and accurately studied,

and a theory in which these three effects coexist must be established. These details will also be discussed in later papers.

§ 2. Cross-linking without Cyclization

Let us consider the case where an exposure to high energy radiation gives cross-linkings to long chain polymers, while no cyclization occurs. For the sake of simplicity, the following assumptions are made: (1) cross-linking takes place at random (all monomer units being equally likely to become cross-linked), (2) the number of cross-links is small compared with the number of monomer units available for cross-linking, (3) cyclization does not occur, (4) degree of polymerization can be treated as continuous (from zero to infinity).

Let a polymer be exposed to radiation with total dose R and the number of molecules having the degree of polymerization p be $n(p, R)$. When the radiation dose increases from R to $R+dR$, the number of molecules which have only one active centre and whose degree of polymerization is p is $pn(p, R)\dot{c}dR$. In this expression $\dot{c}$ represents the probability that a monomer, irradiated by unit radiation dose, has an active centre. Any molecule is assumed to have only one active centre, the number of those molecules which have two active centres at the same time being proportional to $(dR)^2$ and accordingly neglected. Those molecules which have active centres are cross-linked with other molecules, resulting in the increase of the degree of polymerization. Therefore, $n(p, R)$ decreases by the amount given above. Furthermore, those molecules whose degree of polymerization is p and which have no active centre may be cross-linked with molecules with an active centre. The number of such molecules is given by

$$\frac{\int_0^\infty pn(p, R)dp}{pn(p, R)} \int_0^\infty pn(p, R)\dot{c}dRdp \\ = pn(p, R)\dot{c}dR.$$

This effect also contributes to the decrease of $n(p, R)$.

The number of those molecules, which are formed by cross-linking between two molecules, one having the degree of polymerization l and an active centre, and the other having the degree of polymerization $p-l$ and no

active centre, is

$$\frac{(p-l)n(p-l, R)}{\int_0^\infty pn(p, R)dp} l n(l, R) \dot{c} dR \\ = \frac{\dot{c}}{N} l(p-l)n(l, R)n(p-l, R) dR,$$

where N denotes the total number of monomers. This contributes to the increase of $n(p, R)$.

From the foregoing induction, we obtain the following relation

$$dn(p, R) = -2pn(p, R)\dot{c}dR \\ + \frac{\dot{c}}{N} \int_0^p l(p-l)n(l, R)n(p-l, R)dRdl.$$

Putting $\dot{c}R = t$ and $n(p, R)/N = m(p, t)$, it follows:

$$\frac{\partial m(p, t)}{\partial t} + 2pm(p, t) \\ = \int_0^p l(p-l)m(l, t)m(p-l, t)dl. \quad (1)$$

Multiplying this equation by p^k and integrating it with respect to p from zero to infinity, we obtain

$$\frac{df_k}{dt} + 2f_{k+1} = \sum_{i=0}^k k C_i f_{i+1} f_{k-i+1}, \quad (2)$$

where

$$f_k = \int_0^\infty p^k m(p, t) dp$$

and k is integer. When $k=1$, it follows

$$\frac{df_1}{dt} = 2f_2(f_1 - 1).$$

f_1 represents the total number of monomers divided by N , and has a constant value unity. When $k=0$,

$$\frac{df_0}{dt} = f_1(f_1 - 2) = -1,$$

therefore

$$f_0 = f_{0,0} - t,$$

where

$$f_{0,0} = \int_0^\infty m(p, 0) dp.$$

The number average molecular weight M_n is given by

$$M_n = M_{n,0} f_{0,0} / (f_{0,0} - t), \quad (3)$$

where $M_{n,0}$ is the number average molecular weight before irradiation. If we use the notation u for the number average degree of polymerization of polymers before irradiation, we obtain

$$M_n = M_{n,0} / (1 - ut). \quad (4)$$

This does not depend on the initial form of the distribution except through u . When $k=2$, Eq. (2) gives

$$\frac{df_2}{dt} = 2f_2^2.$$

The solution is

$$f_2 = f_{2,0} / (1 - 2tf_{2,0}),$$

where

$$f_{2,0} = \int_0^\infty p^2 m(p, 0) dp.$$

The weight average molecular weight M_w is given by

$$M_w = M_{w,0} / (1 - 2tf_{2,0}), \quad (5)$$

where $M_{w,0}$ denotes the initial weight average molecular weight.

If the initial distribution is Poisson-like, i.e. $m(p, 0) = (1/u^2) \exp(-p/u)$, it follows

$$f_2 = 2u / (1 - 4ut).$$

And if the initial distribution is uniform, it becomes

$$f_2 = u / (1 - 4ut).$$

Therefore

$$M_w = \begin{cases} M_{w,0} / (1 - 4ut) & \text{for Poisson distr.,} \\ M_{w,0} / (1 - 2ut) & \text{for uniform distr.} \end{cases} \quad (6)$$

These results are the same as those deduced by Flory, Stockmayer, and Charlesby, if we put $r = 2ut$, $\delta = 4ut$.

We can obtain higher average molecular weight M_z , M_{z+1} , etc. from Eq. (2). However, the viscosity average molecular weight M_v is not deduced from the equation. For this purpose we must resort to other method to solve Eq. (1).

If we apply to Eq. (1) the Laplace transformation

$$f(s, t) = \int_0^\infty m(p, t) e^{-sp} dp,$$

we obtain

$$\frac{\partial f}{\partial t} = 2 \frac{\partial f}{\partial s} + \left(\frac{\partial f}{\partial s} \right)^2 \quad (7)$$

The characteristic equation is easily integrated and the solution under $t=0$, $s=s_0$ and

$$f = g(s_0) = \int_0^\infty m(p, 0) \exp(-s_0 p) dp$$

is given by

$$f = g(s_0) - \{g'(s_0)\}^2 t, \\ s = s_0 - 2\{1 + g'(s_0)\}t. \quad (8)$$

When $s=0$, Eq. (8) gives

$$\frac{\partial f}{\partial s} = g'(s_0) = \frac{s_0}{2t} - 1.$$

On the other hand, we obtain from the definition of f the following relation

$$\left(\frac{\partial f}{\partial t}\right)_{s=0} = - \int_0^\infty p m(p, t) dp = -f_1 = -1.$$

Therefore, we know that s_0 must be zero at $s=0$. Other f_k 's are given as follows:

$$f_k = (-1)^k \left(\frac{\partial^k f}{\partial s^k} \right)_{s=0},$$

and the average molecular weights are given from these f_k 's.

When the initial distribution is Poisson-like, it follows

$$g(s_0) = 1/(1 + us_0).$$

For $s=0$, we obtain

$$f = 1/u - t,$$

$$\partial f / \partial s = -1,$$

$$\partial^2 f / \partial s^2 = 2u/(1 - 4ut), \text{ etc.}$$

These are the same as the preceding results for f_k .

For the uniform initial distribution, we must use $g(s_0) = (1/u) \exp(-s_0 u)$, and then we can obtain the same results as f_k and the average molecular weights, described before, for the uniform distribution.

For the viscosity average molecular weight, we need the formula

$$\int_0^\infty p^{\alpha+1} m(p, t) dp, \quad \frac{1}{2} \leq \alpha \leq 1,$$

which can be calculated by integration if we know $m(p, t)$. $m(p, t)$ is given from f_k , as follows⁹⁾:

$$\left. \begin{aligned} m(p, t) &= e^{-p/u} \sum_{i=0}^{\infty} c_i L_i \left(\frac{p}{u} \right), \\ c_i &= \sum_{k=0}^i \frac{(i!)^2 (-1)^k}{k! (i-k)!} \frac{f_k}{u^{k+1}}, \end{aligned} \right\} \quad (9)$$

where $L_i(x)$ is Laguerre's polynomial.

This method of calculating $m(p, t)$ is very complicated and f_k cannot be obtained easily for large k . More simple method may be desirable, which will be discussed in forthcoming papers.

The argument of this section shows that the solution of Eq. (1) gives the same results as those obtained by other authors. In following sections we will extend the argument.

§ 3. Cross-linking with Cyclization

When long chain polymers are irradiated by high energy radiation, both inter- and intra-molecular cross-linkings occur. In this section both linkings will be considered.

The assumptions mentioned at the beginning of section 2 are accepted in this section except assumption (3), which is replaced by "(3) cyclization occurs". The probability that an active centre in a molecule composed of p monomers may cross-link with a monomer unit of other molecules is assumed to be, on the average, a function of p and N , say $\varphi(p, N)$.

When radiation dose increases from R to $R+dR$, the number of molecules whose degree of polymerization is p , each of which has an active centre, and which will cross-link with other molecules with no active centre is

$$\varphi(p, N) p n(p, t) dt.$$

And the number of molecules with no active centre whose degree of polymerization is p and which will cross-link with other molecules with an active centre is

$$\frac{p n(p, t)}{N} \int_0^\infty \varphi(l, N) l n(l, t) dl dt,$$

Putting $n(p, t)/N = m(p, t)$, we obtain

$$\begin{aligned} \frac{\partial m(p, t)}{\partial t} + p m(p, t) \int_0^\infty \varphi(l, N) l m(l, t) dl \\ + \varphi(p, N) p m(p, t) \\ = \int_0^p \varphi(l, N) l (p-l) m(l, t) m(p-l, t) dl. \end{aligned} \quad (10)$$

For the simplest case we may assume $\varphi(p, N) = 1 - p/N$. In this case the integral in the right hand side of Eq. (10) can be modified into a symmetric form as follows:

$$\begin{aligned} I &= \int_0^p \left(1 - \frac{l}{N} \right) l (p-l) m(l, t) m(p-l, t) dl \\ &= \int_0^p \left(1 - \frac{p-l}{N} \right) (p-l) l m(p-l, t) m(l, t) dl \\ \therefore I &= \left(1 - \frac{p}{2N} \right) \int_0^p l (p-l) m(l, t) m(p-l, t) dl. \end{aligned}$$

Then Eq. (10) becomes for $p \leq N$:

$$\begin{aligned} \frac{\partial m(p, t)}{\partial t} + p m(p, t) \int_0^N \left(1 - \frac{l}{N} \right) l m(l, t) dl \\ + \left(1 - \frac{p}{N} \right) p m(p, t) \end{aligned}$$

$$= \left(1 - \frac{p}{2N}\right) \int_0^p l(p-l)m(l, t)m(p-l, t)dl, \quad (11)$$

for $p > N$: $m(p, t) = 0$.

Eq. (11) may be solved by PLK method¹²⁾. Assume

$$\left. \begin{aligned} m(p, t) &= m_0(p, x) + \varepsilon m_1(p, x) + \cdots \\ t &= x + \varepsilon \varphi_1(x) + \cdots \end{aligned} \right\} \quad (12)$$

where $\varepsilon = 1/N$, and the unknown functions m_0 , m_1 and φ_1 are determined from the following relations. Substitute Eq. (12) into Eq. (11), multiply (11) by p^2 , and integrate it with respect to p from zero to infinity, then we obtain the following equations by equating the coefficients of each powers of ε to zero:

$$\frac{df_2}{dx} = 2f_2^2, \quad (13)$$

$$\frac{dg_2}{dx} = 4f_2g_2 + 2f_2\left(f_2\frac{d\varphi_1}{dx} - f_3\right), \quad (14)$$

where

$$g_2 = \int_0^\infty p^2 m_1(p, x) dp.$$

From Eq. (13), we get

$$f_2 = f_{2,0}/(1 - 2xf_{2,0}). \quad (15)$$

Assume that φ_1 satisfies the relation

$$f_2 \frac{d\varphi_1}{dx} - f_3 = 0, \quad (16)$$

and that $\varphi_1 = 0$ at $x = 0$, then g_2 always vanishes. From Eq. (2) we obtain

$$f_3 = f_{3,0}/(1 - 2xf_{2,0})^3, \quad (17)$$

where

$$f_{3,0} = \int_0^\infty p^3 m(p, 0) dp.$$

Inserting Eqs. (15) and (17) in Eq. (16) and solving it, we get

$$\varphi_1(x) = f_{3,0}x/f_{2,0}(1 - 2xf_{2,0}). \quad (18)$$

Finally,

$$\left. \begin{aligned} \int_0^\infty p^2 m(p, t) dp &= f_{2,0}/(1 - 2xf_{2,0}), \\ t &= x + \varepsilon f_{3,0}x/f_{2,0}(1 - 2xf_{2,0}). \end{aligned} \right\} \quad (19)$$

The weight average molecular weight is then given by

$$M_w = M_{w,0}/(1 - 2xf_{2,0}).$$

In the preceding section where cyclization does not occur, we assume that the value of t at the gel point is given from the condition that f_2 diverges at the point. The value of

f_2 being unable to exceed N , this condition for the gel point is not correct. However, if we calculate the value of t at the gel point by using the correct condition that f_2 has the value of the order of N at the gel point, we can easily obtain the result that the discrepancy between the true and the approximate value of t at the gel point is merely of the order of $1/N$, which is negligible. We can, therefore, obtain the correct result by assuming the approximate condition. On the contrary, in the case of cyclization we must assume the correct condition as follows.

If we consider that at the gel point the number of monomers contained in the largest molecule is kN , where $0 < k < 1$, then

$$\int_0^\infty p^2 m(p, t) dp = k^2 N.$$

The value of t at the gel point is given by

$$t_g = \frac{1}{2} \left(\frac{1}{f_{2,0}} - \frac{1}{k^2 N} \right) \left(1 + k^2 \frac{f_{3,0}}{f_{2,0}^2} \right).$$

Being $k^2 N \gg 1$, t_g is expressed in good approximation by the following formula:

$$t_g = \frac{1}{2f_{2,0}^2} \left(1 + k^2 \frac{f_{3,0}}{f_{2,0}^2} \right). \quad (20)$$

This shows the fact that the gel formation is retarded by cyclization. k may depend on the method of measurement. For instance, the value of k determined from the measurement of melting point may be larger than that from the measurement of viscosity. The value of t_g for the both kinds of initial distributions are:

$$t_g = \begin{cases} \frac{1}{4u} \left(1 + \frac{3}{2} k^2 \right) & \text{for Poisson distr.,} \\ \frac{1}{2u} (1 + k^2) & \text{for uniform distr.} \end{cases} \quad (21)$$

On the same way, we can obtain the number average molecular weight as follows:

$$\left. \begin{aligned} M_n &= M_{n,0}/(f_{0,0} - x), \\ t &= x - \varepsilon \log \sqrt{1 - 2xf_{2,0}}. \end{aligned} \right\} \quad (22)$$

The value of k in Eq. (21) may be small, so that the retardation of the gel formation due to cyclization may be negligible. We may estimate the value of k by the following experiment.

Let two polymers of the same species whose number average degrees of polymerization are u_1 and u_2 and both of which have the Poisson distribution, be solved in some sol-

vent. Then evaporate the solvent and make the polymers solid. The distribution of polymerization will be

$$m(p, 0) = \frac{c_1}{u_1^2} \exp\left(-\frac{p}{u_1}\right) + \frac{c_2}{u_2^2} \exp\left(-\frac{p}{u_2}\right),$$

where c_1, c_2 , ($c_1 + c_2 = 1$), represents the weight concentration ratio. At the gel point t takes the following value:

$$t_g = \frac{1}{4(c_1 u_1 + c_2 u_2)} \left\{ 1 + \frac{3(c_1 u_1^2 + c_2 u_2^2)}{2(c_1 u_1 + c_2 u_2)^2} k^2 \right\}. \quad (23)$$

If we plot $1/t_g$ to c_1, c_2 , the curve is straight when k is negligible. In case where k cannot be neglected, it may be determined from the deviation from straight line.

§ 4. Branching of Cross-linked Molecules

In this section we consider the case where cross-linking without cyclization takes place. The number of end points of any molecule is always even. Let us call one half of the number of end points branching index. In the polymers irradiated by radiation dose R , the number of molecules which have the degree of polymerization p and the branching index q , both treated as continuous, is $n(p, q, R)$. Putting $n(p, q, R)/N = m(p, q, t)$, we obtain the following equation which represents the variation of distribution:

$$\begin{aligned} \frac{\partial m(p, q, t)}{\partial t} + 2pm(p, q, t) \\ = \int_0^q ds \int_0^p dl (p-1)m(l, s, t)m(p-l, q-s, t)dl. \end{aligned} \quad (24)$$

Multiply this equation by $p^i q^j$ and integrate it with respect to p and q from zero to infinity, then the following formula is obtained:

$$\begin{aligned} \frac{df_{ij}}{dt} + 2f_{i+1j} \\ = \sum_{h=0}^i \sum_{k=0}^j i C_h j C_k f_{h+1k} f_{i-h+1j-k}, \end{aligned} \quad (25)$$

where

$$f_{ij} = \int_0^\infty \int_0^\infty p^i q^j m(p, q, t) dp dq.$$

Making $i=0, j=1$, we get

$$\frac{df_{01}}{dt} = 2f_{11}(f_{10}-1) = 0.$$

By integration

$$f_{01} = 1/u.$$

Accordingly, the number average branching index B_n becomes

$$B_n = f_{01}/f_{00} = 1/(1-ut). \quad (26)$$

On the other hand, inserting $i=1, j=1$ in Eq. (25) and integrating it, we obtain the following formula:

$$f_{11} = 1/(1-2tf_{2,0}),$$

where $f_{2,0}$ is given in section 2. Therefore, the weight average branching index B_w is

$$B_w = f_{11}/f_{10} = 1/(1-2tf_{2,0}). \quad (27)$$

Eqs. (26) and (27) indicate that the weight average branching index diverges at the gel point, while the number average branching index does not.

§ 5. Degradation

We consider in this section the case where linear polymers are degraded by irradiation and the molecular weight distribution is altered. Assumptions made are: (1) degradation takes place at random (all monomer units being equally likely to be ruptured), (2) all polymers are linear, (3) degree of polymerization can be treated as continuous (from zero to infinity).

We use the notation $\dot{r}$ to indicate the probability of the event that a monomer is ruptured by unit radiation dose. When radiation dose varies from R to $R+dR$, the number of molecules which have the degree of polymerization p and are newly ruptured is $pn(p, R)\dot{r}dR$ and the number of molecules which have the degree of polymerization p and are formed by the rupture of molecules which have degree of polymerization greater than p is

$$2 \int_p^\infty n(l, R)\dot{r}ldl dR.$$

Therefore, the variation of distribution is represented as follows:

$$\frac{\partial n(p, \tau)}{\partial \tau} + pn(p, \tau) = 2 \int_p^\infty n(l, \tau)dl, \quad (28)$$

where $\tau = \dot{r}R$. The solution is

$$\begin{aligned} n(p, \tau) = \left\{ n(p, 0) + 2\tau \int_p^\infty n(p, 0)dp \right. \\ \left. + \tau^2 \int_p^\infty dp \int_p^\infty n(p, 0)dp \right\} e^{-p\tau}, \end{aligned} \quad (29)$$

where $n(p, 0)$ represents the initial distribution.

When τ is large enough, the first two terms in the brackets of Eq. (29) can be neglected. Then this formula becomes approximately

$$n(p, \tau) \propto \tau^2 e^{-p\tau}.$$

This is the Poisson distribution. We know that whatever the initial distribution may be, the distribution of polymerization becomes Poisson-like for large radiation dose. This feature was discussed by Charlesby, but his discussion was only about the behaviour of f_2 .

When the initial distribution is Poisson-like, i.e. $n(p, 0) = (N/u^2) \exp(-p/u)$, the solution (29) gives

$$n(p, \tau) = N \left(\frac{1}{u} + \tau \right)^2 e^{-(1/u + \tau)p}.$$

This shows that when the initial distribution is Poisson-like, the distribution conserves the same type. We obtain also the number and the weight average molecular weight as follows:

$$\left. \begin{aligned} M_n &= M_{n,0}/(1+u\tau), \\ M_w &= M_{w,0}/(1+u\tau). \end{aligned} \right\} \quad (30)$$

When the initial distribution is uniform, i.e. $n(p, 0) = (N/u) \delta(p-u)$, Eq. (29) gives

$$n(p, \tau) = \begin{cases} (N/u) \{ \delta(p-u) + 2\tau + (u-p)\tau^2 \} e^{-p\tau}, & p \leq u, \\ 0, & p > u, \end{cases}$$

where

$$\delta(x) = \begin{cases} 0 & x < -\varepsilon/2, \\ 1/\varepsilon & -\varepsilon/2 \leq x \leq \varepsilon/2, \\ 0 & \varepsilon/2 < x. \end{cases}$$

And the average molecular weights are

$$\left. \begin{aligned} M_n &= M_{n,0}/(1+u\tau), \\ M_w &= 2M_{w,0}(e^{-u\tau} - 1 + u\tau)/(u\tau)^2. \end{aligned} \right\} \quad (31)$$

These results are the same as those obtained by Charlesby.

The viscosity average molecular weight for an arbitrary initial distribution has not yet been obtained, but we now easily find it out as follows:

$$M_v = \frac{w}{N} \left\{ \int_0^\infty p^{\alpha+1} n(p, \tau) dp \right\}^{1/\alpha}, \quad (32)$$

where α is constant and w is the mass of a monomer. For the Poisson and the uniform initial distribution, it becomes respectively

$$M_v = \begin{cases} M_{v,0}/(1+u\tau), \\ M_{v,0} \left\{ (\alpha+1)e^{-u\tau} - \frac{(\alpha+1)(\alpha-u\tau)}{u^{\alpha+1}} \right. \\ \quad \left. \times \int_0^u p^\alpha e^{-p\tau} dp \right\}^{1/\alpha}, \end{cases} \quad (33)$$

where $M_{v,0}$ means the initial value of the viscosity average molecular weight.

§ 6. Cross-linking with Degradation

In this section we consider the case where irradiated polymers are cross-linked and degraded, but cyclization may be neglected. Basic assumptions are the same as those in sections 2 and 5. In addition to these, we assume that cross-linking and degradation occur independently of each other. This assumption may be permissible when the densities of cross-linking and degradation are small.

Now we consider two molecules A and B whose degree of polymerization are p_A and p_B , and a third molecule with an active centre C . Generally speaking, the probability that an active centre cross-links with a molecule is proportional to the degree of polymerization. Now suppose that after the centre C cross-links with the molecule A or B , the molecule A is ruptured into two molecules A_1 and A_2 whose degrees of polymerization are p_{A1} and p_{A2} , respectively. Then the probabilities that C cross-links finally with A_1 , A_2 and B are p_{A1}/N , p_{A2}/N and p_B/N respectively, where $N = p_{A1} + p_{A2} + p_B$. Next suppose that after A is ruptured into A_1 and A_2 , C cross-links with A_1 , A_2 or B . Then the probabilities that C cross-links ultimately with A_1 , A_2 and B are similarly p_{A1}/N , p_{A2}/N and p_B/N respectively. Therefore, the statistical result is independent of the order of cross-linking and degradation. When they coexist, we may treat them as if degradation occurs first and then cross-linking follows.

Let us consider the case when a polymer substance the molecules of which are all linear and distributed initially as given by $n(p, 0)$ is irradiated, and cross-linking and degradation occur. First, the consideration of degradation will lead to a new distribution function $n(p, \tau)$ given by Eq. (29), and the consideration of cross-linking will then give the average molecular weights given by Eqs. (4) and (5).

For example, when the initial distribution is Poisson-like, the average molecular weights are given by

$$M_n = \frac{M_{n,0}}{1+u(\tau-t)} = \frac{M_{n,0}}{1+(\dot{r}-\dot{c})uR}, \quad (34)$$

and

$$M_w = \frac{M_{w,0}}{1+u(\tau-4t)} = \frac{M_{w,0}}{1+(\dot{r}-4\dot{c})uR}. \quad (35)$$

From the last formula, we know that the gel

formation occurs only when $\dot{r}/\dot{c} < 4$. This condition of gel formation holds for any initial distribution (*cf* the appendix).

When the initial distribution is uniform, we obtain similarly the average molecular weights:

$$M_n = \frac{M_{n,0}}{1 + u(\tau - t)}, \quad (36)$$

$$M_w = \frac{M_{w,0}}{u} \left/ \left\{ \frac{u\tau^2}{2(e^{-u\tau} - 1 + u\tau)} - 2t \right\} \right.$$

§ 7. Discussion

There may be considered three effects of high energy radiation to long chain polymers. They are cross-linking, degradation and end-linking. In this paper the effects of the first two are discussed. Among several possible methods to investigate these, the author uses the one in which integro-differential equations for the variation of molecular weight distributions are solved. First, in the case of cross-linking the same results as those obtained by Flory, Stockmayer, and Charlesby are given. This fact may be an indirect evidence that this integro-differential equation is valid. Further, by extending this equation to the case including cyclization, it is shown that the gel formation is retarded by the presence of cyclization, but this retardation may not be remarkable. However, the probability $\varphi(p, N) = 1 - p/N$ used in this case is the simplest one, so that it may be necessary to consider steric hindrance of molecules and to use some more practical formula for $\varphi(p, N)$. As for branching index, some experimental facts may be obtained by chemical measurement of the end groups, and compared to the theory. Although the effect of degradation has already been discussed by Charlesby, the distribution function $n(p, \tau)$ was not given in his theory. In this paper it is obtained in a closed form, from which many important quantities can be calculated. In the case where cross-linking and degradation coexist, it is assumed that correct statistical results are obtained by considering that degradation occurs first and then cross-linking follows. A mathematical proof of the validity of this assumption is considered. The treatment developed in this paper gives the result that whatever the initial distribution may be, the gel formation occurs only when $\dot{r}/\dot{c}$ is smaller than 4. This may show the fact that the gel

formation depends only on $\dot{r}$ and $\dot{c}$, but not on the initial distribution.

It is in viscosity that the experimental effect of radiation to polymers appears for rather small radiation dose. Theoretical deduction of viscosity average molecular weight has not been done. It may, however, be possible to obtain it by the author's theory. The details will be described in part II, where the effect of end-linking will also be discussed.

Acknowledgments

The author wishes to express his sincere thanks to Dr. A. Amemiya for his advices about mathematical treatments, to Dr. A. Harasima for his suggestions about statistical aspects, to Dr. K. Shinohara for his informations about experimental features, and to Mr. M. Inokuti for his assistances in mathematical treatments. He also thanks Mr. T. Watanabe and others, the members of the Group for the Study of Irradiated Polymers in Tokyo, to whose discussions the author owes much.

Appendix

The result that, when cross-linking and degradation coexist, whatever initial distribution may be, the gel formation occurs only when $\dot{r}/\dot{c}$ is smaller than 4 is verified as follows:

The gel point is given by the equation

$$1 - 2tf_{2,0} = 0, \quad (37)$$

where

$$\begin{aligned} f_{2,0} &= \int_0^\infty p^2 m(p, \tau) dp \\ &= \int_0^\infty p^2 m(p, 0) e^{-\nu\tau} dp + 2\tau \int_0^\infty p^2 e^{-\nu\tau} dp \\ &\quad \times \int_p^\infty m(l, 0) dl \\ &\quad + \tau^2 \int_0^\infty p^2 e^{-\nu\tau} dp \int_p^\infty dl \int_l^\infty m(h, 0) dh. \end{aligned}$$

By changing the order of integrations we obtain

$$f_{2,0} = \frac{2}{\tau} - \frac{2}{\tau^2} \int_0^\infty m(l, 0)(1 - e^{-l\tau}) dl.$$

Inserting this formula in Eq. (37) and considering $t = \dot{c}R$ and $\tau = \dot{r}R$, the value of τ at the gel point is given by the following equation

$$\frac{\dot{r}}{\dot{c}} - 4 + \frac{4}{\tau} \int_0^{\infty} m(l, 0)(1 - e^{-l\tau}) dl = 0.$$

This leads to the condition $\dot{r}/\dot{c} < 4$.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 2, FEBRUARY, 1958

Paramagnetic Resonance Absorption in Two Copper Salts at Wavelengths of 5.4 mm and 6.6 mm

By Kazuo ÔNO and Mieko OHTSUKA

Institute for Solid State Physics, University of Tokyo

(Received October 30, 1957)

Paramagnetic resonance absorption in single crystals of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$ has been investigated at wavelengths of 5.4 mm and 6.6 mm. The shapes of absorption lines vary remarkably with orientation of the crystal in the magnetic field. This is interpreted in terms of exchange interaction between copper ions. The line shapes are compared with result calculated recently by Anderson. And then the exchange frequencies are estimated to be 1.0×10^{10} and 1.1×10^{10} for $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$ respectively.

§ 1. Introduction

Paramagnetic resonance absorption of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ has been investigated in great detail at the range of centimeterwaves.¹⁾ The crystals contain two dissimilar ions in a unit cell. If there is no exchange coupling between copper ions, two absorption lines would be observed corresponding to the two dissimilar ions. Experimentally, only one line has been observed at longer wavelengths. At the shorter wavelength, $\lambda = 8.5$ mm, however, two lines were found under the appropriate condition. But the result is a very brief one. Similar circumstances have been observed in single crystals of $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$.²⁾

In the present experiments the shapes of absorption lines in single crystals of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$ were studied for various orientations of the crystal in the static magnetic field. All of these measurements

were done at room temperature and wavelengths of 5.4 mm and 6.6 mm.

Recently, Anderson,³⁾ and Yokota and Koide⁴⁾ have quantitatively calculated the line shapes of resonance absorption in two inequivalent ions under strong exchange coupling. The comparison between the calculated and observed line shapes with orientation of the crystals is made in the present paper.

§ 2. Crystallographic Data

The X-ray analysis of the crystal structure of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ given by Beevers and Lipson⁵⁾ shows that there are two inequivalent ions in a unit cell, with parameters (0 0 0) and ($\frac{1}{2}$ $\frac{1}{2}$ 0). Each ion is surrounded by a nearly octahedral arrangement consisting of four water molecules and two oxygen atoms; the angle between the planes of water molecules of the two ions is calculated to be about 82° . The

Cu^{++} ion may be acted by a crystalline electric field of tetragonal symmetry and its g -tensor must be also tetragonal. Since $\text{CrSO}_4 \cdot 5\text{H}_2\text{O}$, which may be isomorphous with $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, has a very small value of fine structure parameter due to a rhombic symmetry compared with that due to an axial symmetry,⁶⁾ then the assumption mentioned above may be reasonable. That of $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$ given by Chrobak⁷⁾ shows that two inequivalent ions are situated at $(0\ 0\ 0)$ and $(\frac{1}{2}\ \frac{1}{2}\ \frac{1}{2})$ respectively. Each ion is surrounded by four chlorine atoms forming a rhomb in the a - a plane and by two water molecules located on the normal of this

Fig. 1. Atomic arrangement of $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$.

plane passing the ion as shown in Fig. 1.

Two rhombs in unit cell are rotated each other by 90° about the c -axis, the line of the two water molecules. Then the Cu^{++} ion may be affected by a crystalline field of rhombic symmetry.

§ 3. Apparatus and Experimental Results

The experimental method consisted in detecting the change in Q value caused by the absorption in the specimen and the detailed description of this apparatus has been given elsewhere.⁸⁾²⁾

a) $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$

The resonance absorption curves observed in $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ at $\lambda = 5.4$ mm with orientation for H in the plane containing the two tetragonal axes γ_1 and γ_2 are shown in Fig. 2.

Great variation of the line shape was found in the Figure. For H parallel to γ' , the external bisector of γ_1 and γ_2 , the width is very small ($\Delta H = 100$ gauss) and seems to be independent of wavelength. The line width increases rapidly with θ , the angle between H and γ' , until the two lines are resolved at

Fig. 2. Variation of line shape of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ in the γ_1 - γ_2 plane at $\lambda = 5.4$ mm.

$\theta = 15^\circ$.

The two separated lines have a remarkable feature. That is; the intensity of the absorption observed at the higher magnetic field is always stronger than that at the lower one.

The line widths at $\theta = 45^\circ$ are 740 ± 50 gauss and 650 ± 50 gauss for the higher and lower magnetic field respectively with $\lambda = 5.4$ mm.

The line width to be expected from magnetic dipolar interaction alone is about 450 gauss and is narrower than that observed. The effect of broadening the line is caused by the exchange interaction between inequivalent Cu^{++} ions. Thus the exchange energy may be determined reliably from the line width.

Fig. 3. Variation of g values of $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ in γ_1 - γ_2 plane at $\lambda = 6.6$ mm. Solid curves are obtained from the experimental results. Dashed curves are calculated with the assumption that there is no exchange interaction.

Fig. 3 shows the observed g -values in the γ_1 - γ_2 plane at $\lambda = 6.6$ mm. The determination of g -values was performed by comparing the magnetic field for absorption peak of the sample with that of α -diphenyl β -picryl hydrazyl ($g = 2.00$ $\Delta H =$ several gauss). The directions where the g -values are maximum coincide with those of the γ_1 and γ_2 axes. So the angle between γ_1 and γ_2 is observed to be

$86^\circ \pm 2^\circ$. In the figure, dashed curves indicate the calculated g -values with the assumption that there is no exchange interaction and g -values are assumed to be $g_{\parallel}=2.46$ and $g_{\perp}=2.06$.¹⁾ It is noted that difference between observed and calculated g -values at the higher magnetic field is always smaller than that at the lower one.

b) $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$

The resonance absorption curves at $\lambda=5.4$ mm in the a - a plane are shown in Fig. 4.

Fig. 4. Variation of line shape of $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$ in the a - a plane at $\lambda=5.4$ mm.

The features are qualitatively the same as those in $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. The line widths are about 100 gauss with H parallel to a -axis and 1150 gauss and 920 gauss with H parallel to c' , the bisector of the two a -axes. The calculated dipolar width is about 380 gauss.

§ 4. Estimation of Exchange Frequency

The effect of exchange coupling in resonance absorption was first qualitatively discussed by Gorter and Van Vleck⁹⁾ and Kumagai et al.¹⁰⁾ Recently, Anderson and Weiss,¹¹⁾ Anderson,³⁾ and Yokota and Koide⁴⁾ have quantitatively investigated this problem and Anderson has given some simple formulae for the widths and shapes of the absorptions.

According to Anderson, the intensity of the spectrum can be represented to be

$$I(\omega) = \frac{8\omega_e^3 x^2}{\omega^4 + 2\omega^2\omega_e^2(2-x^2) + \omega_e^4 x^4} \\ = \frac{8\omega_e \omega_0^2}{\omega^3 + 2\omega^2(2\omega_e^2 - \omega_0^2) + \omega_0^4} \quad (1)$$

where $\pm\omega_0$ are two possible frequency shifts, ω_e is a parameter specifying the rate at which jumping takes place back and forth between two frequencies, and x is ω_0/ω_e . Then we take

$$\omega_0 = \frac{(g_{\parallel} - g_{\perp})}{2\hbar} \beta H \sin 2\theta \sin \alpha$$

where θ is the angle between the direction of the external magnetic field H and c' , and α is the angle between two tetragonal axes.

We can calculate ω_e from the absorption curves in Fig. 1 and Fig. 3 and equation (1). For example ω_e is calculated as follows:

A) At certain angle where one resonance line is near being resolved into two lines, ω_e is

$$\omega_e = \omega_0 / \sqrt{2} \quad (2)$$

B) The actual maximum frequency shift observed is not ω_0 but $\delta\omega$, which is

$$(\delta\omega)^2 = \omega_0^2 - 2\omega_e^2 \quad (3)$$

C) Neglecting the line width due to the dipolar interaction, the widths of resolved line can be asymptotically represented to be

$$\Delta\omega = 2\omega_e \quad (4)$$

as ω_e/ω_0 goes to zero.

The estimated values of ω_e from A), B) and C) are summarized in Table I.

Table 1. The values of ω_e estimated from experimental results with $\lambda=5.4$ mm and $\lambda=6.6$ mm using Eqs. (2), (3) and (4).

	ω_e in 10^{10}		
	$\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$	$\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$	
	$\lambda=5.4$ mm	$\lambda=6.6$ mm	$\lambda=5.4$ mm
(A)	0.90	1.06	0.88
(B)	1.22	1.19	1.33
(C)	0.70	0.82	0.98

In the calculation, we assume the crystal-line field to have a tetragonal symmetry. Then g -values are calculated from the results with the longer wavelengths¹²⁾ to be $g_{\perp}=2.06$ and $g_{\parallel}=2.46$ in $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and $g_{\perp}=2.06$ and $g_{\parallel}=2.38$ in $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$. This is reasonable in copper sulphate considering the crystalline field may have tetragonal symmetry.

The values of ω_e in Table I show no large divergences from each other. Comparing the resonance absorption curves measured at $\lambda=5.4$ mm and $\lambda=6.6$ mm with Eq. (1) we can ultimately estimate the exchange frequencies to be 1.0×10^{10} and 1.1×10^{10} for $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ and $\text{K}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$ respectively.

For copper salts, an estimate of the exchange frequency can be made from the Curie-

Weiss law $\chi=c/(T+\theta)$, with θ obtained from the Weiss molecular field equation as

$$2k\theta = Jz$$

where z is the number of nearest neighbours. The exchange integral J can be expressed⁷⁾ for a simple cubic lattice structure,³⁾

$$\omega_e = 2.12(J/\hbar)^2$$

From the results of the static susceptibility measurements, θ is found to be $0.6^\circ \pm 0.05^\circ \text{K}$ in $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ by Benzie and Cooke¹⁾ and ω_e is calculated to be 3.8×10^{10} . Accordingly, these two estimates of the exchange frequency are fairly consistent.

The reasons for the minor differences may be attributed to the following considerations.

- 1) In the calculation, g is not treated as a tensor.
- 2) The dipolar interaction between copper ions is neglected.
- 3) The exchange interaction between similar and dissimilar ions may be different.
- 4) Crystal structure may not be a simple cubic lattice structure.
- 5) The crystalline electric field of tetragonal symmetry is assumed.
- 6) The exchange interaction may be a function of the temperature.

On the other hand, in the case of $\text{K}_2\text{CuCl}_4 \cdot$

$2\text{H}_2\text{O}$, the susceptibility does not obey the Curie-Weiss law exactly.¹²⁾ So the exchange frequency can not be estimated from the susceptibility measurements.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 2, FEBRUARY, 1958

A Hydrodynamical Model for the Sedimentation

By Mitutosi KAWAGUTI

Institute of Science and Technology, University of Tokyo

(Received October 14, 1957)

The flow of a viscous fluid past a sphere in a frictionless circular pipe is investigated by using Faxén's procedure and the results are applied to the problem of sedimentation. Thus we obtained a formula for the sedimentation velocity V in the form: $V/V_0 = 1 - 1.6493(d_v/M^3)^{1/3} + 0.7968(d_v/M^3)$, where V_0 is the terminal velocity of a particle, d_v the volume concentration and M a constant of order unity which depends on the distribution of sedimenting particles. Although our model is rather rough, it gives as good results as those given by other theories.

§ 1. Introduction

Recently H. Noda³⁾ measured the sedimentation velocity of tiny particles of polystyrene

in a medium of salted water. On the other hand, J. Happel and N. Epstein²⁾ measured the pressure drop in a flow of water through

a circular pipe in which an assemblage of smooth spheres of equal diameter is mechanically suspended and immobilized.

It is also interesting to consider theoretically the relationship between the sedimentation velocity and the concentration of particles in a medium. On this problem, many theoretical investigations have been published (e.g. Burgers,¹⁾ Uchida⁶⁾, but so far as the author is aware, no satisfactory solution is known even in the Reynolds number range where Stokes' approximation is valid, owing to mathematical complexity.

Thus, in order to take into account the interaction between neighbouring particles, we consider the flow past a sphere in a fictitious frictionless circular pipe as a model flow for the sedimentation. The ratio of the radius of the pipe to that of a particle will be determined on a geometrical ground.

To deal with the model flow mentioned above, we shall use Faxén's procedure. It is to be noted that the same problem but with different boundary conditions on the surface of the circular pipe has recently been studied by Wakiya.⁶⁾ The interaction effects between the wall and the obstacle in the flow of a viscous fluid have also been studied by Wakiya⁷⁾ and Takaisi.⁴⁾

In § 2 we shall study the flow of a viscous fluid past a sphere in a frictionless circular pipe, with a view to applying it to the problem of sedimentation in § 3.

§ 2. Viscous Flow past a Sphere in a Frictionless Circular Cylinder

2.1. We consider a sphere of radius a whose centre is on the axis of a circular pipe of radius $r_0 a$. The flow in the pipe is assumed to have uniform velocity U far upstream and downstream. Thus the flow will be axisymmetrical. We make the problem non-dimensional by choosing a , U , ρ as the units of length, velocity and density, respectively.

For an axisymmetrical flow, Stokes' ap-

Fig. 1.

proximate equations of motion and continuity can be written in non-dimensional forms as

$$\frac{\partial p}{\partial r} = \frac{2}{Re} \left(r^2 - \frac{1}{r^2} \right) v_r, \quad (2.1)$$

$$\frac{\partial p}{\partial z} = \frac{2}{Re} r^2 v_z, \quad (2.2)$$

$$\frac{\partial}{\partial r}(rv_r) + \frac{\partial}{\partial z}(rv_z) = 0, \quad (2.3)$$

with cylindrical polar coordinates (r, φ, z) , where

$$r^2 = \frac{\partial^2}{\partial r^2} + \frac{1}{r} \frac{\partial}{\partial r} + \frac{\partial^2}{\partial z^2}, \quad (2.4)$$

and v_r, v_z are the r - and the z -components of velocity, p the pressure, and $Re = 2aU/\nu$ is the Reynolds number, ν being the kinematic viscosity.

The equations (2.1)~(2.4) can be transformed in the spherical polar coordinates (R, θ, φ) as

$$D^4 \psi = 0, \quad (2.5)$$

where

$$D^2 = \frac{\partial^2}{\partial R^2} - \frac{1}{R^2} \frac{\cos \theta}{\sin \theta} \frac{\partial}{\partial \theta} + \frac{1}{R^2} \frac{\partial^2}{\partial \theta^2}, \quad (2.6)$$

and ψ is Stokes' stream function from which the R - and θ -components of velocity v_R, v_θ are given as

$$v_R = \frac{1}{R^2 \sin \theta} \frac{\partial \psi}{\partial \theta}, \quad v_\theta = -\frac{1}{R \sin \theta} \frac{\partial \psi}{\partial R}. \quad (2.7)$$

The boundary conditions appropriate for our problem are

$$\left. \begin{array}{l} v_z \rightarrow 1 \\ v_r \rightarrow 0 \end{array} \right\} \text{ as } z \rightarrow \pm \infty, \quad (2.8)$$

i.e. $\psi \rightarrow \frac{1}{2} r^2 \sin^2 \theta$ as $z \rightarrow \pm \infty$, and

$$v_z = v_r = 0 \quad \text{at } R = 1, \quad (2.9)$$

$$v_r = \partial v_z / \partial r = 0 \quad \text{at } r = r_0. \quad (2.10)$$

Putting

$$\mathbf{v} = \mathbf{u}_0 + \mathbf{u}_1 + \mathbf{u}_2 + \cdots, \quad \mathbf{v}_n = \sum_{i=0}^n \mathbf{u}_i, \quad (2.11)$$

where

$$u_{0z} = 1, \quad u_{0r} = 0, \quad (2.11')$$

i.e. $\psi_0 = \frac{1}{2} r^2 \sin^2 \theta$,

we shall obtain the velocity $\mathbf{v}$ iteratively.

2.2. It is well known that Stokes' solution for the uniform flow past a sphere:

$$\psi_1 = \left(\frac{1}{2} R^2 - \frac{3}{4} R + \frac{1}{8} \frac{1}{R} \right) \sin^2 \theta, \quad (2.12)$$

satisfies the boundary conditions (2.8) and (2.9) but not (2.10). The velocity components are given as follows:

$$v_{1z} = \left(1 - \frac{3}{2} \frac{1}{R} + \frac{1}{2} \frac{1}{R^3}\right) + \frac{3}{4} \left(\frac{1}{R} - \frac{1}{R^3}\right) \sin^2 \theta, \quad (2.13)$$

$$v_{1r} = -\frac{3}{4} \left(\frac{1}{R} - \frac{1}{R^3}\right) \sin \theta \cos \theta. \quad (2.14)$$

Thus we have for the perturbation quantities

$$u_{1z} = \left(-\frac{3}{2} \frac{1}{R} + \frac{1}{2} \frac{1}{R^3}\right) + \frac{3}{4} \left(\frac{1}{R} - \frac{1}{R^3}\right) \frac{r^2}{R^2}, \quad (2.15)$$

$$u_{1r} = -\frac{3}{4} \left(\frac{1}{R} - \frac{1}{R^3}\right) \frac{zr}{R^2}, \quad (2.16)$$

$$p_1 = -\frac{4}{Re} \left(\frac{3}{4} \frac{1}{R}\right) \frac{z}{R^2}. \quad (2.17)$$

We shall modify the expressions (2.15)~(2.17) into forms which are convenient for the

consideration of the boundary conditions (2.10). To this end, we note the formula (Ref. 8, p. 388)

$$\frac{1}{R} = \frac{2}{\pi} \int_0^\infty K_0(r\lambda) \cos z\lambda d\lambda. \quad (2.18)$$

Differentiating (2.18) with respect to r and z , we have

$$\frac{r}{R^3} = \frac{2}{\pi} \int_0^\infty K_1(r\lambda) \lambda \cos z\lambda d\lambda, \quad (2.19)$$

$$\frac{z}{R^3} = \frac{2}{\pi} \int_0^\infty K_0(r\lambda) \lambda \sin z\lambda d\lambda, \quad (2.20)$$

$$\frac{3rz}{R^5} = \frac{2}{\pi} \int_0^\infty K_1(r\lambda) \lambda^2 \sin z\lambda d\lambda, \quad (2.21)$$

$$\frac{2}{R^3} - \frac{3r^2}{R^5} = -\frac{2}{\pi} \int_0^\infty K_0(r\lambda) \lambda^2 \cos z\lambda d\lambda. \quad (2.22)$$

Introducing (2.19)~(2.22) in the expressions (2.15)~(2.17), we have

$$u_{1z} = \frac{2}{\pi} \int_0^\infty \left\{ \frac{3}{4} r\lambda K_1(r\lambda) - \left(\frac{3}{2} + \frac{1}{4} \lambda^2 \right) K_0(r\lambda) \right\} \cos z\lambda d\lambda, \quad (2.23)$$

$$u_{1r} = -\frac{2}{\pi} \int_0^\infty \left\{ \frac{3}{4} r\lambda K_0(r\lambda) - \frac{1}{4} \lambda^2 K_1(r\lambda) \right\} \sin z\lambda d\lambda, \quad (2.24)$$

$$p_1 = -\frac{4}{Re} \frac{2}{\pi} \int_0^\infty \frac{3}{4} \lambda K_0(r\lambda) \sin z\lambda d\lambda. \quad (2.25)$$

2.3. It is easily shown that

$$u_{2z} = \frac{2}{\pi} \int_0^\infty [F(\lambda)r\lambda I_1(r\lambda) + \{2F(\lambda) + G(\lambda)\}I_0(r\lambda)] \cos z\lambda d\lambda, \quad (2.26)$$

$$u_{2r} = \frac{2}{\pi} \int_0^\infty [F(\lambda)r\lambda I_0(r\lambda) + G(\lambda)I_1(r\lambda)] \sin z\lambda d\lambda, \quad (2.27)$$

$$p_2 = \frac{4}{Re} \frac{2}{\pi} \int_0^\infty F(\lambda)\lambda I_0(r\lambda) \sin z\lambda d\lambda \quad (2.28)$$

are a set of solutions of Eqs. (2.1)~(2.3), where $F(\lambda)$ and $G(\lambda)$ are arbitrary functions of z .

As a next step, we shall determine u_2 so that $u_1 + u_2$ will satisfy the boundary conditions (2.10):

$$\left. \begin{aligned} u_{1r} + u_{2r} &= 0, \\ \frac{\partial}{\partial r}(u_{1z} + u_{2z}) &= 0 \end{aligned} \right\} \quad \text{at } r = r_0 \quad (2.29)$$

$$(2.30)$$

(u_0 satisfies the conditions (2.10)). Substituting (2.23), (2.24), (2.26) and (2.27) into (2.29) and (2.30), we have

$$\int_0^\infty [F(\lambda)r_0\lambda I_0(r_0\lambda) + G(\lambda)I_1(r_0\lambda) - \frac{3}{4}r_0\lambda K_0(r_0\lambda) + \frac{1}{4}\lambda^2 K_1(r_0\lambda)] \sin z\lambda d\lambda = 0, \quad (2.31)$$

$$\int_0^\infty \left[F(\lambda)r_0\lambda^2 I_0(r_0\lambda) + \{3F(\lambda) + G(\lambda)\}\lambda I_1(r_0\lambda) - \frac{3}{4}r_0\lambda^2 K_0(r_0\lambda) + \left(\frac{9}{4} + \frac{1}{4} \lambda^2 \right) \lambda K_1(r_0\lambda) \right] \cos z\lambda d\lambda = 0. \quad (2.32)$$

Since (2.31) and (2.32) must be satisfied for an arbitrary value of z , we have

$$r_0\lambda I_0(r_0\lambda)F(\lambda) + I_1(r_0\lambda)G(\lambda) = \frac{3}{4}r_0\lambda K_0(r_0\lambda) - \frac{1}{4}\lambda^2 K_1(r_0\lambda), \quad (2.33)$$

$$\{r_0\lambda^2 I_0(r_0\lambda) + 3\lambda I_1(r_0\lambda)\}F(\lambda) + \lambda I_1(r_0\lambda)G(\lambda) = \frac{3}{4}r_0\lambda^2 K_0(r_0\lambda) - \left(\frac{9}{4} + \frac{1}{4}\lambda^2\right)\lambda K_1(r_0\lambda). \quad (2.34)$$

Solving these equations for $F(\lambda)$ and $G(\lambda)$, we have

$$F(\lambda) = -\frac{3}{4} \frac{K_1(r_0\lambda)}{I_1(r_0\lambda)}, \quad (2.35)$$

$$G(\lambda) = \frac{3r_0\lambda I_0(r_0\lambda)K_1(r_0\lambda)}{4\{I_1(r_0\lambda)\}^2} + \frac{3r_0\lambda K_0(r_0\lambda)}{4I_1(r_0\lambda)} - \frac{\lambda^2 K_1(r_0\lambda)}{4I_1(r_0\lambda)}. \quad (2.36)$$

Although the solution thus obtained satisfies the boundary conditions (2.10), it cannot satisfy (2.9) exactly. Then we shall be content with the approximate condition that (2.9) may be satisfied by our solution on an average. Putting

$$v_z = 1 + c(u_{1z} + u_{2z}), \quad (2.37)$$

$$v_r = c(u_{1r} + u_{2r}), \quad (2.38)$$

$$p = c(p_1 + p_2), \quad c: \text{const}, \quad (2.39)$$

we shall determine the constant c by the condition that the mean velocity over the

surface of the sphere ($R=1$) vanishes:

$$\int_0^\pi v_z \sin \theta d\theta = 0, \quad \int_0^\pi v_r \sin \theta d\theta = 0. \quad (2.40)$$

It is easily seen that

$$\left. \begin{aligned} v_z(\theta) &= v_z(\pi - \theta), \\ v_r(\theta) &= -v_r(\pi - \theta) \end{aligned} \right\} \text{ on } R=1, \quad (2.41)$$

so that second equation in (2.40) is automatically satisfied, and the first one reduces to

$$\int_0^{\pi/2} v_z \sin \theta d\theta = 0, \quad \text{on } R=1. \quad (2.42)$$

We can easily show that

$$\int_0^{\pi/2} 1 \times \sin \theta d\theta = 1, \quad (2.43)$$

$$\int_0^{\pi/2} [u_{1z}]_{R=1} \sin \theta d\theta = -1, \quad (2.44)$$

$$\int_0^{\pi/2} [u_{2z}]_{R=1} \sin \theta d\theta = \frac{2}{\pi} \int_0^\infty F(\lambda) \frac{\lambda^2}{3} d\lambda + \frac{2}{\pi} \int_0^\infty \{2F(\lambda) + G(\lambda)\} d\lambda, \quad (2.45)$$

using the formula (Ref. 8, p. 376)

$$\int_0^\infty (x^2 - t^2)^{\frac{1}{2}\nu} \cos t I_\nu(\sqrt{x^2 - t^2}) dt = \frac{I'(\frac{1}{2}) x^{2\nu+1}}{2^{\nu+1} \Gamma(\nu + \frac{3}{2})}, \quad (2.46)$$

for the calculation of (2.45). Substituting (2.43)~(2.45) into (2.42), we can determine the constant c as

$$c^{-1} = 1 - \frac{2}{\pi} \int_0^\infty [F(\lambda) \frac{\lambda^2}{3} + 2F(\lambda) + G(\lambda)] d\lambda. \quad (2.47)$$

Using the explicit forms for $F(\lambda)$ and $G(\lambda)$ as given by (2.35) and (2.36) respectively, we have

$$\int_0^\infty F(\lambda) \frac{\lambda^2}{3} d\lambda = -\frac{1}{4} \frac{1}{r_0^3} \int_0^\infty A^2 \frac{K_1(A)}{I_1(A)} dA, \quad (2.48)$$

$$\int_0^\infty [2F(\lambda) + G(\lambda)] d\lambda = -\frac{1}{4} \frac{1}{r_0^3} \int_0^\infty A^2 \frac{K_1(A)}{I_1(A)} dA + \frac{3}{4} \frac{1}{r_0} \int_0^\infty \frac{1}{I_1(A)} \left\{ AK_0(A) + \frac{AK_1(A)I_0(A)}{I_1(A)} - 2K_1(A) \right\} dA. \quad (2.49)$$

These integrals can be evaluated numerically. Thus we have

$$\int_0^\infty F(\lambda) \frac{\lambda^2}{3} d\lambda = -0.62580 r_0^{-3}, \quad (2.50)$$

$$\int_0^\infty [2F(\lambda) + G(\lambda)] d\lambda = 2.59072 r_0^{-1} - 0.62580 r_0^{-3}. \quad (2.51)$$

Substituting (2.50) and (2.51) into (2.47), we finally have

$$c^{-1} = 1 - 1.64931 r_0^{-1} + 0.79680 r_0^{-3}. \quad (2.52)$$

2.4. For determining the drag D , we first consider the pressures far upstream and downstream. Clearly we have $[p_1]_{z \rightarrow \pm \infty} = 0$ and from (2.28) and (2.35) we have

$$\begin{aligned} [p_2]_{z \rightarrow \pm \infty} &= -\frac{6}{Re\pi} \lim_{z \rightarrow \pm \infty} \int_0^\infty \frac{K_1(r_0\lambda)}{I_1(r_0\lambda)} \lambda I_0(r\lambda) \sin z\lambda d\lambda \\ &= \mp \frac{6}{r_0^3} \frac{1}{Re}, \end{aligned} \quad (2.53)$$

applying Dirichlet's integral theorem. Hence, in order to maintain the total flux through the pipe in the presence of a sphere at a value corresponding to the undisturbed uniform flow, a pressure difference Δp must be applied such that

$$\Delta p = \frac{1}{Re} \frac{12}{r_0^3} c, \tag{2.54}$$

between the upstream and downstream ends of the pipe.

Thus the drag coefficient can be given as:

$$\begin{aligned} C_D &\equiv \frac{D}{\frac{1}{2} \rho U^2 \pi a^2} = \frac{24c}{Re} \\ &= \frac{24}{Re} \frac{1}{1 - 1.64931 r_0^{-1} + 0.79680 r_0^{-3}}. \end{aligned} \tag{2.55}$$

§ 3. Application to the Problem of Sedimentation

It is interesting to relate the solution thus obtained with the problem of sedimentation or the flow past many particles.

In the course of sedimentation, the distribution of the particles in the medium becomes random so that we may consider that the effects of particles far upstream and downstream of the particle under consideration will be cancelled on an average and we may assume that the flow is uniform there. But we cannot neglect the effects of the particles in the neighbourhood of the particle considered, because of the fact that the existence of these particles leads to the increase of effective mean velocity near the particle, and hence to the increase of the drag of the particle under consideration. These effects will be roughly taken into account by assuming the existence of a fictitious frictionless circular pipe around the particle under consideration. Then the solution obtained in the preceding section may be used as a model for the problem of the sedimentation.

We consider a system of equal spherical particles whose radius and density are a and ρ_p respectively in a medium of density ρ_s . Then the force acting on a particle due to the gravitational acceleration g is given as

$$(\rho_p - \rho_s) \frac{4}{3} \pi a^3 g. \tag{3.1}$$

On the other hand, the drag of one sphere can be given from (2.55) as

$$D = 6\pi a U \mu (1 - 1.6493 r_0^{-1} + 0.7968 r_0^{-3})^{-1}. \tag{3.2}$$

Thus the terminal velocity V can be determined, by equating the force (3.1) and the drag (3.2):

$$V = (1 - 1.6493 r_0^{-1} + 0.7968 r_0^{-3}) \frac{2}{9} (\rho_p - \rho_s) \frac{a^2 g}{\mu}. \tag{3.3}$$

The effective radius of smooth pipe can be determined in the following manner. Let the mass concentration of the particles (the ratio of the total mass of the particles to that of the medium and the particles) be d_m and the number of the particles in unit volume be n , then we have

$$n = \frac{d_m \rho_s}{\frac{4}{3} \pi a^3 \{ \rho_p - (\rho_p - \rho_s) d_m \}}. \tag{3.4}$$

If we assume the simple cubic and the body-centred lattice configuration of the particles, the relations between n and b are found to be

$$(a) \quad b = n^{-1/3}, \quad (\text{simple cubic}) \tag{3.5a}$$

$$(b) \quad b = (n/2)^{-1/3}, \quad (\text{body-centred}) \tag{3.5b}$$

respectively where b is the distance between neighbouring particles. Then we assume

Fig. 2. Lattice configuration; a) simple cubic lattice, b) body-centred lattice.

that the effective radius of frictionless circular pipe r_0a is given by the relation:

$$2(r_0a)^2\pi=2b^2. \tag{3.6}$$

From (3.4)~(3.6), we have

$$r_0=M^3\sqrt{\frac{\rho_p-(\rho_p-\rho_s)d_m}{d_m\rho_s}}, \tag{3.7}$$

M being 0.9095 and 1.1458 for the cases (a) and (b) respectively.

In the formula (3.7), we can neglect the term $(\rho_p-\rho_s)d_m$ compared with ρ_p , considering that $(\rho_p-\rho_s)$ and d_m are both small in the problem of sedimentation. Then we have

$$r_0=M^3\sqrt{\frac{\rho_p}{d_m\rho_s}}=M(d_v)^{-1/3}, \tag{3.8}$$

where d_v is the volume concentration of the particles. Thus we have for the velocity of sedimentation

$$V=\left[1-1.6493\sqrt[3]{\frac{d_v}{M^3}}+0.7968\frac{d_v}{M^3}\right]\frac{2(\rho_p-\rho_s)a^2g}{9\mu}. \tag{3.9}$$

When there is a single particle, its terminal velocity V_0 is given as

$$V_0=\frac{2}{9}(\rho_p-\rho_s)\frac{a^2g}{\mu}, \tag{3.10}$$

by making $r_0\rightarrow\infty$ in (3.3). Thus we finally have

$$\frac{V}{V_0}=1-1.6493\sqrt[3]{\frac{d_v}{M^3}}+0.7968\frac{d_v}{M^3}, \tag{3.11}$$

where

$$\left. \begin{aligned} (a) \quad M &= 0.9095, \\ (b) \quad M &= 1.1458 \end{aligned} \right\} \tag{3.12}$$

for the simple cubic and the body-centred lattice approximations respectively.

Comparison with the Experiments. In Fig. 3, the relation between the sedimentation velocity V/V_0 and the concentration d_v is plotted, and is compared with other theoretical and experimental results. Noda's experimental data³⁾ were obtained from the measurement of sedimentation velocities of the spherical particles of polystyrene (Dow polystyrene latex 580 G lot 2584), whose radius and density are $a=134\text{ m}\mu$ and $\rho_p=1.052$ respectively, in a salted water ($\rho_s=1.0042$). On the other hand, Happel and Epstein²⁾ measured the pressure drop in a flow of water through a circular pipe of diameter 10 cm in which an assemblage of smooth cellulose acetate spheres of equal diameter (4.90 mm) is mechanically suspended and immobilized at simple cubic lattice points.

Fig. 3. Sedimentation velocity vs. volume concentration.

Although our model for the problem of sedimentation is rather rough, yet it gives as good results as those of other calculations^{1), 5)} based on the assumption that particles are situated at lattice points. It is also noteworthy that our data agree well with Happel and Epstein's experiments of the flow through pipe past spherical particles in lattice configurations. As for the origin of the discrepancy between our theory and the experiments of the sedimentation, it seems to the author that although in the theory all the distances between the neighbouring particles are assumed to be nearly equal, the distribution of the sedimenting particles will not be uniform but rather completely at random as to the distances between the neighbouring particles, and this fact may lead to the reduction of the drag of each particle and consequently to the increase of the sedimentation velocity.

§ 4. Summary

The flow of a viscous fluid past a sphere in a frictionless circular pipe is investigated by using Faxén's procedure and the results are applied to the problem of sedimentation. Although our model is rather rough, it gives as good results as those given by other

theories.

Acknowledgements

In conclusion, I wish to express my hearty gratitude to Professors Isao Imai and Saburô Asaka for their discussion and kind inspection of the manuscript, to Professor Haruo Noda who kindly showed me unpublished data, and to Professor Shôichi Wakiya for his advice.

On a Theorem for Estimating Eigenvalues

By Hiroshi FUJITA and Tosio KATO

Department of Physics, Faculty of Science, University of Tokyo

(Received November 15, 1957)

Elementary proof is given for a theorem estimating eigenvalues of linear transformations with the form T^*T , which was used elsewhere in calculating the fundamental frequency of a square plate with free edges.

§ 1. Introduction

Some time ago one [3] of the authors of the present note proposed an approximation method for the eigenvalue problem of a self-adjoint transformation of the type T^*T in a Hilbert space. This method is based on the theorems stated in Section 3 and Section 4,

which were proved with the aid of the Neumann-Murray theory [5, 7] concerning transformations T^*T , TT^* and a generalization of the Temple formula [2] [4, p. 103-105]. The purpose of the present note is to give elementary and direct proofs of these theorems. For simplicity we shall treat the

problem in the case of finite-dimensional vector spaces, though the application of these theorems lies mostly in systems with infinite degrees of freedom. The generalization of the results to the latter cases is straightforward and does not offer any essential difficulty.

Section 2 is devoted to a brief exposition of some known results regarding transformations T^*T and TT^* . In Section 3 and Section 4, we state and prove the theorems. Section 5 contains some remarks for the application of these theorems to continuous systems.

§ 2. Preliminary Remarks

Let $\mathfrak{H}$ and $\mathfrak{H}'$ be two (possibly identical) real Euclidean vector spaces with the inner products and the norms defined and denoted in the ordinary way. We consider a linear transformation T from $\mathfrak{H}$ into $\mathfrak{H}'$. T^* , the adjoint of T , is a linear transformation from $\mathfrak{H}'$ into $\mathfrak{H}$ and satisfies, by definition, the identity

$$(Tu, v) = (u, T^*v) \quad (1)$$

for any $u \in \mathfrak{H}$ and any $v \in \mathfrak{H}'$. T^*T and TT^* are symmetric transformations in $\mathfrak{H}$ and $\mathfrak{H}'$ respectively. The obvious relations

$$(T^*Tu, u) = \|Tu\|^2 \geq 0, \quad (TT^*v, v) = \|T^*v\|^2 \geq 0 \quad (2)$$

show that the symmetric transformations T^*T , TT^* and therefore their eigenvalues are non-negative. If we designate by $\mathfrak{N}$ the zero point set of T^*T , i.e., the set of u such that $T^*Tu = 0$, (2) shows that $\mathfrak{N}$ is at the same time the zero point set of T :

$$Tu = 0 \quad \text{for any } u \in \mathfrak{N}. \quad (3)$$

Similarly, it holds that

$$T^*v = 0 \quad \text{for any } v \in \mathfrak{N}', \quad (4)$$

where $\mathfrak{N}'$ is the zero point set of TT^* . 0 is an eigenvalue of T^*T (TT^*) if and only if $\dim \mathfrak{N} \neq 0$ ($\dim \mathfrak{N}' \neq 0$), i.e., $\mathfrak{N} \neq \{0\}$ ($\mathfrak{N}' \neq \{0\}$).

Let $\lambda_1^2, \lambda_2^2, \dots, \lambda_\sigma^2$, ($\lambda_k > 0$, $k=1, 2, \dots, \sigma$), be the totality of the positive eigenvalues of T^*T and let

$$\mu_1^2 \leq \mu_2^2 \leq \dots \leq \mu_n^2 \leq \dots \leq \mu_p^2, \quad (\mu_n > 0, n=1, 2, \dots, p), \quad (5)$$

be the arrangement of $\{\lambda_k^2\}$ in the ascending order, where any degenerate eigenvalue is to appear repeatedly in conformity with its multiplicity. It should be remarked that $p = \dim \mathfrak{H} - \dim \mathfrak{N}$. We introduce a system $\{\varphi_n; n=1, 2, \dots, p\}$ of eigenvectors of T^*T such that

$$T^*T\varphi_n = \mu_n^2\varphi_n,$$

$$(\varphi_n, \varphi_m) = \delta_{nm}, \quad (n, m=1, 2, \dots, p). \quad (6)$$

Evidently $\{\varphi_n\}$ is complete in $\mathfrak{H} \ominus \mathfrak{N}$. Furthermore, if we put

$$\psi_n = \frac{1}{\mu_n} T\varphi_n, \quad (n=1, 2, \dots, p), \quad (7)$$

then ψ_n is an eigenvector of TT^* with the eigenvalue μ_n^2 and the system $\{\psi_n\}$ is orthonormal, for the relations

$$\left. \begin{aligned} TT^*\psi_n &= \frac{1}{\mu_n} TT^*T\varphi_n = \mu_n T\varphi_n = \mu_n^2\psi_n, \\ \mu_n\mu_m(\psi_n, \psi_m) &= (T\varphi_n, T\varphi_m) \\ &= (T^*T\varphi_n, \varphi_m) = \mu_n^2(\varphi_n, \varphi_m) = \delta_{nm}\mu_n^2 \end{aligned} \right\} \quad (8)$$

are true for $n, m=1, 2, \dots, p$. Moreover, $\{\psi_n\}$ is complete in $\mathfrak{H}' \ominus \mathfrak{N}'$. In fact, let v be an eigenvector of TT^* with a positive eigenvalue μ'^2 ($\mu' > 0$), i.e.,

$$TT^*v = \mu'^2v, \quad (\mu' > 0, v \neq 0). \quad (9)$$

Then, $\|T^*v\|^2 = (TT^*v, v) = \mu'^2\|v\|^2 \neq 0$ and

$$T^*T(T^*v) = T^*(TT^*v) = \mu'^2T^*v,$$

which means that T^*v is an eigenvector of T^*T with the positive eigenvalue μ'^2 . Hence T^*v is to be expressible as

$$T^*v = \sum_{n=s}^t a_n \varphi_n, \quad (10)$$

where $\mu_s = \mu_{s+1} = \dots = \mu_t = \mu'$. Thus, by means of (9) we obtain

$$v = \frac{1}{\mu'^2} TT^*v = \frac{1}{\mu'^2} \sum_{n=s}^t a_n T\varphi_n = \frac{1}{\mu'} \sum_{n=s}^t a_n \psi_n \quad (11)$$

showing the desired completeness of $\{\psi_n\}$.

Summarizing the results obtained above, we conclude.* The multiplicities being taken into account, the set of the positive eigenvalues of T^*T is identical with that of TT^* ; we can choose a pair of orthonormal systems $\{\varphi_n\}$, $\{\psi_n\}$, ($n=1, 2, \dots, p$), such that $\{\varphi_n\}$ and $\{\psi_n\}$ are complete in $\mathfrak{H} \ominus \mathfrak{N}$ and $\mathfrak{H}' \ominus \mathfrak{N}'$ respectively (thus, $p = \dim \mathfrak{H} - \dim \mathfrak{N} = \dim \mathfrak{H}' - \dim \mathfrak{N}'$) and are connected with each other by the relations

$$T\varphi_n = \mu_n \psi_n, \quad T^*\psi_n = \mu_n \varphi_n, \quad (n=1, 2, \dots, p). \quad (12)$$

* These results correspond to Schmidt's theorem [8] concerning "pairs of adjoint eigenfunctions" of nonsymmetric integral equations. Also the Neumann-Murray theory can be regarded as a generalization of these results to general transformations in Hilbert spaces.

§ 3. Estimation of Eigenvalues

For any $u \in \mathfrak{H}$ and $v \in \mathfrak{H}'$ subjected to the conditions

$$\|u\|^2 = 1, \quad \|v\|^2 = 1, \quad (13)$$

$$(Tu, v) \geq 0, \quad (14)$$

we define the following quantities

$$\eta = (Tu, v) = (u, T^*v), \quad (15)$$

$$\varepsilon^2 = \frac{1}{2} [\|Tu\|^2 + \|T^*v\|^2] - \eta^2, \quad (\varepsilon \geq 0). \quad (16)$$

The use of the notation $\varepsilon^2 (\varepsilon \geq 0)$ is seen to be legitimate in virtue of the relation

$$2\varepsilon^2 = \|Tu - \eta v\|^2 + \|T^*v - \eta u\|^2, \quad (17)$$

which is an easy consequence of (15) and (16). Also (17) implies that $\varepsilon = 0$ occurs if and only if both of the equalities

$$Tu = \eta v, \quad T^*v = \eta u \quad (18)$$

are satisfied, i.e., if and only if u and v are respectively eigenvectors of T^*T and TT^* with the eigenvalue η^2 .

Making use of φ_n, ψ_n ($n=1, 2, \dots, p$) introduced in Section 2, we can write

$$\left. \begin{aligned} u &= u_0 + a_1\varphi_1 + a_2\varphi_2 + \dots + a_p\varphi_p, \\ v &= v_0 + b_1\psi_1 + b_2\psi_2 + \dots + b_p\psi_p, \end{aligned} \right\} \quad (19)$$

where $u_0 \in \mathfrak{N}$, $v_0 \in \mathfrak{N}'$ are the projections of u, v on $\mathfrak{N}, \mathfrak{N}'$ respectively, and where

$$\left. \begin{aligned} a_n &= (u, \varphi_n), \quad b_n = (v, \psi_n), \\ (n &= 1, 2, \dots, p). \end{aligned} \right\} \quad (20)$$

In view of (3), (4) and (12), we observe

$$\left. \begin{aligned} Tu &= \mu_1 a_1 \psi_1 + \mu_2 a_2 \psi_2 + \dots + \mu_p a_p \psi_p, \\ T^*v &= \mu_1 b_1 \varphi_1 + \mu_2 b_2 \varphi_2 + \dots + \mu_p b_p \varphi_p. \end{aligned} \right\} \quad (21)$$

If we put

$$\|u_0\| = a_0, \quad \|v_0\| = b_0 \quad (22)$$

and introduce

$$\mu_0 = 0, \quad (23)$$

by convention, (13), (15) and (16) are reduced to the following forms:

$$\sum_{n=0}^p a_n^2 = 1, \quad \sum_{n=0}^p b_n^2 = 1, \quad (24)$$

$$\eta = \sum_{n=1}^p \mu_n a_n b_n = \sum_{n=0}^p \mu_n a_n b_n, \quad (25)$$

$$2(\varepsilon^2 + \eta^2) = \sum_{n=1}^p \mu_n^2 (a_n^2 + b_n^2) = \sum_{n=0}^p \mu_n^2 (a_n^2 + b_n^2). \quad (26)$$

We now prove the following Lemma.

Lemma 1. Let η and ε be as given above. Let ρ be a positive number and set

$$r = r(\rho) = \sqrt{\varepsilon^2 + (\rho - \eta)^2}. \quad (27)$$

Then under the condition $\varepsilon > 0$, each of the half-closed intervals $(\rho - r, \rho + r]$ and $[\rho - r, \rho + r)$ contains at least one of $\mu_0, \mu_1, \dots, \mu_p$.

Proof. Multiplying both sides of

$$(\mu_n - \rho)^2 - r^2 = \mu_n^2 - 2\rho\mu_n + (\rho^2 - r^2)$$

by $a_n^2 + b_n^2$ and then summing up both sides with respect to n , we have

$$\begin{aligned} & \sum_{n=0}^p [(\mu_n - \rho)^2 - r^2] (a_n^2 + b_n^2) \\ &= \sum_{n=0}^p \mu_n^2 (a_n^2 + b_n^2) - 4\rho \sum_{n=0}^p \mu_n a_n b_n \\ & \quad + (\rho^2 - r^2) \sum_{n=0}^p (a_n^2 + b_n^2) - 2\rho \sum_{n=0}^p \mu_n (a_n - b_n)^2 \\ &= 2(\varepsilon^2 + \eta^2) - 4\rho\eta + 2(\rho^2 - r^2) - 2\rho \sum_{n=0}^p \mu_n (a_n - b_n)^2 \\ &= 2[\varepsilon^2 + (\rho - \eta)^2 - r^2] - 2\rho \sum_{n=0}^p \mu_n (a_n - b_n)^2, \end{aligned}$$

by means of (24), (25) and (26). Thus, by virtue of (27),

$$\begin{aligned} & \sum_{n=0}^p [(\mu_n - \rho)^2 - r^2] (a_n^2 + b_n^2) \\ & \quad + 2\rho \sum_{n=0}^p \mu_n (a_n - b_n)^2 = 0. \end{aligned} \quad (28)$$

Suppose now that the interval $(\rho - r, \rho + r]$ does not contain any of $\mu_0 (=0), \mu_1, \dots, \mu_p$. (The other interval can be treated similarly.) Then each term in (28) is non-negative and therefore must vanish. Noting that $\mu_0 = 0$ and $\mu_n > 0$ ($n \geq 1$), we should conclude that

$$a_n = b_n \quad \text{for } n = 1, 2, \dots, p \quad (29)$$

and that

$$a_n = b_n = 0 \quad \text{if } \mu_n \neq \rho - r. \quad (30)$$

If $\mu_n \neq \rho - r$ for every n , (30) evidently contradicts (24). On the other hand, if $\mu_s = \mu_{s+1} = \dots = \mu_t = \rho - r$ ($0 \leq s \leq t \leq p$) and the other $\mu_n \neq \rho - r$, (29) and (30) yield $\eta = \rho - r$ and

$$2(\varepsilon^2 + \eta^2) = 2(\rho - r)^2,$$

by means of (24), (25) and (26). In consequence we are led to $\varepsilon = 0$, which again contradicts the assumption and complete the proof.

We are now ready to proceed to the following Theorem.

Theorem 1. Let T, T^* be as above. For $0 \leq \alpha < \beta$, let the open interval (α^2, β^2) contain at most one eigenvalue of T^*T . For a pair of $u \in \mathfrak{H}, v \in \mathfrak{H}'$ subjected to (13) and (14), let the inequality

$$(\eta - \alpha)(\beta - \eta) > \varepsilon^2 \quad (31)$$

be satisfied, where η and ε are given by (15)

and (16).

Then there certainly exists a positive eigenvalue $\tilde{\lambda}^2$ of T^*T in the interval (α^2, β^2) such that

$$\xi \leq \tilde{\lambda} \leq \zeta, \quad (32)$$

where

$$\xi = \eta - \frac{\varepsilon^2}{\beta - \eta}, \quad \zeta = \eta + \frac{\varepsilon^2}{\eta - \alpha}. \quad (33)$$

Proof. First we remark that (31) implies

$$\alpha < \xi \leq \eta \leq \zeta < \beta. \quad (34)$$

The two cases $\varepsilon > 0$ and $\varepsilon = 0$ are dealt with separately. In the case $\varepsilon > 0$, we determine a positive number ρ' in such a way that

$$\rho' - r(\rho') = \alpha.$$

Then Lemma 1 asserts that the interval $(\alpha, \rho' + r(\rho'))$ contains at least one μ_n ($n=0, 1, \dots, p$). ρ' is determined by noting that $\rho' - \eta - r(\rho') = \alpha - \eta$ and $r(\rho')^2 - (\rho' - \eta)^2 = \varepsilon^2$. The result is

$$\rho' = \frac{1}{2} \left[\eta + \alpha + \frac{\varepsilon^2}{\eta - \alpha} \right],$$

$$r(\rho') = \frac{1}{2} \left[\eta - \alpha + \frac{\varepsilon^2}{\eta - \alpha} \right].$$

Hence

$$\rho' + r(\rho') = \eta + \frac{\varepsilon^2}{\eta - \alpha} = \zeta.$$

Evidently the interval $(\alpha, \zeta]$ excludes $\mu_0 = 0$ so that $(\alpha^2, \zeta^2]$ contains at least one positive eigenvalue λ'^2 of T^*T . On the other hand, if another positive number ρ'' is chosen in such a way that

$$\rho'' + r(\rho'') = \beta,$$

we get similarly

$$\rho'' - r(\rho'') = \eta - \frac{\varepsilon^2}{\beta - \eta} = \xi$$

and see, according to Lemma 1, that the interval $[\xi, \beta)$ contains at least one μ_n ($n=0, 1, \dots, p$). Since $[\xi, \beta)$ cannot contain $\mu_0 = 0$ by virtue of $0 < \xi$, there exists at least one positive eigenvalue λ''^2 of T^*T included in $[\xi^2, \beta^2)$.

It follows from these results, combined with the assumption that (α^2, β^2) contains at most one eigenvalue of T^*T that the above-mentioned λ' and λ'' are both unique and mutually identical. Thus the validity of the Theorem has been established for the case $\varepsilon > 0$.

If $\varepsilon = 0$, η^2 itself turns out to be an eigen-

value of T^*T as shown near the beginning of this Section. On the other hand, we have clearly, $\xi = \eta = \zeta$. Hence the Theorem is also true on account of (34).

§ 4. Estimation of Eigenvectors

Theorem 2. In Theorem 1, let $\tilde{\lambda}^2$ be non-degenerate and let $\tilde{u}$ be the eigenvector of T^*T with the eigenvalue $\tilde{\lambda}^2$ normalized as

$$\|\tilde{u}\|^2 = 1, \quad (u, \tilde{u}) \geq 0. \quad (35)$$

Then, $\tilde{v} = \text{const. } T\tilde{u}$ is an eigenvector of TT^* with the same eigenvalue $\tilde{\lambda}^2$. If $\tilde{v}$ is normalized as

$$\|\tilde{v}\|^2 = 1, \quad (v, \tilde{v}) \geq 0, \quad (36)$$

we have

$$\frac{1}{2} [\|u - \tilde{u}\|^2 + \|v - \tilde{v}\|^2] \leq \frac{\varepsilon^2}{\delta^2} \left(1 - \frac{\varepsilon^2}{\delta^2}\right)^{-1/2}, \quad (37)$$

provided that $\varepsilon < \delta = \min(\eta - \alpha, \beta - \eta)$.

Proof. Let all notations be as before. The fact that $\tilde{v}$ is an eigenvector of TT^* with the eigenvalue $\tilde{\lambda}^2$ was already proved in Section 2. Also we may assume without loss of generality that

$$\tilde{\lambda} = \mu_r \neq \text{the other } \mu_n, \quad \tilde{u} = \varphi_r, \quad \tilde{v} = \psi_r$$

for some $r \geq 1$. Thus we have

$$(u, \tilde{u}) = (u, \varphi_r) = a_r \geq 0, \quad (v, \tilde{v}) = (v, \psi_r) = b_r \geq 0. \quad (38)$$

We further suppose that $\eta - \alpha \leq \beta - \eta$, i.e., $\delta = \eta - \alpha$, since the other case can be treated quite similarly. According to Theorem 1, μ_r and only μ_r is contained in the open interval (α, β') among all μ_n ($n=0, 1, 2, \dots, p$) where $\beta' = \eta + \delta$, for

$$\zeta = \eta + \frac{\varepsilon^2}{\eta - \alpha} = \eta + \frac{\varepsilon^2}{\delta} < \eta + \delta = \beta'.$$

If we introduce the quadratic expression $f(x) = (x - \alpha)(x - \beta')$, it follows that $f(\mu_r) < 0$ and $f(\mu_n) \geq 0$ for $n \neq r$. Also $f(-\mu_n) \geq 0$ holds for $n=0, 1, \dots, p$ by virtue of $0 \leq \alpha$, $0 \leq \mu_n$. Hence we have

$$\sum_{n=0}^p f(\mu_n)(a_n + b_n)^2$$

$$+ \sum_{n=0}^p f(-\mu_n)(a_n - b_n)^2 \geq f(\mu_r)(a_r + b_r)^2. \quad (39)$$

By means of (24), (25) and (26), the left side of (39) is reduced to

$$2 \sum_{n=0}^p \mu_n^2 (a_n^2 + b_n^2)$$

$$\begin{aligned}
& +2\alpha\beta' \sum_{n=0}^p (a_n^2 + b_n^2) - 4(\alpha + \beta') \sum_{n=0}^p \mu_n a_n b_n \\
& = 4(\varepsilon^2 + \eta^2) + 4\alpha\beta' - 4(\alpha + \beta')\eta \\
& = 4[\varepsilon^2 + f(\eta)] \\
& = 4(\varepsilon^2 - \delta^2),
\end{aligned}$$

where at the last step use is made of $f(\eta) = -\delta^2$. On the other hand,

$$f(\mu_r) \geq \min f(x) = f(\mu) = -\delta^2.$$

In this way, we are led to

$$4(\varepsilon^2 - \delta^2) \geq -\delta^2(a_r + b_r)^2,$$

namely,

$$\left(\frac{a_r + b_r}{2}\right)^2 \geq 1 - \frac{\varepsilon^2}{\delta^2}. \quad (40)$$

Since, by (35), (36) and (38)

$$\frac{1}{2}[\|u - \tilde{u}\|^2 + \|v - \tilde{v}\|^2] = 2\left(1 - \frac{a_r + b_r}{2}\right), \quad (41)$$

we arrive at the desired inequality (37) with the aid of (40) and the elementary inequality $2(1-x) \leq (1-x^2)/x$, ($x > 0$).

Remark. In theorem 2, the assumption of non-degeneracy of $\tilde{\lambda}^2$ is essential. For example, if $\mu_r = \mu_{r+1} = \tilde{\lambda}$, it may occur that $\tilde{u} = \varphi_r$, $u = \varphi_{r+1}$, $\tilde{v} = \phi_r$, $v = \phi_{r+1}$. Then the left side of (37) is equal to 2, while the other side vanishes owing to $\varepsilon = 0$.

§ 5. Concluding Remarks

Remark 1. Our results stated in Theorem 1 and Theorem 2 can be generalized to more general cases in which $\mathfrak{H}$, $\mathfrak{H}'$ are complex Hilbert spaces and T is a closed linear (in general unbounded) transformation from $\mathfrak{H}$ into $\mathfrak{H}'$ with its domain $\mathfrak{D}_T$ dense in $\mathfrak{H}$ [3]. Then T^* exists and turns out to be a closed linear transformation from $\mathfrak{H}'$ into $\mathfrak{H}$ with its domain $\mathfrak{D}_{T^*}$ dense in $\mathfrak{H}'$. In such cases, Theorem 1 and Theorem 2 retain their validity, if u , v are subjected to the additional conditions

$$u \in \mathfrak{D}_T, \quad v \in \mathfrak{D}_{T^*}, \quad (42)$$

so that η , ε^2 given by (15), (16) are meaningful.

Remark 2. From the view point of practical

application, our Theorems, in particular Theorem 1, can be regarded as an approximation method of variational character. According to Theorem 1 we can calculate an approximate value, with error estimation, of the eigenvalue $\tilde{\lambda}^2$ in question as soon as we can construct suitable "admissible vectors" u, v and also are provided, in one way or another, with α^2 and β^2 , i.e., a rough upper bound for the next lower eigenvalue and a rough lower bound for the next upper eigenvalue. Thus the scope of application of our Theorems is rather wide, for most eigenvalue problems differential systems in mathematical physics can be reduced to the form $T^*Tu = \lambda^2u$ by a suitable choice of $\mathfrak{H}$, $\mathfrak{H}'$. Though some of the conveniences of this method was illustrated by a simple example in [3], as typical examples of this application we refer the readers to papers by us and our collaborators on the vibration problem of an elastic plate with free edges. One [6] of them gives rather rough approximate values by using simple admissible vectors, while the other [1] adopts more complicated admissible vectors and gives much improved approximate values as the result. Also some detailed prescriptions of auxiliary procedures needed for good estimation and brief discussions of the relative advantages and disadvantages of this method in comparison with other methods can be found in [1].

Anomalous g -shifts of Excited States of Cr^{3+} in Ruby

By Ikuji TSUJIKAWA

Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

and Satoru SUGANO

Department of Physics, Tokyo University, Tokyo

(Received December 5, 1957)

In the previous note, Tanabe and one of the present authors¹⁾ tried to explain the Zeeman effect of the characteristic doublets R_1 and R_2 of ruby observed at 83°K by Lehmann²⁾ and found that the theoretical results contradicted with his observations only in quantitative aspects.

Under these circumstances, we have repeated studies of the Zeeman effects³⁾ on the same absorption lines at 20°K and 4.2°K, using a concave grating of dispersion 2.5Å/mm (1st order) and a magnetic field $H_0=24000\phi$. As it was found in preliminary experiments that the spectral widths were broad at high Cr^{3+} concentration (a few per cent), we have used synthetic ruby of 4mm thickness which contains 0.28 weight percent Cr_2O_3 .

Our results show that the quantitatively strange points in Lehmann's results are removed and Zeeman levels of the ground states which are observed directly in the Zeeman patterns of R_1 , R_2 when $H_0 \perp C_3$ (since $g_{0\perp} \sim 0$) agree well with those ob-

served by the paramagnetic resonance method.⁴⁾ However, the $g_{e//}$ -shifts of the excited states of R_1 and R_2 are found to be anomalous; $g_{e//}(R_1) \approx 2+2\Delta$, $g_{e//}(R_2) \approx 2-2\Delta$ ($\Delta \approx 0.2$) and so $g_{e//}(R_1) + g_{e//}(R_2) \approx 4$.

One of our results which shows these anomalies is schematically described in Fig. 1. While the main three Zeeman components are completely resolved on our photographic plates, the central two lines closely located each other appear as a somewhat broad line. The superposition of these central lines is only found from its apparent shift relative to the side components when temperature is varied from 20°K to 4.2°K. This apparent shift is due to the decrease of the electron population of the upper Zeeman levels of the ground state at 4.2°K. The other strong evidence which confirms the anomalous behavior of $g_{e//}$ -shifts is seen in the observed separations of the side components which are $\approx 2(2+\Delta)$ for both R_1 and R_2 when the electric vector E of the incident light is parallel to the optic axis C_3 .

The observed remarkable relation $g_{e//}(R_1) + g_{e//}(R_2) \approx 4$ and the shift $\Delta g_{e//}(R_1) \approx 0.4$ can be explained by the dominant effect of the third order perturbation $L_Z \cdot V \cdot V \cdot \beta H_0$ (V is the trigonal field) which is linear in H_0 and involves no term of spin-orbit interaction H_{SO} . In these excited states of ruby none of the second order perturbations contributes to the g -shift and the contributions from the other types of the third order's which involve H_{SO} are all small because $H_{SO} < V$.⁵⁾

The Zeeman effects on the other lines B_1 and B_2 located at $\sim 21000\text{ cm}^{-1}$ have also been studied and the remarkably large splittings were found in one of them. The experimental details and other results will be published soon.

One of the authors S. S. should like to express his sincere thanks to Prof. E. Kanda and other members of Research Institute for I. S. O. M. for their hospitality.

Theoretical Considerations on Radiation-Induced Reactions of Saturated Long-Chain Hydrocarbons

By Mitio INOKUTI and Tsutomu WATANABE

Department of Applied Physics, Faculty of Engineering, University of Tokyo, Tokyo

(Received November 2, 1957)

Proposed mechanisms of radiation-induced cross-linking of saturated long-chain hydrocarbons, based on the observed linear dose-dependence of both the amount of evolved hydrogen gas and the number of crosslinks, require the following process as an essential step.¹⁾

Using a semiempirical method of bond-eigenfunctions, the adiabatic potential of the ground doublet state of the reacting system was calculated by perturbation procedure, taking as bases the wavefunction ψ_1 describing the hydrocarbon and the hydrogen atom infinitely separated from each other, and ψ_2 describing the hydrocarbon radical and the hydrogen molecule infinitely separated from each other. The Hamiltonian matrixelements were then reduced to linear combinations of two-body interactions, neglecting higher-order permutations and many-center integrals:

$$\mathcal{H}_{11} = E(\text{C}_0\text{H}) + E(\text{H}_0\text{H}) + U \quad (2)$$

$$\mathcal{H}_{22} = {}^1E(\text{H}_0\text{H}) + (3/4){}^3E(\text{C}_0\text{H}_0) - (3/4){}^1E(\text{C}_0\text{H}_0) + E(\text{C}_0\text{H}) + U \quad (3)$$

$$\mathcal{H}_{12} = (1/2)\{{}^1E(\text{H}_0\text{H}) + {}^3E(\text{C}_0\text{H}) + U\} \quad (4)$$

$$U = E(\text{H}_0'\text{H}) + 2 \sum_{\nu=1}^{\infty} E(\text{C}_\nu\text{H}) + 2 \sum_{i=1}^{\infty} \{E(\text{H}_i\text{H}) + E(\text{H}_i'\text{H})\} \quad (5)$$

${}^1E(\text{XY})$ and ${}^3E(\text{XY})$ are the adiabatic potentials for the lowest ${}^1\Sigma$ and ${}^3\Sigma$ state of the molecule XY, $E(\text{XY})$ being their multiplicity-average. We remark, however, that ${}^1E(\text{CH})$ or ${}^3E(\text{CH})$ means the potential, not of the real CH molecule, but of a virtual one bonded by an electron in 1s hydrogen AO and one in the tetrahedrally hybridized carbon AO directed to the hydrogen. Suffixes and primes refer to the atoms in hydrocarbon as seen in Fig. 1. The non-orthogonality ($\psi_1\psi_2$) turns out 1/2 in our approximation. The perturbed energy is shown to be lowest when the hydrogen atom lies on the straight line along a CH-bond so that (2), (3), (4) and numerical work refer to this case. ${}^1E(\text{HH})$ and ${}^3E(\text{HH})$ were obtained by good approximate formulas by Hirschfelder and Linnett³⁾. ${}^1E(\text{CH})$ was approximated by a Morse function, parameters determined by spectroscopic and thermochemical data of lower hydrocarbons. An approximate for-

mula for ${}^3E(\text{CH})$ was established by a semiempirical Heitler-London type calculation.

Fig. 1. (After Bunn⁽²⁾).

Fig. 2.

Our results are given in Fig. 2, with the cases $-\text{CH}_2-\text{CH}_3 + \text{H}$ and $\text{CH}_4 + \text{H}$, obtained by proper modifications in (5). The calculated activation energy for (1) seems rather high. But in solid hydrocarbon samples the reacting hydrogen atom is originally not at zero-potential, but at a finite potential; moreover there may be some attractive polarization forces and changes of hybridization in ψ_2 , not taken into account here. These situations may reduce the activation energy appreciably in solid state. The reaction of hydrogen atom with a chain-end methyl group requires much lower activation energy than with a mid-chain. The calculated activation energy for $\text{CH}_4 + \text{H}$, 0.79 eV, may be compared with the observed value, 0.40~0.56 eV,⁴⁾ Our treatment should be superior to Gorin et al's,⁵⁾ resulting in too low activation energy and a doubtful prediction of a stable complex CH_5 , because of their adoption of a too short-range potential as ${}^3E(\text{HH})$, which contributes to U remarkably.

We are grateful to Prof. A. Amemiya for helpful discussions throughout the work.

Liquid-Like Layers in the Adsorbed Film of H₂O on Glass

By Koji KAWASAKI, Kyoichi KANOU
and Yoshiyasu SEKITA

*Electrotechnical Laboratory, Nogatacho,
Tokyo, Japan*

(Received November 11, 1957)

The adsorption isotherm of water vapour and the d.c. surface conductivity were measured for some kinds of glass as given in Table I. The isotherms

Table I.

Material	No.	SiO ₂	Al ₂ O ₃	CaO	Na ₂ O
Glass-A	4	62.34	8.48	7.80	21.38
	6	59.75	11.82	7.97	20.46
Glass-B	3	75		7	18.91
	5	67		15	16.86
in wt %					

were obtained by the gravimetric method using powdered specimens; the d.c. conductivity was measured on glass plates by means of a galvanometer.¹⁾ The samples had been cleaned with NaOH aqueous solution, chromic acid mixture and distilled water.

The surface conduction current i divided by i_0 , the current for $\theta=0$, is plotted in Fig. 1 versus

Fig. 1.

the number of the adsorbed layers θ as determined by the BET method. It can be seen that i/i_0 linearly increases with θ when θ exceeds some critical value

which is characteristic to the specimen. This could be explained if one assumes that the lower, or the inner, adsorbed layers are immobile being under the influence of the strong attraction field of the glass surface, while the upper, or the outer, layers are mobile: the conduction current would increase materially only when the mobile or the liquid-like layers are present.

The above assumption is supported by the following consideration.

The calculations by Hill²⁾ and others show that, for the case of the liquid-like adsorbate, in which the effective molecular interaction is supposed to be exclusively of the van der Waals type the adsorption isotherm is represented by

$$\ln x = \ln(p/p_0) = -K/\theta^3, \quad (1)$$

where θ is the number of layers at a pressure p , and p_0 is the saturation pressure. K is a certain constant which depends on various parameters characterizing the molecular interactions. Eq. (1) is a special case of the more general equation proposed by Halsey³⁾:

$$\ln(p/p_0) = -K/\theta^s. \quad (2)$$

Now, the adsorption isotherms we obtained experimentally for Glass-B are plotted in Fig. 2. The

Fig. 2.

curves are, at high relative pressures, in good agreement with the theoretical isotherms with $s=3$ in Eq. (2), suggesting that the adsorbed layers are liquid-like. The values of s for representing the experimental isotherms at high relative pressures for Glass-A, Nos. 4 and 6, by Eq. (2) are 2.0 and 3.2 respectively.

In conclusion, we would like to point out that our adsorption isotherms are qualitatively in good agreement for $p/p_0 \leq 0.93$ with the one obtained by Garbatski and Folman⁴⁾ for a well defined glass plate. Investigations on the adsorption at very high relative pressures when capillary condensation may have pronounced influence are wanted.

Current Amplification by Electron Bombardment in the Semiconductor Barrier Layer

By Kenichi TAKEYA and Keiichi NAKAMURA

Technical Research Laboratory, Broadcasting Corporation of Japan, Tokyo

(Received December 4, 1957)

The experiment described in this paper is intended to find how much excess current will flow when a semiconductor barrier layer is bombarded by high energy electron beams. It is expected that the characteristic features of these excess current are closely related with those observed in a p - n junction photo-diode, since the phenomena arise from the separation of free electron-hole pairs excited near the barrier field region. No one has hitherto tried experiment of this sort so extensively, except that W. Ehrenberg and his co-workers (1) carried out the measurement of electron voltaic effect of some selenium and cuprous oxide cells. For Se photo-cells, under best conditions, they obtained a max. current gain of about 500 when bombarding electron energy was in the vicinity of 50 KV. and for Cu_2O , about 150 at 90 KV.

Using similar Se photo-cell, and giving proper reverse bias voltage to the barrier layer, we obtained very large current gain under electron bombardment. In the experiments, the Se photo-cell was bombarded by electron beam perpendicular to its barrier layer. Furthermore, these experiments were performed for alloyed Ge- and grown and diffused, Si p - n junctions. In these cases, except for Si diffused junction, electron beam was directed so as to strike bare p - n junction region nearly parallel to its junction layer. For Si diffused junction, the arrangement was the same as that of Se photo-cell.

Excess currents were measured potentiometrically. The current gain δ was defined as the ratio of excess current i_2 to bombarding current i_1 . The observed δ versus reverse bias voltage V_B characteristics were shown in the figures (1-4). The energy of bombarding electron is indicated on each curve. For Se photo-cell, no reasonable explanation for the observed properties has yet been found. Probably, exponential rise of δ as V_B increases will be the increase in collec-

tion efficiency of charge carriers released by electron bombardment. For Ge and Si p - n junctions, these characteristics are just those expected

Fig. 1.

Fig. 2.

Fig. 4.

Fig. 3.

from the rectifying I-V characteristics and analogous to the photo-diode properties.

These results indicate, as Ehrenberg et al. suggested, a new method of measuring electron beams and of multiplication of electrons created in vacuum.

Fading of Coloration of Irradiated Glass*

By Sohei KONDO

National Institute of Genetics, Misima, Japan

(Received November 30, 1957)

Schulman, Klick and Rabin¹⁾ found that changes in absorption coefficient of phosphate glass provide a simple method of measuring radiation doses up to 2×10^6 röntgen which 5% accuracy. It has also been found that ordinary slide glass²⁾ and window glass plates³⁾ are surprisingly homogeneous with respect to γ -ray induced absorption changes. For further improvement of the accuracy of glass dosimetry, correction for fading must be taken into account. The fading of coloration of gamma irradiated phosphate glass was studied by Rabin and Price⁴⁾. They found the following fading formula.

$$\mu(t) \propto t^{-0.067}, \tag{1}$$

where $\mu(t)$ is the change in absorption coefficient of glass measured at t hours after short exposures. A similar relation holds for fading of coloration of ordinary window glass irradiated by Co^{60} gamma rays as shown in Fig. 1.

It has been found that the following equation for fading gives a very good agreement with ob-

Fig. 1. Fading of irradiated window glass. These specimens were exposed to Co^{60} γ -rays for about one day at various dose rates.

served data over wide temperature ranges,

$$\mu(t) \propto t^{-\lambda}, \tag{2}$$

$$\lambda = e^{-A+BT}, \tag{3}$$

where A and B are constants dependent only on glass and the used wavelength^{**}, and T denotes the absolute temperature. A comparison of (3) with the experimental data is shown in Fig. 2 for ordinary window glass. Integration of (2) shows that the change in absorption coefficient $\mu(\tau, t)$ induced by τ hour irradiation fades with time t after cessation of the irradiation as follows (see also reference 4):

$$\mu(\tau, t) = \mu(\tau, t_0) \frac{(1+t/\tau)^{1-\lambda} - (t/\tau)^{1-\lambda}}{(1+t_0/\tau)^{1-\lambda} - (t_0/\tau)^{1-\lambda}} \tag{4}$$

The relative fading $\mu(\tau, t)/\mu(\tau, 0)$ depends only on t/τ and λ . Then, it is convenient to express the fading in terms of t/τ . A comparison of (4) with observed values is given in Table I where numerical values of λ are taken from Fig. 2. It may be

Surface Area Variation of Evaporated Barium Film by Oxidation

By Yutaka TUZI and Hiroaki OKAMOTO

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Kawasaki

(Received November 6, 1957)

It seems that the surface area determination of an evaporated barium film¹⁾ by the B. E. T. method has never been tried, probably because of its high activity and its small size. We tried it successfully using ethylene as the adsorbate.²⁾

In the experimental procedures, special attentions were paid to the following points: (1) Prior to the experiment, the sample chamber was thoroughly evacuated (baked out at 360°C, 8 hr.). (2) No grease cocks were used in the high vacuum side of the liquid oxygen trap. The details of the experimental device have been published elsewhere.³⁾

The barium film was evaporated uniformly on to the inner wall of a spherical glass bulb (ca. 50 cm²) at room temperatures and 10⁻¹~10⁻³ μ Hg. The results of the repeated measurements of the surface area of a barium film are shown in Fig. 1. We can infer from this curve as well as from the hysteresis of the adsorption isotherms at the liquid oxygen temperature that the ethylene is chemisorbed on fresh barium surfaces even at -183°C⁴⁾. Let us assume that the difference between the first and the third measurement is due to chemisorption, and adopt the steady value obtained after the third measurement as the real surface area S_r . S_r is again decreased if the film is annealed for 30 min. at 105°C or higher temperatures (Fig. 1); a similar decrease can be observed when the high temperature annealing is carried out immediately after the evaporation. It is supposed that, in these cases, a few monolayers of barium oxide are formed on the evaporated film.

Further variation of S_r was pursued allowing the film to absorb oxygen. In Fig. 2, the surface area S_r as well as the rate of absorption of oxygen (determined by the constant volume method) are plotted versus the amount of oxygen absorbed. The weights of the films examined and the temperatures at which the annealing or the measurement was carried out are also jotted in the figure.

The following points would be worth mentioning: (1) S_r is 4~10 times as large as the geometrical area of the film. (2) S_r decreases as Q ,

the amount of oxygen absorbed, increases, reaches a minimum value at $Q=10\sim20$ 1 μ Hg (3~10 layers of BaO), and then increases almost linearly with Q . (3) The rate of increase of S_r depends on the thickness (i.e. weight) of the film.

Our experiment also gives a suggestion to the

Fig. 1. Surface area vs. number of measurement. Weight of film = 2.9 mg.

Fig. 2. Real surface area and rate of absorption of O₂ vs. amount of O₂ absorbed.

mechanism of the increase in the rate of absorption of oxygen at the beginning. This has been explained assuming that the oxidation starts exclusively at some specific points on the barium film.⁵⁾ Fig. 2 suggests, however, that the change of the rate of oxygen absorption has something to do with the variation in the physical nature (e.g. S_r) of the oxide film.

The authors are indebted to Dr. S. Asao for his kindness in reading the original manuscript, and Mr. H. Oda for his helpful aid.

Crystal Growth of CdS by the Vacuum Sealed Method

By Hirosuke YAMASHITA and Sumiaki IBUKI
*Engineering Laboratory, Mitsubishi Elec. Mfg.
 Co., Amagasaki-City, Japan*

(Received November 1, 1957)

Last year we reported a method of growing CdS single crystals utilizing the condensation of sublimated vapor from polycrystalline powders heated in nitrogen gas flows.¹⁾ As results of our trials, we could obtain fairly large single crystals and some interesting informations about the growth of

single crystals,²⁾ nevertheless it was too difficult to get thick crystals. We describe here about the CdS single crystals being recrystallized in a vacuum sealed vessel at high temperatures.

Putting chemically purified CdS powders into a quartz container, we seal it off at high vacuum after sufficiently outgassing the powders. The sealed vessel is kept at a temperature from 1,000°C to 1,200°C for several hours in an electric furnace having a proper temperature gradient, is thereafter slowly cooled at the rate of about 10°C/hr. Thus we can obtain several large single crystals having the sizes of about 10×8×5 mm.

Some interesting samples grown at 1,200°C are shown in Fig. 1 and 2. We can observe that crystals are used to grow along the direction paral-

Fig. 1. Grown crystal.

Fig. 2. Grown crystal.

Fig. 3. Spiral terraces.

Fig. 4. Conical terraces.

are found pretty number of conical terraces, and some of them are spiral terraces as shown in Fig. 3. There are also observed some spiral pits having similar appearances as those on Ge and Si surfaces,³⁾ which indicate the presence of spiral dislocations. Several terraces of trigonal prisms are found on (110) surfaces, those of hexagonal half-pyramids on (010) surfaces.

Orange crystals which are grown at lower temperature emit weak green fluorescence at the room temperature when irradiated by 3650 Å ultra-violet rays.

Details of the above-mentioned report will be published later.

Asymmetry of Proton Resonance Signals
in Some Hydrates of Iron Group Salts

By Syukuro YANO and Sōji SASAKI

Department of Applied Physics,
Kyoto University, Kyoto

Tunahiko SIDEI

Department of Nuclear Science,
Kyoto University, Kyoto

(Received October 30, 1957)

We have observed many asymmetric proton resonance signals from hydrated salts of iron group elements in powdered form at room temperature. The typical line shapes are shown in Fig. 1. Table I shows the asymmetry of the resonance lines and their apparent shifts which mean the difference of magnetic field in gauss between maximum point of the absorption signal and the normal free water

Fig. 1. A record of proton resonance derivative in powdered $\text{CoCl}_2\cdot 6\text{H}_2\text{O}$ at 20°C .

resonance field. This results show the parallelism between shift and asymmetry.

To confirm that these asymmetric lines come

Fig. 2. Second moment of proton resonance in powdered $\text{CoCl}_2\cdot 6\text{H}_2\text{O}$ at room temperature in different external fields.

from paramagnetism of iron group ions, we measured the lines of $\text{CoCl}_2\cdot 6\text{H}_2\text{O}$ in several different magnetic fields. The lines showed marked field dependence in their shapes and second moments. The variation of second moment with external magnetic fields are shown in Fig. 2. These values were calculated from the center of gravity of the integrated absorption curve which nearly fell on the point 1 gauss higher than the zero point of absorption derivative. The values of $(kH_0)^2$ in Fig. 2 are in agreement with $(\bar{\mu}/r^3)^2$ in order of magnitude, taking $r=2.5\text{ \AA}$ and $\bar{\mu}=5\mu_p$ for about 4000 gauss and room temperature, where $\bar{\mu}$ represents the effective magnetic moment of cobalt ion and μ_p represents the magnetic moment of proton. Field independent part of the second moment of about 30 gauss² comes from nuclear dipole-dipole interaction.

The line shapes of $\text{CoCl}_2\cdot 6\text{H}_2\text{O}$ can be decomposed into three displaced parts. The shifts of these component lines originating from electronic paramagnetism contribute to the second moment of the composed curve and this term corresponds to the field dependent part of Fig. 2.

Theoretical line shapes for a pair of single nuclear

Table I.			
Sample	Asymmetry*	Apparent shift (gauss) at about 4200 gauss	Second moment (gauss ²) at about 4200 gauss

$\text{CuCl}_2\cdot 2\text{H}_2\text{O}^{**}$	(-)	< 0.5	21.5
$\text{CuSO}_4\cdot 5\text{H}_2\text{O}$	(-)	$-0.6\sim -1.3$	
$\text{ZnSO}_4\cdot 7\text{H}_2\text{O}^{**}$	(-)	< 0.1	26

* (+) indicates the line has asymmetry and (-) no asymmetry.

** For both paramagnetic $\text{CuCl}_2\cdot 2\text{H}_2\text{O}$ and diamagnetic $\text{ZnSO}_4\cdot 7\text{H}_2\text{O}$ as a reference sample, line shapes were those of two spin system.

spin and an electronic spin of a magnetic ion, are easily calculated assuming that the electronic spins are parallel or antiparallel to the external field. This result does not give a gaussian shape but an asymmetric and displaced line. When three spin system which is composed of a pair of nuclear spins and an electronic spin is treated,¹⁾ the calculated lines have an asymmetry which is in nearly agreement with experimental curves.

Another origin of asymmetry may arise from the anisotropy of g -factor of the magnetic ion,²⁾ which may well be large for the cobalt salts. The order of magnitude is nearly equal to the anisotropy of the paramagnetic shift above stated.

It is interesting to note that some information about the states of paramagnetic ions and crystalline field will be obtained by proton resonance further, when these experiments are carried out at low temperature.

Magnetostriction Constants of Nickel-Copper and Nickel-Cobalt Alloys

By Mikio YAMAMOTO and Takurô NAKAMICHI

The Research Institute for Iron, Steel and Other Metals, Tôhoku University, Sendai

(Received November 28, 1957)

We have determined, for the first time, the magnetostriction constants, λ_{100} and λ_{111} , of Ni-Cu and face-centered cubic Ni-Co alloys at room temperature, using single-crystal specimens and the strain gauge technique.¹⁾ The specimens used are disks with (110) or (100) plate surfaces, cut out from single crystal ingots prepared from nickel and copper or cobalt, all of electrolytic origin, by the Bridgman method in a vacuum Tammann furnace. Ni-Cu crystal disks containing 0, 7.0, 16.4, and 25.8 at.-%Cu are 15 mm in diameter and 1.5 mm in thickness, and Ni-Co crystal disks containing 10.5, 21.3, 32.8, 44.7, and 54.2 %Co are 10 mm in diameter and 1.0 mm in thickness. The out-put unbalanced voltage of a Wheatstone bridge formed by a strain gauge cemented along a certain crystallographic direction on the plate surface of the specimen together with other three similar gauges, which was proportional to the strain of the specimen, was detected directly by a galvanometer. The strain sensitivity was 0.53×10^{-6} per mm of the scale. The specimen was placed in magnetic field of some 4000 Oe, strong enough to saturate it, as produced from a rotatable

Fig. 1. Concentration dependence of the magnetostriction constants of Ni-Cu alloys.

electromagnet and its magnetostrictive strain along the fixed direction was measured as a function of the direction of the magnetic field.

The two principal magnetostriction constants, λ_{100} and λ_{111} , thus obtained are plotted against the alloy composition in Figs. 1 and 2 for Ni-Cu and Ni-Co alloys, respectively. Values of λ_{100} and λ_{111} for nickel are -54.1 and -22.4×10^{-6} , respectively, which are in good agreement with available data²⁾. In Ni-Cu alloys, both constants are negative irrespective of the composition and their absolute values decrease monotonously with increasing copper content, vanishing at some 35 at.-%Cu, as may be expected from the magnetostriction vs. magnetic field curves for polycrystalline specimens.³⁾ The absolute values of saturation magnetostriction, $|\lambda_s|$, for isotropic polycrystals as calculated from our single crystal constants according to the formula $\bar{\lambda}_s = (1/5)(2\lambda_{100} + 3\lambda_{111})$

Fig. 2. Concentration dependence of the magnetostriction constants of Ni-Co alloys.

are somewhat higher than the measured data for polycrystalline specimens.^{3,4)} This discrepancy may be due mainly to the non-uniformity of domain distribution at unmagnetized state in polycrystalline specimens.

In face-centered cubic Ni-Co alloys, the concentration dependence is quite different for λ_{100} and λ_{111} ; λ_{111} is negative irrespective of the composition, showing a flat minimum centered at about 30%Co, while λ_{100} increases almost linearly with increasing cobalt content and, passes through zero, at about 20%Co, reaching to the large value of 116×10^{-6} at 55%Co. The present data agree qualitatively well, but quantitatively not so well, particularly for high-cobalt alloys, with the data obtained previously by one of the authors and Miyasawa⁵⁾ from the analysis of the magnetostriction vs. magnetic field curves of polycrystalline specimens (cf. Fig. 2). This discrepancy may due mainly to the lack of

saturation of the magnetostriction vs. field curves measured by them. The values of saturation magnetostriction for isotropic polycrystals calculated in the same way as in the above-mentioned case of Ni-Cu alloys are in good agreement with the measured data by Went⁴⁾ who used magnetic field strong enough to saturate specimens.

(Received October 2, 1957)

Using 5.7 Mev protons from the cyclotron, the angular distributions of protons elastically scattered from Fe, Cr and Ti were investigated by means of nuclear emulsion technique. The angular distributions of the elastically scattered protons by these nuclei were similar to that of Ni, that is, the differential cross sections in the ratio to those of the Rutherford scattering increase linearly at large angles. Some qualitative arguments are given about this characteristic feature of these nuclei, together with previously measured elements Ni^(1,2) and Zn⁽¹⁾.

§ 1. Introduction

As was pointed out in Bromley and Wall's paper⁽¹⁾ and our previous works^(2,3), the differential cross sections of the elastically scattered protons from even-Z nuclei in the medium weight region were expected to show the characteristic feature in comparison with odd-Z nuclei. According to the previous measurements^(1,2), the behaviours at large scattering angles were very different between even-Z and odd-Z nuclei; i.e., the differential cross sections in the ratio to the Rutherford cross sections for even-Z nuclei (Ni and Zn) increase linearly with the scattering angles, while they do not rise for odd-Z nuclei (Co and Cu). Bromley and Wall⁽¹⁾ suggested, based on their experiments using 5.25 Mev protons, that the difference seemed to be depending on target spins, and we⁽²⁾ concluded, from the experiments of 5.7 Mev protons, that the behaviour was not sensitive to the incident energy for Ni and Cu.

Kliucharev, Bolotin and Lutsik⁽⁴⁾ have investigated the elastic scattering of 5.4 Mev protons by some elements in light and medium weight region, and have obtained the angular distributions in the ratio to the Rutherford cross sections having similar form for all cases of Zn, Cu and Ni, and these angular dependences are quite similar to our previous result for Cu. They pointed out the qualitative similarity in the form of the angular distributions from neighboring nuclei, but it is contrast with the above mentioned Bromley and Wall's suggestion and also with our expecta-

tion. Therefore, in order to obtain the further informations, it is required to accumulate the many experimental data for the elastic scattering of protons at various energies and from a number of nuclei in such medium weight region.

In the present work, we have extended these investigations to adjacent even-Z nuclei, Fe ($Z=26$), Cr ($Z=24$) and Ti ($Z=22$), by the use of 5.7 Mev proton beam from Osaka University cyclotron⁽⁵⁾ and the nuclear emulsion technique.

§ 2. Experimental

The experimental arrangement and procedure were same as our previous experiments⁽²⁾. In the present investigation, the used nuclear emulsions were Ilford C2 and Fuji ET-6B, and their thicknesses were 100 μ and 70 μ , respectively.

The Ti target was a rolled foil of 1.2 mg/cm² thickness. The Cr foil of 3.7 mg/cm² thick was prepared by electroplating method. The thickness of Fe target was 3.8 mg/cm² and it was also a rolled foil. All these targets were self supporting and set at 45° with respect to the beam direction.

The beam current was collected by the Faraday cup connected to 0.025 μ F polystyrene condenser and was measured by electrometer.

§ 3. Results and Discussions

In order to check the experimental arrangement and the geometrical accuracy of the camera, the differential cross sections for Au

were measured and satisfactory results were obtained as was shown already in our preliminary report³⁾. As the targets were rather thick in the both cases of Cr and Fe, the complete separation of the inelastically scattered proton groups from low lying levels of each isotopes were not expected, but the amounts of the target impurities were negligible. In Fig. 1, the typical range distribution of the scattered protons from Fe target is shown. The experimental errors causing from the

Fig. 1. The typical range distribution of the scattered protons from Fe. (1 div. = 1.2 μ)

Fig. 2. Ratios of measured cross sections in the center of mass system to the Rutherford for Ti, Cr and Fe. Errors were only statistical ones.

various parts of the experimental arrangement and procedure were described already in previous paper²⁾.

The angular distributions in the ratio to the Rutherford cross sections are shown in Fig. 2. The overall tendencies of the angular dependences for these elements are similar to the case of Ni. Fig. 3 contains all these curves together, with the previous results of Ni²⁾

Fig. 3. A composite presentation of the experimental curves obtained in the scattering of 5.25 Mev (Zn)¹⁾ or 5.7 Mev (Ti, Cr, Fe and Ni) protons from the even-Z nuclei.

and Zn¹⁾ to compare the angular distributions from even-Z nuclei. From Figs. 2 and 3, one may point out that there are two characteristic features in all cases of elements; one is the appearance of a remarkable valley at $80^\circ \sim 90^\circ$ and the other is monotonous rise at large scattering angles. Comparing these five curves for even-Z nuclei in Fig. 3 with the results^{1), 2)} for odd-Z nuclei, the behaviour at large scattering angles seems to be characteristic property of even-Z nuclei in medium weight region for incident energy of few Mev, though with exceptions of Kliucharev, *et al.*'s 5.4 Mev results⁴⁾ for Ni and Zn.

The appearance of a valley at $80^\circ \sim 90^\circ$ in

all cases may be interpreted in terms of cloudy crystal ball model, since according to this model, the pattern in the differential cross section is expected to be quite similar for neighbouring elements. For the behaviour at large scattering angles, the effect of the potential edge may be important, because the situation in backward direction is affected strongly by incident waves with the higher angular momentum which are determined mainly at the edge of potential well. Then, the different behaviour between even- Z and odd- Z nuclei at large angles may be explained by the use of the different shape of the potential edge for even- Z and for odd- Z nuclei.

For the Kliucharev, *et al.*'s 5.4 Mev data on Ni and Zn which differ from Bromley and Wall's (5.25 Mev) and our (5.7 Mev) results, we cannot give the reasonable interpretation but one may speculate that in this energy region the scattering may be affected by elas-

tic contribution from the compound nucleus. We have an attempt to continue the investigation with various incident energies.

Acknowledgments

We are indebted to Mr. W. Watari for valuable discussions and also thank to Fuji Film Corporation for supplying the nuclear plates for us.

Excited States of ^{40}Ca

Yasuo HIRAO, Eiji OKADA, Iwao MIURA and Tetsuo WAKATSUKI

*Department of Physics and the Laboratory of Nuclear Studies
Faculty of Science, Osaka University, Osaka, Japan*

(Received October 7, 1957)

By bombarding a natural calcium target with 5.7 MeV protons, gamma rays of energy 3.7 MeV and 3.9 MeV were observed with a NaI(Tl) three crystal pair spectrometer. The intensity of 3.7 MeV gamma ray is about 25% of 3.9 MeV gamma ray.

Angular distribution of these gamma rays was measured with a single crystal scintillation spectrometer. The result can be expressed as follows: $1 + 1.90 \cos^2\theta - 1.03 \cos^4\theta$.

From comparison with theory it is highly probable that 3.90 MeV state has spin 2.

§ 1. Introduction

^{40}Ca is a nucleus with doubly magic nucleon number. In the shell model the first excited state of a doubly magic nucleus should lie relatively high. The removal of one nucleon from the closed configuration implies the breaking of a pair, and the pairing energy can be estimated to be 2 to 3 MeV at Z and $N=20$. An excited state brought about by the removal of two nucleons from the $d_{3/2}$ level into

$f_{7/2}$ level should therefore lie not much higher than a single particle excitation state, because for two nucleons the pairing energy in the $f_{7/2}$ level can even overbalance the energy which is required for raising the second particle from the $d_{3/2}$ into the $f_{7/2}$ level. The configuration $(d_{3/2})^{-1}(f_{7/2})^1$ has odd parity and spin ≥ 2 , while the configuration $(d_{3/2})^{-2}(f_{7/2})^2$ has even parity and most probably zero spin in its lowest state.

On the other hand the experimental result of the magnetic analysis of protons inelastically scattered by $^{40}\text{Ca}^{1)}$ showed that the level energies of the first, second and third excited states are 3.35, 3.73 and 3.90 MeV respectively. These energies are in general accord with the above considerations.

R. D. Bent, T. W. Bonner and J. H. McCrary²⁾ showed that the first level is followed by no gamma transition but nuclear pair emission. The spin and parity of this state is, therefore, 0^+ and the configuration is inferred as $(d3/2)^{-2}(f7/2)^2$.

In our present experiment the higher excited states were investigated by the analysis of gamma rays in the inelastic scattering of protons by ^{40}Ca .

§ 2. Experimental Methods

Molecular ion beam of hydrogen accelerated by Osaka University 44 inch cyclotron was focused onto calcium target located at about 7 meters from the cyclotron by a wedge type focussing magnet through concrete shield wall of 1.5 meters in thickness. The energy of the proton was estimated to be 5.7 ± 0.1 MeV from the measurements of range in air and in nuclear emulsion. The beam defining slit was made of a gold plate with a circular hole one centimeter in diameter. Proton current was about a few hundredths of a microampere.

A thin target of natural calcium of a few mg/cm^2 in thickness was prepared by evaporating the metal onto a thick gold backing.

We have used a NaI(Tl) three crystal pair spectrometer³⁾ to observe gamma ray spectrum. The energy resolution of this spectrometer was about 6% for 4.43 MeV gamma ray. For the measurement of the pulse height distribution a 20 channel pulse height analyzer was used.

We have also used a single crystal spectrometer with NaI(Tl) $1\frac{1}{2}$ inches in diameter and 2 inches in length for the measurement of angular distribution.

To avoid the background gamma rays, the spectrometers were surrounded by lead blocks ten centimeters in thickness, and moreover the beam was lead onto the target through lead wall ten centimeters in thickness.

§ 3. Results

Fig. 1 shows the gamma ray spectrum ob-

served with the three crystal spectrometer placed at right angles with the proton beam

Fig. 1. Three crystal pair spectrum: calcium + proton at 5.7 MeV and 90° with respect to the proton beam.

Fig. 2. Three crystal pair spectrum: polyethylene + proton at 5.7 MeV and 90° with respect to the proton beam.

when the thin calcium target was bombarded by 5.7 MeV protons.

Fig. 2 shows the spectrum of well known 4.43 MeV gamma ray in $^{12}\text{C}(p, p'\gamma)^{12}\text{C}$ reaction by the same spectrometer with a polyethylene target.

In these observations these two targets were bombarded alternately many times in order to ensure the determination of the gamma ray energies. The energy shift of the detector was less than 3% throughout the measurement.

By comparison of these two spectra, the peak is estimated to be at 3.90 MeV. Subtracting the spectrum of 3.90 MeV gamma ray whose shape is deduced from the 4.43 MeV gamma ray, we may get the residual gamma ray spectrum. It is inferred that this spectrum is due to 3.73 MeV gamma ray and the intensity is about 25% of the 3.90 MeV gamma ray. These results are consistent with the experiment by Braams on the inelastic scattering of protons by $^{40}\text{Ca}^{1)}$.

Fig. 3 shows angular distribution of the gamma rays whose energies are greater than 2.5 MeV. This angular distribution is due for the most part to the 3.90 MeV gamma ray but includes the influence of 3.73 MeV gamma ray.

Fig. 3. Angular distribution of the gamma rays higher than 2.5 MeV. The curve shows $W(\theta) = 1 + 1.90 \cos^2 \theta - 1.03 \cos^4 \theta$.

§ 4. Discussions

The angular distribution in Fig. 3 has the form $W(\theta) = 1 + A \cos^2 \theta + B \cos^4 \theta$. The measured values of these coefficients in $W(\theta)$ are 1.90 and -1.03 ± 0.09 respectively.

Further analysis of the distribution consisted of an attempt to compare the measured values of the coefficients with those calculated for the inelastic scattering process.

By the aid of the formula for the angular distribution of a two stage particle reaction followed by gamma emission as given by A. A. Kraus, J. P. Schiffer, F. W. Prosser, and L. C. Biedenharn⁴⁾, one can calculate these coefficients for every case. The expansion coefficients of $P_{\lambda}(\cos \theta)$ for $l, l' \leq 3, j \leq 3$ and except for interference term are given in Table I, where l and l' are the incoming and outgoing proton angular momenta, J is the spin of the compound state, j is the spin of the gamma emitting state, and $P_{\lambda}(\cos \theta)$ is Legendre function. These coefficients were calculated by Dr. S. Takagi and Mr. S. Yamazaki in our University.

According to Kraus et al.⁴⁾, if the outgoing particle is not observed incoming l values and channel spins add coherently and incoherently respectively, while outgoing l values and channel spins add incoherently and coherently respectively. Moreover, since λ is only even for sharp angular momentum j , there are no interference terms between states of opposite parity. In other words, the cross section can be broken into two parts, one part for even parity compound states and the other for odd parity states.

As a probable case for this energy of protons, we assumed a process due to the absorption of a d -wave proton followed by emission of a s -wave proton. If the gamma emitting state has spin $2+$, only one channel spin is possible for either angular momentum for the compound state and therefore coherent interference does not exist.

The angular distribution is as follows:

$$\begin{aligned} \sigma(\theta) &= 1 + \cos^2 \theta & \text{for } J=3/2+ \\ \sigma(\theta) &= 1 + 6 \cos^2 \theta - 5 \cos^4 \theta & \text{for } J=5/2+ \end{aligned}$$

Compounding these two distributions in the ratio of 4:1, one can get as follows:

$$1 + 2 \cos^2 \theta - \cos^4 \theta$$

in conformity with the experimental result.

As another case, we may consider a process due to the absorption of a p -wave proton followed by emission of a s -wave proton. If the gamma emitting state has spin $2-$, the angular distribution is as follows:

$$\sigma(\theta) = 1 + \cos^2 \theta \quad \text{for } J=3/2-$$

If the absorption of a f -wave proton is followed by emission of a s -wave proton and the gamma emitting state has spin $2-$, the angular distribution is as follows:

Table I. The coefficients of $P_J(\cos \theta)$ in the angular distribution of the gamma ray in the inelastic scattering of proton by even-even nucleus. l and l' are the angular momenta of incoming and outgoing proton respectively, s' is outgoing channel spin, J and j is the spin of compound and gamma emitting state respectively, and $P_J(\cos \theta)$ is Legendre function.

$J=3/2 \ (l=1, 2)$						$J=5/2 \ (l=2, 3)$

		3	1	-0.156	0			0	1	0	0
			1	5/28	0				1	25/98	9/98
			1	-0.059	0				1	5/42	-1/14
									1	-0.0339	-0.0408

$\sigma(\theta)=1+6 \cos ^2 \theta-5 \cos ^4 \theta$ for $I=5 / 2-$
Same result can be obtained in this case as above described.

These calculated coefficients show good agreement with the measured values within 5%. The curve in Fig. 3 shows this calculated angular distribution. For other processes, we can not get good agreement even if we consider interference terms. From the estimation of barrier penetrability it is reasonable that the incoming and outgoing l value is assumed to be ≤ 3 .

Then it is highly probable that the gamma emitting state, whose energy is 3.90 MeV, has spin 2.

§ 5. Acknowledgment

The authors wish to thank Prof. S. Kikuchi for his kind interest in this work, and Dr. S. Takagi and Mr. S. Yamazaki who calculated the coefficients of angular distributions and

Angular Distribution of Protons Inelastically Scattered from Mg^{24}

By Shotaro YAMABE

Department of Physics, Osaka University, Osaka

(Received October 24, 1957)

The angular distributions of protons inelastically scattered from Mg^{24} ($Q = -1.368$ MeV) were measured from 22.5° to 165° in the laboratory system at incident proton energies of 5.1 and 5.4 MeV. The 44'' Osaka University cyclotron was used to provide a proton beam, and the scattered protons were detected by nuclear emulsion technique. Both distributions obtained show an asymmetry about the center of mass scattering angle $\theta = 90^\circ$ and a strong dependence with the energy of primary protons.

§ 1. Introduction

Up to the present time, the angular distributions of protons inelastically scattered from Mg^{24} , being left in the first excited level (1.368 MeV, 2, +), have been measured at various proton energies from 4.7 MeV to 18 MeV⁽¹⁾⁻⁽⁹⁾. All these data indicate the asymmetry about the center of mass scattering angle $\theta = 90^\circ$ without any exception.

From the compound nucleus picture, it may be plausible that at such energies of the incident protons the compound states are in an intermediate region of the two extreme, that is, the region where the reaction proceeds through a single level of the compound nucleus—resonance region—or through the continuum region of the compound nucleus—statistical region—, in both cases the angular distributions are predicted to be symmetric about $\theta = 90^\circ$.⁽¹⁰⁾⁻⁽¹²⁾ But the range of the excitation energy of compound state produced by protons of energies from 4.7 MeV to 18 MeV, is so large that it cannot be attributed only to this circumstance.

Fischer⁽⁵⁾ has interpreted his 10 MeV data by combining the statistical theory of the compound nucleus and the direct interaction proposed by Austern, Butler and McManus⁽¹³⁾. Besides the direct interaction proposed by Austern, et al., Hayakawa and Yoshida⁽¹⁴⁾ have shown theoretically that the other possibility

may be considered as the excitation of the rotational level of the nucleus.

Greenlees, et al.^{(6),(7)} suggested an interference effect between the processes of compound nucleus formation and of direct interaction to explain the rapid change of the angular distributions with the incident proton energies in their experiments of 8~10 MeV region.

In this paper the angular distributions of inelastically scattered protons from Mg^{24} are studied at proton energy 5.1 MeV and 5.4 MeV by means of nuclear emulsion technique.

§ 2. Experimental Arrangement and Procedure

The 44'' Osaka University Cyclotron⁽¹⁵⁾ was used to provide a beam of 5.7 ± 0.1 MeV protons, and nuclear emulsion was used to detect the scattered protons. The experimental details concerning the scattering chamber, the collimator system, and the current integrator were same as mentioned in the previous paper^{(16),(17)} of Osaka University plate group.

In Fig. 1 the schematic arrangement is shown. The foil changer box, contained ten sectors of aluminium foil, was inserted in front of the collimator system to reduce the primary proton energy by a step of about one hundred keV. Two plate cameras were constructed, the one (No. 1 camera) was for the study of angular distributions, the other (No.

2 camera) was for the study of excitation functions. The grancing angles of the plate were increased to 15° for both cameras in order to reduce the background track due to elastic portion which escaped from emulsion and had the same range in emulsion as inelastic group.

No. 1 camera had plate-holders at an interval of 7.5° from -7.5° to -75° and from 15° to 165° with respect to the incident beam direction in the laboratory system, and was set in the scattering chamber in the case of the measurement of angular distributions. Since the numbers of the elastically scattered protons at small angles were very large, the exposure of the plates at small angles was made about one-fifth of that of the plates at large

angles by the shutter in front of the camera, and the normalization in angular distribution was done at 75° both from the ratios of the integrated current and of the intensities of elastically scattered protons.

No. 2 camera also had ten plate-holders at an interval of 7.5° . The experimental procedure obtaining the excitation function is shown in Fig. 2. The camera could be rotated in the horizontal plane around the axis of the scattering chamber. The plates were blinded by the aluminium blinder in front of the camera. This blinder had a slit at 90° with respect to beam direction, and the exposures of the plates were done one by one with the rotation of the camera. The proton energy could be changed by aluminium foil in front of the collimator system, thus the excitation functions could be obtained.

The target was a self-supporting Mg foil 1.2 mg/cm^2 thickness, and was prepared by vacuum evaporation onto a glass plate and was peeled off by a blade of a safty razor. Though the target was stored in vacuum, a small amounts of contaminations of hydrogen and oxygen could not be removed. The used emulsions were Ilford C-2 ($200\ \mu$, $100\ \mu$) and Fuji ET-6B ($70\ \mu$) nuclear emulsions.

§ 3. Result and Discussions

In order to check the experimental procedure for No. 2 camera, preliminary run was made for the excitation function of the elastic scattering of protons from Au at 90° in the laboratory system. Incident energies of protons were changed from 5.7 MeV to 4.8 MeV by a step of 100 keV. The results are illu-

Fig. 1. The schematic illustration of experimental arrangement.

Fig. 2. The experimental arrangement for obtaining the excitation function.

Fig. 3. The excitation function of the elastic scattering of protons from Au at 90° in the laboratory system. Ordinate indicates the product of the differential cross section and the square of incident energy in arbitrary scale.

strated in Fig. 3. It is a plausible estimation that in these energy region the differential cross sections for Au are approximately equal to Rutherford cross sections, so the product of the differential cross section and the square of incident energy of protons must be constant. The result obtained here is very satisfactory.

The excitation function obtained for Mg^{24} ($Q = -1.368$ MeV) is illustrated in Fig. 4 together with the previous results of Greenlees⁸⁾.

Fig. 4. The excitation function for Mg^{24} ($Q = -1.368$ MeV) together with the previous results of Greenlees.

The uncertainty in the absolute cross section were estimated to be about 20% both for the excitation function and the angular distribution. There is a resonance feature at the incident proton energy of 5.1 MeV, which agrees qualitatively with the previous result and the distributions were measured at 5.1 MeV and 5.4 MeV.

The typical range distribution is shown in Fig. 5 and the angular distributions obtained are shown in Fig. 6. These curves show apparent asymmetries about 90° and the shape changes with variation of incident proton energy. In the present case, the excitation energies of compound states of Al^{26} were considerably low, so it would be expected that so many levels were not excited. Then the asymmetry and the energy variation of the angular distribution might be explained by

the interference of levels of different parties.

To obtain further information about the mechanism of the reaction the experiment for the angular distribution at other bombarding energies is now undertaking and then the detailed discussion will be given.

Magnetic Moment of the First Excited State of $^{152}_{62}\text{Sm}$

By Kenzo SUGIMOTO

*Department of Physics, Faculty of Science,
Osaka University, Osaka*

(Received November 28, 1957)

The first excited state (122-keV) of the even-even nucleus Sm^{152} was excited by the Coulomb excitation with 2-MeV protons. The angular distribution of the de-excitation radiation was investigated. The attenuation factor of the angular distribution $G_2 \sim 0.6$ was obtained using a samarium oxide target. The rotational change of the pattern in the angular distribution was examined under the condition of applying an external magnetic field vertical to the incident protons. The apparent g -factor for this state obtained was $g(\text{Sm}^{152}, 2^+) = +(0.36 \pm 0.16)$ n.m. A brief discussion about the effect of nuclear surroundings affecting the present determination was given.

§ 1. Introduction

A possibility of the determination of the magnetic moment in the nuclear excited state was pointed out by Brady and Deutsch¹⁾, by investigating the influence of an external magnetic field on the angular correlation of successive nuclear radiations. This method was successfully applied to the determination of the magnetic moment of the first excited state of Cd^{111} by Zürich group²⁾. Recently, this method was also applied to the $(p, p' \gamma)$ reaction and the magnetic moment of the second excited state of F^{19} was determined

by several investigators³⁾.

The determination of the magnetic moment depends on the nuclear precession in the magnetic field during the life of the excited state, and if one investigates the rotational change of the pattern in the angular correlation of radiations, one may hope to determine the magnetic moment of the short lived excited state in the range of 10^{-9} sec. The so-called fast E2-transition from the first to the ground state in the rotational spectrum of the strongly deformed nucleus lies in this range of life, and one may hope to get a direct information

about the g -factor of the strongly deformed even-even nucleus. The first excited states of these nuclei can be excited by the Coulomb excitation, and the angular distribution of the de-excitation radiation can be predicted theoretically⁴⁾. As the first example of the strongly deformed nucleus, Sm^{152} was investigated in the present work, because of its very marked position of neutron number 90 from which a distinct group of nuclei having the rotational spectrum arises.

§ 2. Instruments and Experimental Procedure

2 MeV protons accelerated by the static generator of Osaka University were used to initiate the Coulomb excitation.

Fig. 1. Electro-magnet and its excitation curve. The pole pieces are made of cobalt-iron alloy. The pole face is 18 mm in diameter and the pole gap is 12.3 mm wide. The winding of the coil is 2400 turns, and the maximum dissipation is 1.6 kilo watts for producing the field of 23000 gauss.

An electro-magnet was specially designed for this work. The pole pieces of the magnet were made of cobalt-iron alloy. And the magnetic field up to 23000 gauss can be produced. The schematic drawing and the excitation curve of the magnet are shown in Fig. 1.

The target assembly is shown in Fig. 2. The target was prepared by depositing the natural samarium oxide* on a copper foil of 7-microns in thickness, and mounted in an aluminium container. The thickness of the target was thick for protons and thin for gamma-rays.

A magnetic shielding for the incident protons minimized the deflection of the beam by the stray magnetic field. In order to determine the deflection of the beam, a photograph was taken by exposing a photographic plate to the proton beam at the target. The photograph by the magnetic field of 23000-gauss is shown in Fig. 3. The deflection angle of the incident protons was measured as $10.4^\circ \pm 0.5^\circ$ for 23000-gauss.

Fig. 2. Target apparatus and magnetic shield for incident protons.

Fig. 3. Photograph of the beam path around the target.

* This sample was produced by Johnson, Matthey & Co., Limited (Hatton Garden, London), and the nominal purity was 99.95%.

The detector arrangement is shown in Fig. 4. Gamma-rays were detected with a NaI (Tl) scintillation spectrometer 1.5-in. in diameter and 1.5-in. in length. The effect of the magnetic field on the spectrometer was examined utilizing a gamma-ray source of Cs^{137} ,

Fig. 4. Plan view of the detector arrangement.

Fig. 5. Pulse height spectrum obtained by bombarding the samarium oxide target with 2 MeV protons. The 122 keV and 82 keV peaks were identified with the de-excitation radiation from the samarium isotopes of Sm^{152} and Sm^{154} respectively.

and the variation of the pulse height spectrum was reduced within 2% with the magnetic shielding of heavy iron plates on the photomultiplier. The geometrical centering of the arrangement was checked by measuring the intensity of gamma-rays from the source of Cs^{137} placed at the target, and the centering was corrected within 1%.

The pulse height spectrum of the scintillation spectrometer obtained by bombarding the samarium oxide target with 2-MeV protons is shown in Fig. 5. Radiation from a tantarum target was used to calibrate the energy scale. When the angular yield was measured, the net yield for the 122-keV radiation was determined from the count of the peak portion of the spectrum by subtracting the back ground which was estimated by extrapolating the just upper part of the spectrum.

§ 3. Experimental Results and Derivation of g -factor

The observed angular distributions of the 122-keV radiation at the magnetic field of ± 22000 -gauss are shown in Fig. 6.

Fig. 6. The angular distribution of the 122 keV radiation at the magnetic field of ± 22000 gauss. The solid curves are least-squares fits of the distribution to the form $W(\theta) = a + b \cdot \cos 2\theta + c \cdot \sin 2\theta$. The angular deflection of the pattern includes the deflection of the incident protons.

The theory of the Coulomb excitation predicts the angular distribution of the 122-keV radiation following the excitation by 2-MeV protons as follows,

$$W(\theta) = 1 + 0.142 \cdot \cos 2\theta + 0.002 \cdot \cos 4\theta.$$

When the analysis of the observed distribution was done, the term of $\cos 4\theta$ was neglected. And the experimental points were fitted by the method of least-squares. The apparent angular shift of the pattern thus obtained was

subtracted by the deflection angle of the incident protons, and the angular shift $\Delta\theta$ due to nuclear precession was obtained as $2\Delta\theta = 8.7^\circ \begin{smallmatrix} +3.6^\circ \\ -3.8^\circ \end{smallmatrix}$.

The relation between the nuclear precession and the angular shift of the pattern in the angular distribution for the present case, by neglecting the influence of nuclear surroundings, can be given by⁶⁾

$$2\Delta\theta = \text{tg}^{-1}(2\omega\tau), \text{ where } \omega = g \cdot \mu_N \cdot H / \hbar,$$

and where τ is the life time, ω is the Larmor frequency, g is the nuclear g -factor, and μ_N is the nuclear magneton. Using the value of the half life $T_{1/2} = (1.40 \pm 0.10) \cdot 10^{-9}$ sec. obtained by Sunyar⁶⁾, the apparent g -factor was obtained to be

$$g(\text{Sm}^{152}, 2^+) = +(0.36 \pm 0.16) \cdot \mu_N.$$

The present value is in good agreement in magnitude with the value obtained by Scharenberg and Goldring⁷⁾.

Though the effects of the nuclear surroundings affecting the present determination are complex, the effects can be estimated from the attenuation factor G_2 of the coefficient in the angular distribution when the external magnetic field was not applied. G_2 can be determined by comparing the observed distribution with the theoretical one. $G_2 \sim 0.6$ was obtained by the present measurement in agreement with the result obtained by Simmons, et al.⁸⁾ using a samarium oxide target. Scharenberg and Goldring⁷⁾ have observed the distribution using a metallic samarium target and also a target in liquid form, and obtained $G_2 = 0.65$ and $G_2 = 0.95$ respectively.

The effects of the surroundings which cause the attenuation of the angular distribution, especially for the solid target, are considered as follows. Because of the recoil energy up to 50-keV, the recoil atom will find itself at a strange position of the lattice, so that the excited nucleus will be exposed to a strong electric field gradient. The effect due to the atomic hyperfine structure must also be considered, because of the special character of the atomic $4f$ electrons of the samarium atom. But this atomic moment is believed to fluctuate very rapidly ($\lesssim 10^{-12}$ sec.) relative to the nuclear precession ($\sim 10^{-9}$ sec.) above the room temperature. It is, therefore, reasonable to consider that the difference between the attenuation factor G_2 for the solid targets and

the liquid target is attributed to the difference in electric quadrupole interaction, so that the apparent g -factor may be increased at most by 40% from this cause.

Another cause which is due to the strong paramagnetism will strengthen the effective magnetic field at the nucleus, because the atom is partially polarized along the external magnetic field. This effect was estimated by considering the behavior of the atomic $4f$ electrons⁹⁾, and the effect on the determination of the g -factor was calculated to be 20% at 300°K and 10% at 700°K, so that the apparent g -factor must be decreased about 10% from this cause.

In spite of these uncertainties, the sign of the g -factor could be conclusive. It is interesting to remember that the uniform model predicts the g -factor $g \sim Z/A \sim 0.41$ irrespective of the deformability of the nucleus.

Acknowledgement

It is a pleasure to acknowledge the continued interest and encouragement of Professor S. Kikuchi and Professor T. Wakatsuki in this work. The author would like to thank Professor T. Nagamiya and Dr. J. Kanamori for their discussion and numerical estimations about the extra nuclear effects. He also wishes to thank Mr. A. Mizobuchi for his indispensable aid and Mr. H. Iwata for his technical assistance.

Optical Study on the Resultant Movement of Many Walls in Rochelle Salt

By Ryuji ABE

Department of Physics, Osaka University, Osaka

(Received September 24, 1957)

A new optical device to study the resultant movement of many walls in rochelle salt was constructed. It was found that the rotating angle of the optical plane is nearly in proportion to the spontaneous polarization. Some characteristics of the resultant wall motion were studied from the information of the rotating angle. From these experimental results we are inclined to conclude that the fatigue effect will be caused by either the displacement of dislocations or neutral vacancies.

§ 1. Introduction

Recently the domain structure and the wall motion in rochelle salt have been observed by several investigators¹⁾⁻³⁾ by means of polarizing microscope. These direct observations are very useful to investigate the mechanism of the individual motion of every wall. They are, however, not sufficient to study the essential mechanism of wall motions as a whole, because the observed motion of a wall is sensitively influenced by the local stresses in the vicinity of the wall. This influence of local stresses can be excluded in the measurement of the resultant movement of many walls, because the influence on every walls are averaged over. Therefore such a resultant measurement is also important to study the mechanism of the wall motion.

In the present experiment we have investigated various characteristics of the resultant movement of many walls by means of the high sensitive optical system. It was found that this optical method is very useful to study the characteristics of wall motion at very low frequencies. The measuring device is given in § 2 and some experimental data on the fatigue effect and the other phenomena are given in § 3.

§ 2. Experimental

Specimen. The crystal used in the present experiment was thin slab normal to a -axis, of which dimension is about $3 \times 2 \times 0.2$ cm³. Silver electrodes were evaporated *in vacuo* on both sides of the slab. The thickness of the electrodes was limited within a few hundred Å so that a measurable intensity of light passes through the crystal.

Chamber that contains specimen. To keep the temperature and the humidity constant during an experiment the crystal was set in the closed chamber (Fig. 1). The temperature was controlled by circulating water which was kept at a constant temperature, while the humidity was controlled by changing the con-

centration of sulphuric acid in the chamber. The crystal was placed on a disk which rotates around its center by operating the outer dial.

Circuit. The diagram of the circuit is shown in Fig. 2, where the polarized light falls in perpendicular onto an *a*-plate crystal and the light which has passed through the crystal is introduced into photo-electric tube. The induced photoelectric current is amplified by electrometer tube and the amplified current is detected by high sensitive galvanometer. The area of the crystal surface which was irradiated by the polarized light was about $1.5 \times 1.5 \text{ cm}^2$.

§ 3. Experimental Result

Rotation of optical plane versus temperature. Rochelle salt crystal is orthorhombic in its paraelectric region and its optical axes exist in (010) plane⁴⁾. If the polarized light is thrown in perpendicular to *a*-plane, it is divided into two extraordinary rays i.e. the one ray which oscillates in *b*-plane and the other ray which oscillates in *c*-plane. These two rays are recombined when they have passed through the crystal and a certain component of the recombined ray passes through the analyzer which is crossed to the polarizer. Then the intensity of the light which has passed through the crystal is given by

$$I = \gamma I_0 \sin^2 2\theta = \frac{1}{2} \gamma I_0 (1 - \cos 4\theta) \quad (1)$$

where I_0 is the intensity of incident polarized light, θ is the angle between *b*-plane and the plane of the polarization of the incident light. γ is a certain constant which becomes $\sin(2\pi d/\lambda_0)$ if the wave length of polarized light is a constant λ_0 and the crystal surfaces are perfectly flat, where d is the optical path difference between the two extraordinary rays. In the ferroelectric region the crystal becomes monoclinic and the optical plane differs from the *b*-plane*. Therefore the previous Eq. (1) must be modified to be

$$I^a = \frac{1}{2} \gamma I_0 (1 - \cos 4(\theta - \varphi_s)) \quad (1')$$

for the state (a) (Fig. 3), and

$$I^b = \frac{1}{2} \gamma I_0 (1 - \cos 4(\theta + \varphi_s)) \quad (2)''$$

* Here the *b*-plane denotes *b*-plane in the paraelectric state.

for the state (b), where φ_s is the angle between the optical plane and the *b*-plane when the polarization of the crystal is saturated in one direction. If the state of the crystal changes from (b) to (a) by applying electric field, then the intensity of the light which has passed through the crystal changes by

$$I_a = \gamma I_0 \sin 4\theta \sin 4\varphi_s. \quad (2)$$

$(\theta - \varphi_s)$ in Eq. (1)' and $\sin 4\varphi_s$ in Eq. (2) are approximately equal to θ and $4\varphi_s$ respectively, because φ_s is smaller than 1° as proved later. Hence, from equations (1)' and (2) φ_s is given by

[Fig. 3. Two polarizing states of rochelle salt. P.P.: Plane of polarized light O.P.: Optical plane

The broken line indicates *b*-plane in the paraelectric state.

Fig. 4.

Fig. 5. Dependence of rotating angle on temperature.

$$\varphi_s = \frac{(I_d)_{\theta=\pi/8}}{4(I)_{\theta=\pi/4}} \quad (3)$$

Therefore if the relative intensities of both $(I_d)_{\theta=\pi/8}$ and $(I)_{\theta=\pi/4}$ are measured, the absolute value of φ_s for every temperature* can be obtained. The dependences of φ_s on temperature and on spontaneous polarization are shown in Fig. 5 and Fig. 6 respectively, and some values of φ_s are given in Table I. These

Fig. 6. Rotating angle versus spontaneous polarization.

Table I.

Temp. (°C)	2.2	5.2	8.5	11.9	14.6	17.8	19.2
φ_s (min)	58.0	58.9	53.6	45.8	43.0	37.4	32.5

figures clearly show that φ_s is proportional to P_s^{n**} . The value of n is determined to be 1.25 ± 0.2 from the experiment data.

It will be noted here that φ_s is nearly proportional to spontaneous polarization, because the value of n nearly equals unity. In the following experiment, accordingly, we use the resultant rotating angle φ as the measure of the resultant displacement of many walls. φ is given by $\varphi = V_+ \varphi_s - V_- \varphi_s$, where V_+ and V_- are the volumes of positive and negative domain respectively.

Dependence of φ on electric field. Under a constant temperature and a constant humidity, φ increases with the increase of applied field, as shown in Fig. 8. It is clearly seen from this figure that in the ferroelectric region φ increases abruptly at a certain field. This "critical field" will correspond to the coercive field in the hysteresis loop obtained by Sawyer and Tower method. The "critical field", however, is much lower than the coercive field

* It is really ascertained that the simple relations (1) and (2) are satisfied for the persent crystal (Fig. 4).
** Temperature dependence of spontaneous polarization is a little affected by humidity. Here we use the data of spontaneous polarization obtained from the hysteresis loop at 60% humidity (Fig. 7).

given by Sawyer-and-Tower-hysteresis loop and the slope near the crytical field is fairly steeper than the slope in the hysteresis loop. The same conclusion has been obtained from different experimental measurement by a few investigators⁶⁾⁻⁸⁾. This conclusion indicates that the coercive field is dependent on the changing rate of field with time. An explanation for this dependence is given in our previous paper⁸⁾.

Fig. 7. Dependence of spontaneous polarization on temperature.

Fig. 8. Rotating angle versus applied field.

As shown in the following, φ changes with time remarkably, and shows a marked fatigue effect. Hence it was necessary to apply static fields to a crystal successively, as shown in the upper part of Fig. 8 in order to avoid the influence of the fatigue effect.

Change of φ with time. The angle φ reaches the equilibrium value soon after the application of field if the field is higher than the critical field mentioned above. However, it does not reach the equilibrium value within 20~30 sec after the application of field if the

field is lower than the critical field (Fig. 9). This phenomenon corresponds to the phenomenon found by Takahashi and Hara⁵⁾ by electrical means, although the present saturation frequency is about 3~4 times higher than their saturation frequency.

Fatigue effect. It is well known that rochelle salt comes to fatigue when a static field is applied to a crystal for a long time. About

Fig. 9. The change of ϕ with time after the application of field.

Fig. 10.

the origin of this effect, however, no satisfactory explanation has yet been proposed, because the experimental data on this effect are very complicated and fluctuated. Therefore for the study of this origin a more concentrated and detailed experiment must be done.

In the present experiment we have investigated various features of this effect by means of the present optical method. This method was very advantageous to study the displace-

ment of walls at very low frequencies, because the measurement is not influenced by the existence of surface leak and ionic current. Fig. 10 gives an example of the recovery of ϕ with time after the removal of applied field which is high enough to saturate the polarization of crystal in one direction (150 volts/cm). The ordinate is ϕ in arbitrary scale and the abscissa is the time t_p that lapsed after the removal of field. The duration of field τ is given by the figures near the every curve and the quasi-equilibrium value* of ϕ is given by the figures in the parentheses. Though the result is not shown in this figure, the crystal almost recovers its original state after a sufficiently long time has lapsed. In Fig. 11 the change of the initial value of recovering velocity is shown as a function of the duration of field. The ordinate is the ini-

Fig. 11.

Fig. 12.

* The quasi-equilibrium value means the value of ϕ when the same period as the duration of applied field has lapsed after the removal of applied field.

tial value of recovering velocity which is determined by the gradient of φ - t_p curve at $t_p=0$, and the abscissa is the duration of applied field τ . In Fig. 12 the change of φ is shown when the reverse field is applied for 30 sec after the removal of the forward field. The ordinate is φ in arbitrary scale and the abscissa is the time that lapsed after the removal of the reverse field. The strength of field equals in both direction (150 volts/cm) and is high enough to saturate the polarization of the crystal. These experimental results are almost reproducible for the same crystal and the characteristic features of each curve are similar respectively for another crystal with the dimension, $3.5 \times 2.5 \times 0.5$ cm³.

Now from these experimental results we can obtain some informations useful to discuss about the origin of the fatigue effect: (1) the crystal does not recover its original state for a few hours if the duration of field is longer than about 10 minutes, although it recovers the original state after the sufficiently long time. This fact suggests that a certain change of internal structure such as the dislocation or the movement of ions or vacancies is caused in the crystal. This suggestion is also supported by the result that the recovering velocity in the reverse direction increases with increase of duration of the forward field (Fig. 12). (2) the recovering velocity of wall becomes the order of 10^{-5} cm/sec, if we assume that the crystal is composed of equivalent lamellae of 180° domains with the breadth of $10^{-3} \sim 10^{-4}$ cm (according to our observation) and the walls move only sideways (Fig. 11). This velocity is much lower than the velocity of wall at low fields observed by Mitui and Furuichi¹⁾. (3) the fatigue begins to appear abruptly when the duration of applied field is longer than about 30 sec (Fig. 11). This fact seems to mean that the velocity of the imperfections which cause the fatigue is the order of $d/30$ cm/sec, where d is the distance between the imperfection and the source of the recovering force. (4) the recovering velocity changes a little with the change of sign of the applied field. Therefore, it is likely that the source of the recovering force is related with the secondary structures of the crystal or the surface states of the electrodes. (5) the initial value of recovering velocity increases a little with the increase of tempera-

ture (Fig. 13). The recovering velocity, accordingly, seems to be independent of spontaneous polarization. Referring these experimental results a few discussions on the origin of the fatigue effect will be given in the following section.

Fig. 13. Dependence of initial recovering velocity on temperature.

Fig. 14.

Effect of surface charge. In the foregoing experiments, to avoid the appearance of true charge both electrodes were shortcircuited when the applied field was removed. On the contrary, if both electrodes are left open when the applied field is removed, it will be expected that all domains little recover their original volumes for a short time, because the true charge induced in the electrodes prevents the movement of every domain. Actually at 10°C and at 55% humidity no change of φ was observed at least for 2 minutes after the removal of applied field which was high enough to saturate the polarization of crystal, although at the temperatures higher than about 20°C the fairly rapid change of φ was observed.

* The drastic increase of the recovering velocity may be due to the increase of the surface conductivity of the crystal.

(Fig. 14). This fact indicates that the rochelle salt crystal is a good insulator even at relatively high humidity.

§ 4. Discussions

1) The surface-charge layers due to ionic current will influence the recovery of crystal. This mechanism may be proposed as a possible explanation of the fatigue effect. This explanation seems to be adequate, because it reminds us the fact that surface space-charge layers exist in BaTiO_3 crystal^{9), 10)}. Rochelle salt, however, is a good insulator as proved by Takahasi and Hara¹¹⁾, and therefore the ionic current in the crystal is very small. For example if the resistance of the crystal is $10^{15}\Omega$ (referring to the Takahasi and Hara's data) and the applied field is 500 volts/cm, the charge caused by ionic current is smaller than about 1×10^{-11} coulomb/cm² for 10 minutes. This charge is much small than the charge caused by spontaneous polarization. Therefore the surface-charge layers in rochelle salt will little affect the recovering velocity of every domain. This fact seems to suggest that the fatigue of the crystal may be due to either the movement of dislocations or neutral vacancies, and independent of charge movement.

2) In the recent paper Kinase and Takahasi¹²⁾ pointed out that the defects in electrodes may cause the nucleation of new domains because depolarizing charges appear at the defects. For the present specimen such defects may also be the important sources of new domains because the evaporated electrodes are very thin, and therefore many defects may be contained. As discussed in 1),

however, the depolarizing charge on the crystal surface is little neutralized by true charge for a short time. Therefore to explain the observed fatigue effect i.e. the decrease of the recovering velocity, it is rather favorable to consider that the other origin of the recovering force exists in the crystal besides the surface defects. Screw dislocations¹³⁾ or impurities in the crystal may be the important causes of the recovering force.

Finally the author wishes to express his appreciation to M. Y. Fuzishiro and Mr. K. Ichie for their helpful assistances. This work was supported by the Scientific Research Fund of the Ministry of Education.

On the Screened Field around an Impurity Atom in Metal

By Hiroshi FUJIWARA

*Department of Physics, Minami-Bunko
Hiroshima University, Minami-machi-3
Hiroshima City*

(Received December 5, 1957)

By using a newly proposed model, in which the positive charges of bare nuclei of an impurity atom and the matrix atoms are put at the lattice points and all the electrons, valence electrons as well as core ones, are treated by Thomas-Fermi method, the deviation of the potential from the periodic one for the pure matrix metal due to the presence of an impurity atom has been calculated and compared with the screened Coulomb potential obtained in previous papers.

In the case of pure metals, a similar treatment was made by Slater and Krutter, so that our model may be regarded as an extension of theirs to the case of substitutional impurity.

Our obtained potential is nearly proportional to ΔZ , where $\Delta Z = Z_i - Z$, Z_i and Z being atomic numbers of the impurity and the matrix atom respectively and in this paper, we have treated the cases of $\Delta Z = \pm 1$ and ± 1 .

§ 1. Introduction

As one of the applications of the Thomas-Fermi (to be referred to as T.F. hereafter) approximation, we have been investigating the screened potential around an impurity atom in the dilute solid solution which consists of two metals with different valencies.

Up to date, we have treated the case where a trace of di- or trivalent metal is dissolved as a substitutional impurity in a monovalent metal; for example, Zn or Ga in Cu.

Our previous studies¹⁾, as well as most of the work done by other investigators²⁾, were based on the following model: i.e., only the valence electrons of atoms of matrix and impurity metals were treated in T.F. method; the charge $(\Delta Z)e$, where ΔZ is the excess of the valency of the impurity over that of the matrix, was concentrated at the position of the nucleus of the impurity atom and the remaining charges due to core electrons and the nuclei were smeared out so as to form a uniform positive charge distribution.

On this model, the problem was rather easy to treat and it reduces to the construction of a spherical symmetric solution of the T.F. equation.

This model has, however, several unsatisfactory features; (a) In the first place, because of the smearing out of the charge, the lattice structure of the matrix metal is completely

lost in our model, so that, e.g., the crystal symmetry of the matrix metal cannot be taken into account. (b) Secondly, the impurity atom is characterized by a single parameter ΔZ , so that this model cannot distinguish between the different impurity atoms of the same valency, e.g., Zn and Cd or Ga and In. As to the matrix, it is characterized by the average density of valence electrons, which determines the Fermi energy. (c) In the case when ΔZ is negative, a negative point charge $(\Delta Z)e$ is to be put at the position of the nucleus of the impurity atom. In this connection, we encounter a further difficulty when we want to treat impurity atoms of transition metals. Let us consider, for example, the case of dilute solution of Co in Cu. According to our model negative charges of 28 electrons per atom (corresponding to $(1s)^2(2s)^2(2p)^6(3s)^2(3p)^6(3d)^{10}$ configuration) and the positive nuclear charge $29e$ (corresponding to Cu nuclei) are smeared out uniformly so as to yield a constant positive volume charge of $+e$ per atom as the background, and a negative point charge $-2e$ ($= (Z_{Co} - Z_{Cu})e$) is put at the position of Co nucleus. Since positive holes of electrons are not allowed in T.F. method, our model requires that Co impurity atom must exist at least as singly ionized negative ion Co^- , which does not seem to be physically plausible. If we want to assume the Co atom, which is not

mally in $(3d)^7(4s)^2$ configuration, to contribute two $4s$ electrons to valence electrons which are to be included in our T.F. treatment, we have to locate $+e$ at the position of Co nucleus; in this formulation, however, we could not distinguish between Co and Zn cases.

From a somewhat different point of view, this difficulty may be considered as due to the ambiguity of assigning the number of valence electrons in transition metals.

In view of these unsatisfactory features of the simple model, we propose here a new model, in which the positive charges of bare nuclei are put at the lattice points and all the electrons, valence electrons as well as core ones, are treated by T.F. method. In the case of pure metals, the similar treatment was made by Slater and Krutter³⁾ some twenty years ago, so that our model may be regarded as an extension of theirs to the case of substitutional impurity.

Assuming the concentration of the impurity to be so small that the interaction between impurity atoms is negligible, we may treat the case in which at all lattice points are located the positive charges Ze except a single lattice point where a point charge Z_ie is located. Hereafter we denote the atomic number of matrix atom and that of impurity atom by Z and Z_i respectively. We expect that in the vicinity of the impurity atom, electron distribution will adjust itself so as to screen the excess charge $(Z_i - Z)e$, and as we go farther and farther from the impurity atom, electron distribution will tend more and more closely to the periodic one characteristic to the pure matrix metal. This electron distribution, as well as the corresponding potential distribution, will be determined by T.F. method.

This is nothing but the most straightforward and consistent way of applying T.F. method to our problem, and no ambiguity is left, for instance, about the choice of the number of electrons to be treated.

In this model, $|Z_i - Z|$ may be quite large; in fact, we could treat the case of vacancy simply by putting $Z_i = 0$. And the lattice structure can be fully taken into account.

Further our calculation may be of some interest from the mathematical point of view as an application of cellular method to crystals containing an impurity atom.

We do not believe, however, that our model is completely satisfactory. Since, T.F. method cannot account for the shell structure of electrons in atoms, the concept of "valency" is almost completely lost in our present model. The observed trend of the residual electric resistance, for instance, seems to show the significance of the concept of valency, at least as a guide to rough estimation.

In order to preserve the concept of closed shells, valency, etc. and at the same time, to take the lattice structure and other properties about individual element of the periodic table into account, it seems to us desirable to represent the distribution of core electrons by the use of Hartree and Hartree-Fock field, and to treat the electrons outside these cores by T.F. method. We are now proceeding this way and we hope to report the results in a near future.

§2. General Considerations about Our New Model

We consider the introduction of a single foreign impurity atom (hereafter abbreviates as i -atom) by substituting one of the solvent matrix atoms (hereafter abbreviates as m -atoms) which are arranged in a face-centered cubic crystal.

The lattice point thus substituted by an i -atom is denoted by $\mathbf{R}_0$, while those occupied by m -atoms are $\mathbf{R}_n$ ($n \neq 0$).

In order to remove the deficits in the former model as stated in the introduction, all the electrons in the crystal are taken into consideration and we assume that the bare nuclei with positive charges $+Ze$ and $+Z_ie$ of m -atoms and an i -atom are located at $\mathbf{R}_n$ and $\mathbf{R}_0$ as point charges.

The fundamental problem in obtaining the crystal potential is to find the solution of the T.F. equation which is appropriate for this arrangement of positive point charges. Now let $u(\mathbf{r})$ be the electrostatic potential at the point $\mathbf{r}$ valid over the entire impure crystal in which every atom is supposed to be at rest at its lattice point. Then, $u(\mathbf{r})$ is given from the solution of usual T.F. equation:

$$\nabla^2 u(\mathbf{r}) = \alpha u^{3/2} \quad (1)$$

where

$$\alpha = \frac{32\pi^2 e}{3h^3} \cdot (2me)^{3/2} \quad (2)$$

under the following conditions in the vicinity of each lattice point, due to the presence of bare nuclei

$$u(\mathbf{r}): \quad (=u_0) = \frac{Ze}{|\mathbf{r}-\mathbf{R}_0|} + (\text{finite terms})$$

near $\mathbf{R}_0$ (3a)

$$(\quad =u_n) = \frac{Ze}{|\mathbf{r}-\mathbf{R}_n|} + (\text{finite terms})$$

near $\mathbf{R}_n \quad (n \neq 0) \quad (3b)$

In order to solve this problem, we use the "cellular method", i.e., we subdivide the crystal into polyhedra of equal size and form neglecting the distortion of the lattice due to the presence of an impurity atom. Each polyhedron, except one in which the bare nucleus of an i -atom is located at its center, has the bare nucleus of m -atom at its center.

We shall denote, hereafter, the polyhedron belonging to an i -atom or its neighboring m -atoms by P_0 or P_n and the solutions of (1) in P_0 and P_n by u_0 and u_n respectively.

Then, u_0 and u_n must be smoothly connected over the surface of each neighboring polyhedron, i.e., the continuity of the potentials and their derivatives must hold.

Rigorously speaking, the boundary conditions must be satisfied at all points on the surface of the polyhedron. In the case of the face-centered cubic lattice, the surface consists of twelve planar polygons, and the distance r of the surface points from the center falls in the range $(1/2\sqrt{2})a < r < (1/2)a$, a being the lattice constant. Since we introduce only a finite number of adjustable parameters in the actual calculation, we impose the boundary conditions only at the centers of polygons, which are midpoints between $\mathbf{R}_0$ and $\mathbf{R}_n$. We replace, however, in this calculation the distance $(1/2\sqrt{2})a$ by the radius $r_c = (3/16\pi)^{1/3}a$ of the atomic sphere whose volume is equal to the atomic polyhedron; since r_c is an average of the distances of the surface points from the center, we hope to be able thereby to take account, to some extent, of the fact that the distances of the surface points from the center are not constant.

Therefore, we replace the polyhedra P_0 and P_n , by the spheres of S_0 and S_n of equal volume, and, instead of at the midpoint between the centers of two polyhedra, apply the boundary conditions at the points where the line $\mathbf{R}_0\mathbf{R}_n$ intersects with the atomic sphere,

on the surface of the atomic sphere. Then our problem reduces to solving the T.F. equation within these spheres S_0 and S_n . This approximation seems to be particularly good for cubic metal which has very symmetrical atomic polyhedra.

While Slater and Krutter solved T.F. equation by using the cellular method for pure metals, our new model may be regarded as an extension of theirs to the case of impure metals.

Hitherto, for pure metals*, the potential in each atomic sphere has always been assumed as spherically symmetric. But, in our study of impure metals, we have to take account of the deviation of the potential in the atomic sphere from the spherical symmetry. Of course, the potential in the distance from the impurity must be the same as in the pure matrix metal, which we assume as spherical symmetric in each atomic sphere. On the other hand, in the atomic sphere S_0 for the impurity atom, the potential must have octahedral symmetry, and the deviation from the spherical symmetry appears only in the 4th degree spherical harmonics, so that we may safely neglect this deviation. In the atomic spheres S_n neighboring to S_0 , however, the potential has much lower symmetry, and we take into account of the lower symmetry by writing:

$$u_n = U(r) + f_n(r, \theta, \varphi) \quad n \neq 0 \quad (4)$$

where $U(r)$ is the potential for undisturbed matrix metal and the small term f_n depends not only on r but also on the direction θ, φ (r, θ, φ are the spherical polar co-ordinates with its origin at the center of S_n).

The potentials u_0 in S_0 and u_n in its neighboring spheres S_n obtained by integrating T.F. equation involve a certain number of parameters, which we shall determine by virtue of an appropriate set of boundary conditions.

* Even for the case of pure metals, when the symmetry of the crystal is low, the cellular polyhedron is not well approximated by a sphere, for example in diamond-type structure. Therefore, the angular terms in the potential within the polyhedron may be of some importance. From this side of the non-spherical properties of crystal potential, recently Bell et al.⁴⁾ investigated on lead sulphide, and March⁵⁾, using T.F. method, has made an attempt to estimate the size of the angular terms for silicon.

The details will be described in the following section.

§ 3. Equation in Each Atomic Sphere and the Boundary Conditions

(i) Let us first consider the solution u_0 of T.F. equation within the atomic sphere S_0 of the impurity atom. u_0 , being spherical symmetric due to the consideration stated in § 2, satisfies:

$$\frac{1}{r} \frac{d^2(u_0 r)}{dr^2} = \alpha u_0^{3/2} \tag{5}$$

Near the center, u_0 is given as follows:

$$u_0 = Z_i e / r + c_1 + \cdots \tag{6}$$

If the screening of the excess charge ($Z_i \sim Z$) e is complete in S_0 itself, the total charge contained within this sphere must be zero, i.e., the neutrality condition $(\partial u_0 / \partial r) = 0$ is to be satisfied at r_c , as is the case for the pure metal. But, in the actual case, the screening will be more or less incomplete and the distribution of the excess charge has its tail outside of S_0 to some extent, so that the neutrality condition does not hold. Therefore, we have to leave c_1 in (6) as an adjustable parameter, and determine its value in such a way that u_0 may be smoothly joined to u_n in the nearest neighbors.

(ii) As to the potential u_n within the spheres of m -atoms in the neighborhood of i -atom, we assume, in the first approximation, as follows:

(α) the deviation f_n does not vanish within the spheres of the nearest and 2nd neighbors.

(β) u_n does not deviate from spherical symmetry any longer within the spheres of further than 2nd neighbors and is equal to $U(r)$ of the pure matrix metal.

Both potentials u_n and U satisfy the T.F. equation:

$$\nabla^2 u_n = \alpha u_n^{3/2} \tag{7}$$

$$\nabla^2 U = \alpha U^{3/2} \tag{8}$$

$U(r)$, the potential for pure matrix metal, was already obtained by Slater and Krutter⁶⁾ from the solution of equation (8) subject to the boundary conditions:

$$U \rightarrow Ze / r \quad \text{as } r \rightarrow 0 \tag{9a}$$

$$(\partial U / \partial r) = 0 \quad \text{at } r = r_c \tag{9b}$$

In order to show the geometrical relations

about neighboring atoms to an impurity i -atom, we use such projection for face-centered cubic crystal as is shown in Fig. 1(a). In this projection, open circles denote those atoms located on the plane of the paper and the solid circles are on a plane at the $(\pm \frac{1}{2}a)$ height from the plane of the paper. In this figure, we assume i to be an impurity atom, then

Fig. 1 (a) The projection to show the geometrical relations about neighboring atoms to an impurity i -atom in the face-centered cubic crystal.

Open circles $\bigcirc$ denote those atoms located on the plane of the paper and the solid circles $\bullet$ are on a plane at the $(\pm \frac{1}{2}a)$ height from the plane of the paper.

Fig. 1 (b)

the atoms $m_{1,j}$ (i.e., $m_{1,1}$, $m_{1,2}$, $m_{1,3}$, $m_{1,4}$, etc.) are the nearest neighbors to i -atom, $m_{2,k}$ (i.e., $m_{2,1}$, $m_{2,2}$, etc.) are the 2nd neighbors, and so on. Hereafter, the lower suffix n , expressing the matrix m -atom, is substituted by the double suffixes (k, j) . First suffix k is the order of neighborhood and second one j is the number for m -atoms. And the atomic spheres corresponding to the atoms $m_{1,1}$, $m_{1,2}$, $\cdots$ etc.

are denoted as $S_{1,1}, S_{1,2}, \dots$ etc..

The potentials in the twelve atomic spheres corresponding to the nearest neighbors have the same form and are different only in the orientation in space. Therefore, we pay our attention to one representative m -atom $m_{1,1}$ among the twelve nearest neighbors $m_{1,j}$. Twelve nearest neighbors to this $m_{1,1}$ consist of one impurity atom, four $m_{1,j}$ atoms, two $m_{2,k}$ atoms, four $m_{3,h}$ atoms and one $m_{4,1}$, as is shown in Fig. 1(a).

The boundary conditions to be satisfied by our solutions are constructed between twelve pairs of atomic spheres, i.e., between the central sphere $S_{1,1}$ and each one of its twelve nearest neighbors.

According to the discussions in §2, the boundary conditions concerning each of the above pairs can be imposed at one representative point Q_p , on the surface of the sphere $S_{1,1}$ and there are twelve these points. But, due to the symmetry properties of u_n in each sphere, there are only five independent points (five independent pairs) among these twelve pairs.

As is shown in Fig. 1(b), the polar coordinates r, θ, φ in $S_{1,1}$ are constructed in such a way that its origin is at $m_{1,1}$, i.e., the center of $S_{1,1}$, θ is taken from the line $\overrightarrow{R_{1,1}R_0}$ and φ is the angle from the plane of the paper.

Thus, our boundary conditions are formulated at five points $Q_0(r_0, \theta_0, \varphi_0)$, $Q_1(r_0, \theta_1, \varphi_1)$, $Q_2(r_0, \theta_2, \varphi_2)$, $Q_3(r_0, \theta_3, \varphi_3)$ and $Q_4(r_0, \theta_4, \varphi_4)$ corresponding to five independent pairs of spheres, i.e., $(S_{1,1}, S_0)$, $(S_{1,1}, S_{1,2})$, $(S_{1,1}, S_{2,1})$, $(S_{1,1}, S_{3,1})$ and $(S_{1,1}, S_{4,1})$ respectively.

These circumstances are also shown in Fig. 1(a). Since the line $\overrightarrow{R_{1,1}R_0}$ is two-fold symmetry axis, the term f_n , expressing the deviation from the spherical symmetry, can be expanded in spherical harmonics as follows:

$$\begin{aligned} f_n(r, \theta, \varphi) = & a_0 \chi_0(r) + a_1 \chi_1(r) P_1(\cos \theta) \\ & + a_2 \chi_2(r) P_2(\cos \theta) + \dots \\ & + b_2 \chi_2(r) P_2^2(\cos \theta) \cos 2\varphi \\ & + b_3 \chi_3(r) P_3^2(\cos \theta) \cos 2\varphi + \dots \end{aligned} \quad (10)$$

In this expansion, the coefficients $a_0, a_1, \dots$ and $b_2, \dots$ are adjustable parameters which should be determined by the boundary conditions and it depends on the number of our

boundary conditions that how many terms we can take into our consideration.

On these preparations, our boundary conditions can be formulated as follows:

$$(1) \text{ at } Q_0: \theta_0 = 0$$

$$u_n(r_0, \theta_0, \varphi_0) = u_0(r_0) \quad (11)$$

$$(\partial u_n / \partial r)_{r_0} + (\partial u_0 / \partial r)_{r_0} = 0 \quad (12)$$

$$(2) \text{ at } Q_1: \theta_1 = \frac{\pi}{3}, \quad \varphi_1 = \frac{1}{2} \cos^{-1} \left(-\frac{1}{3} \right)$$

As the potential within $S_{1,2}$ is the same one as in $S_{1,1}$, except the orientation, the continuity condition for the potential itself is automatically satisfied. The condition for the derivatives is

$$(\partial u_n / \partial r) = 0 \quad (13)$$

$$(3) \text{ at } Q_2: \theta_2 = \frac{\pi}{2}, \quad \varphi_2 = 0$$

According to our assumptions, u_n in $S_{2,1}$ will deviate from $U(r)$ to some extent, and its form is not known in advance. In order to utilize the boundary condition at Q_2 , we have to treat u_n in $S_{1,1}$ and in $S_{2,1}$ simultaneously and this would complicate the calculation considerably. Under these circumstances, it may be a reasonable approach to our problem to drop the boundary condition at Q_2 in the first approximation, and on finding u_n in $S_{1,1}$, to determine u_n in $S_{2,1}$ in the next stage. Further, the facts that there are only two points of Q_2 whereas there are four points of Q_1 and Q_3 , and that 10 points of Q_0, Q_1, Q_3 and Q_4 are distributed rather uniformly over the surface of $S_{1,1}$ may be considered as suggesting that the neglect of the boundary condition at Q_2 is not so serious.

$$(4) \text{ at } Q_3 \text{ and } Q_4:$$

$$\theta_3 = \frac{2}{3}\pi, \quad \varphi_3 = \frac{1}{2} \cos^{-1} \left(-\frac{1}{3} \right); \quad \theta_4 = \pi$$

From the assumption (β) in this section, both potentials within $S_{3,1}$ and $S_{4,1}$ are taken as equal to U . Therefore, we can obtain the condition of the same form for these two cases, i.e.,

$$u_n(r_0, \theta_3, \varphi_3) = U(r_0) \quad (14)$$

$$(\partial u_n / \partial r)_{r_0} = 0 \quad (15)$$

$$u_n(r_0, \theta_4, \varphi_4) = U(r_0) \quad (16)$$

$$(\partial u_n / \partial r)_{r_0} = 0 \quad (17)$$

With these seven conditions from (11) to

(17), six adjustable parameters a_0, a_1, a_2, a_3, b_2 and b_3 in f_n can be determined, besides the remaining parameter c_1 in (6).

The equation which the term f_n should satisfy, is obtained as follows: We substitute the formula $u_n = U + f_n$ into (7) and, assuming f_n to be small in comparison with U , expand the equation in powers of f_n . Then we obtain the following differential equation:

$$r^2 f_n = -\frac{3}{2} \cdot \alpha \sqrt{U} \cdot f_n \quad (18)$$

by taking the equation (8) into account and neglecting the terms higher than the second order in f_n .

Then inserting the expression (10) as to f_n into (18), we find that the radial function $\chi_l(r)$ satisfies the following equation:

$$\frac{d^2 \chi_l}{dr^2} + \frac{2}{r} \frac{d\chi_l}{dr} + \left(-\frac{l(l+1)}{r^2} - \frac{3}{2} \alpha \sqrt{U} \right) \chi_l = 0 \quad (19)$$

If we put:

$$\chi_l(r) = r^{-1} R_l(r) \quad (20)$$

the equation (19) reduces to:

$$\frac{d^2 R_l}{dr^2} = \left(\frac{l(l+1)}{r^2} + \frac{3}{2} \alpha \sqrt{U} \right) R_l \quad (21)$$

From (11), (12) and the condition (9b), the following relations between u_0 and u_n are obtained.

$$[a_0 \chi_0 + a_1 \chi_1 + a_2 \chi_2 + a_3 \chi_3]_{r=r_c} = u_0(r_c, c_1) - U(r_c) \quad (22)$$

$$[a_0 \chi_0' + a_1 \chi_1' + a_2 \chi_2' + a_3 \chi_3']_{r=r_c} = -(\partial u_0 / \partial r)_{r_c} \quad (23)$$

On the other hand, each of the five conditions (13) to (17) is written as a linear homogeneous relation for a_0, a_1, a_2, a_3, b_2 and b_3 , so that by solving these simultaneous equations, we can express $a_1, \dots$ and b_3 as definite multiples of a_0 . Therefore, the ratio of left-hand sides of (22) and (23) is completely determined in terms of $\chi_l(r_c)$ and $\chi_l'(r_c)$. This ratio, which we denote by A_0 , is to be equated to the ratio of their right-hand sides:

$$A_0 = \frac{u_0(r_c, c_1) - U(r_c)}{-(\partial u_0 / \partial r)_{r_c}} \quad (24)$$

And the parameter c_1 is determined by this implicit equation. With this value of c_1 , the function u_0 is completely determined, and further the explicit value of a_0 can be determined

from either (22) or (23).

§ 4. The Solutions of the Thomas-Fermi Equations

First, we have to find the solution $U(r)$ of T.F. equation for the pure metal. The method is essentially the same as that of the Slater and Krutter, and is briefly described as follows:

By the substitutions,

$$U(r) = \frac{Ze}{r} \cdot \phi \quad (25a)$$

$$r = \mu_n x \quad (25b)$$

(here, $\mu_n = 0.8853 a_h / Z^{1/3}$, a_h being Bohr radius), the Poisson equation is transformed into dimensionless form:

$$\frac{d^2 \phi}{dx^2} = \frac{\phi^{3/2}}{\sqrt{x}} \quad (26)$$

with the boundary condition:

$$\phi = 1 \quad \text{at} \quad x = 0 \quad (27)$$

In the region where x is small, ϕ is expanded in powers of $x^{1/2}$ with an adjustable initial slope C :

$$\phi = 1 + Cx + \frac{4}{3} x^{3/2} + \frac{2}{5} Cx^{5/2} + \dots \quad (28)$$

Then, the numerical integration is performed from the origin to large x for several different values of C . We determine the value of C corresponding to the correct solution in such a way that the boundary condition (9b) is satisfied, which is expressed in our notation as:

$$\phi'(x_c) = \frac{\phi(x_c)}{x_c} \quad (29)$$

at $x_c = r_c / \mu_n$.

Secondly, we construct the function $u_0(r_c, c_1)$ valid in S_0 . By the substitution similar to (25a) and (25b), i.e.,

$$u_0 = \frac{Ze}{r} \cdot \phi_0, \quad r = \mu_l x \quad (30)$$

$$\mu_l = 0.8853 a_h / Z_l^{1/3}$$

we obtain the same equation:

$$\frac{d^2 \phi_0}{dx^2} = \frac{\phi_0^{3/2}}{\sqrt{x}} \quad (31)$$

$$\phi_0 = 1 + C_0 x + \frac{4}{3} x^{3/2} + \dots \quad (32)$$

we carry out the numerical integration for different values of C_0 , for the interval x which corresponds to the interval $(0, r_c)$ of r . The

value of x which corresponds to r_0 will be denoted by x_i , which is different for different choice of the i -atom.

The equation (21) is expressed in (x, ϕ) coordinates as follows:

$$\frac{d^2R_l(x)}{dx^2} = \left[\frac{l(l+1)}{x^2} + \frac{3}{2} \sqrt{\frac{\phi}{x}} \right] R_l(x) \quad (33)$$

with the value of ϕ previously obtained above. $R_l(x)$ is obtained by performing the numerical integration of the differential equation (33) from the origin to large x starting with the initial condition $R_l(x)=x^{l+1}$. The amplitude of $R_l(x)$ may be taken arbitrary, because the product $a_lR_l(x)$ is independent of the change of normalization of $R_l(x)$.

§ 5. Calculations

In this paper, we take Cu as the matrix metal and Ga, Zn, Ni and Co as the impurity atoms. These impurities are chosen as examples for the cases of $\Delta Z=+2, +1, -1$ and -2 respectively. Hereafter, (ϕ_0, C_0) corresponding to the impurity atom Ga or Zn or Ni or Co and (ϕ, C) corresponding to the matrix pure metal Cu are denoted as $(\phi_{\text{Ga}}, C_{\text{Ga}})$ or $(\phi_{\text{Zn}}, C_{\text{Zn}})$ or $\cdots$ and $(\phi_{\text{Cu}}, C_{\text{Cu}})$ respectively. The numerical integration of the dimensionless T.F. equation (26) and (31) are performed on the electronic computer "Fujic" of Fuji Photographic Film Co. Ltd.

The (x, ϕ) tables thus obtained may be useful for the investigations of metals or complex ions besides atoms or molecules, so the full tables, including those of ϕ which have not been used in this paper, will be published in separate paper.

From these tables, the initial slope C_{Cu} corresponding to the correct solution ϕ_{Cu} for the pure metal Cu is found to be -1.587855 . And by using this ϕ_{Cu} for ϕ in (33), $R_l(x)$ is obtained by numerical integration with previously stated procedures. Further χ_i and χ_i' are calculated.

Thus, the adjustable parameters a_1, a_2, a_3, b_2 and b_3 are obtained as multiples of a_0 and a_0 itself is also calculated from (22) for each choice of the impurity.

These values for the coefficients are tabulated in Table I.

The value of A_0 calculated from $\chi_i(r_0)$ and $\chi_i'(r_0)$ is 0.48. The correct numerical values of C_0 as a quantity characterizing the solution

Table I.

(A) The values of the coefficients in f_n (expressed as the multiples of a_0).

a_1	$0.533a_0$	b_2	$-0.044a_0$
a_2	$0.048a_0$	b_3	$-0.003a_0$
a_3	$0.001a_0$		

(B) The values of a_0 for different choice of impurity.

Impurity atom	ΔZ	a_0^*
Co	-2	$-0.000032e$
Ni	-1	$-0.000011e$
Zn	$+1$	$+0.000014e$
Ga	$+2$	$+0.000029e$

* The values of a_0 are the average of the two values corresponding to two values of C_0 which are tabulated in Table II.

Fig. 2. The curve representing the relation between A and C_0 . The figure in the abscissa indicates the 5th place of decimals, i.e., for example, -1.58787 corresponds to figure 7.

ϕ_0 for each impurity i -atom is obtained from ϕ_0 with which the right-hand side value (to be denoted as A) of (24) is equal to A_0 .

As to the numerical values of ϕ or ϕ_0 in the vicinity of x_0 or x_i , there is about 1% difference between those two values of ϕ , which correspond to their C 's having unit difference at their sixth place of decimals.

The curve representing the relation between A and C_0 are of the hyperbolic form and is shown in Fig. 2 for the case of Zn in Cu as an example.

Table II. The values of the initial slopes C_0 and $C_{0,p}$.

Impurity atom	ΔZ	C_0	$C_{0,p}$
Co	-2	between $\begin{Bmatrix} -1.587821^* \\ 22 \end{Bmatrix}$	between $\begin{Bmatrix} -1.587827 \\ 28 \end{Bmatrix}$
Ni	-1	between $\begin{Bmatrix} -1.587838 \\ 39 \end{Bmatrix}$	-1.587842
Zn	+1	between $\begin{Bmatrix} -1.587869 \\ 70 \end{Bmatrix}$	-1.587867
Ga	+2	between $\begin{Bmatrix} -1.587882 \\ 83 \end{Bmatrix}$	between $\begin{Bmatrix} -1.587878 \\ 79 \end{Bmatrix}$

* The figure, for example as to the case of C_0 of Co,

$$\text{between } \begin{Bmatrix} -1.587821 \\ 22 \end{Bmatrix}$$

shows the following affair;

$$-1.587821 > C_0 > -1.587822 .$$

Similarlity is referred to other figures concerning other C_0 and $C_{0,p}$.

Certainly, the potential u_0 within S_0 for the i -atom which is introduced into the m -atom, should be different from that of pure i -metal (to be referred to u_0 (pure)). u_0 (pure) is obtained in the same way as for pure Cu. The values of C_0 corresponding to u_0 and that of u_0 (pure), denoted as $C_{0,p}$, are listed in Table II.

§ 6. The Screened Potential around an Impurity Atom

From our present model, the screened Coulomb

potential is expressed as follows:

$$V(r) = -e(u_0 - U) \\ -e^2 \left[\frac{Z_i}{r} \phi_0 \left(\frac{r}{\mu_i} \right) - \frac{Z}{r} \phi_{Cu} \left(\frac{r}{\mu_m} \right) \right] \tag{34}$$

where ϕ_0 for the four kinds of impurities (i.e., ϕ_{Ga} , ϕ_{Zn} , ϕ_{Ni} and ϕ_{Co}) and ϕ_{Cu} are obtained numerically.

Then it is found that the numerical values in the bracket of (34) are proportional to ΔZ and $V(r)$ can be expressed as:

Fig. 3. The curves of the values in the bracket of (34),

i.e., $\frac{Z_i}{r} \phi_0 \left(\frac{r}{\mu_0} \right) - \frac{Z}{r} \phi_{Cu} \left(\frac{r}{\mu_m} \right)$
Curve 1: impurity Ga ($\phi_0 \equiv \phi_{Ga}$).
Curve 2: impurity Zn ($\phi_0 \equiv \phi_{Zn}$).

Fig. 4. The behavior of the potential due to the methods of treatment.

Curve D_1 : present result.
Curves D_2 , D_3 and D_4 : results in the previous work and stated in the sentence.

$$V(r) = -\frac{e^2}{r} \cdot \Delta Z \cdot F(r) \quad (35)$$

within the limit of 1% error.

The curves for the cases of Ga in Cu and Zn in Cu are shown in Fig. 3.

To compare $V(r)$ in this paper with those obtained in the previous work, four curves are plotted in Fig. 4. The case of Zn in Cu is taken as an example.

In this figure, the curve D_1 corresponds to that of (34), D_2 , D_3 are those obtained in our previous work (D_2 : with exchange⁷⁾, D_3 : without exchange⁸⁾) and D_4 is the usual one obtained analytically from the linearized T.F. equation i.e., $V(r) = -(e^2/r) \cdot \Delta Z \cdot \exp(-qr)^{9)}$.

As stated in the early part of § 3, the degree of the screening of excess charge $(\Delta Z)e$ will be incomplete within S_0 itself.

Table III. The values of ρ .

(A) The variations of ρ due to the method of treatments (the case is Zn in Cu, i.e., $\Delta Z = +1$).

Case	ρ
D_1 (present one)	$0.03e$
D_2 }	$0.12e$
D_3 } (previous ones)	$0.21e$
D_4 }	$0.28e$

(B) The variations of ρ due to the choice of impurities according to the present model.

Impurity	ΔZ	ρ
Co	-2	$-0.06e$
Ni	-1	$-0.03e$
Zn	+1	$+0.03e$
Ga	+2	$+0.06e$

The remaining charge ρ which can not be screened completely within the sphere S_0 is calculated from the following formula:

$$\begin{aligned} \rho &= \int \rho'(r) dV = -\frac{1}{4\pi} \int \frac{\partial(u_0 - U)}{\partial r} dS \\ &= -r_0^2 \left(\frac{\partial(u_0 - U)}{\partial r} \right)_{r_0} \cdot e \quad (36) \end{aligned}$$

We take the case of Zn in Cu as an example and the calculated values of ρ for the four cases from D_1 to D_4 just stated above, are tabulated in Table III.

And in this Table, also those ρ 's for the

cases of $\Delta Z = \pm 2$ and ± 1 in this paper are listed respectively.

§ 7. Results and Discussions

The work reported in this paper, is done for the purpose of removing the deficits in the previous model that we could not take the lattice distortion of the matrix metal into account and so on, as stated in the introduction, and the following results are obtained.

(i) The convergency of the values of coefficients in f_n , is comparatively fast and the deviation from spherical symmetry is small even at Q_0 , where f_n may be largest.

The magnitude of $f_n(r_0, \theta_0, \varphi_0)$ is estimated about 1% or less of $U(r_0)$. And since the corresponding value at Q_2 is very small, it is not serious that the boundary condition at Q_2 has been neglected.

Fig. 5. The variations of f_n in the atomic sphere $S_{1,1}$ along the line $\overline{R_0 R_{4,1}}$.

The behavior of the variation of f_n within $S_{1,1}$ is shown in Fig. 5 as the multiples of a_0 . f_n is calculated along the line $\overline{R_0 R_{4,1}}$. It is found from this figure that the deviation f_n from the spherical symmetric one U , almost vanishes at the center of $S_{1,1}$. This fact may be regarded as a justification of our assumption that the potential u_n within the sphere of higher than the 2nd neighbors to an impurity atom equals to $U(r)$ of pure metal.

(ii) As is indicated in Table II, the values of $C_{0,p}$ corresponding to the pure i -metal subject to the neutrality condition on its atomic sphere, are, to some extent, different from C_0 for i -atom when it is present as an impurity. $|C_0|$ is larger than $|C_{0,p}|$ for the case

of Ga or Zn and the opposite result is obtained for Ni or Co. This is conformity with the situation that Ga or Zn atom (i.e., $\Delta Z > 0$) is positively ionized to some extent when it is introduced into Cu and Ni or Co atom ($\Delta Z < 0$) exists as a negative ion in Cu.

(iii) The two curves in Fig. 3 for the cases of Ga ($\Delta Z = +2$) and Zn ($\Delta Z = +1$) in Cu, coincide almost exactly with those of Co ($\Delta Z = -2$) and Ni ($\Delta Z = -1$) with each other, except their signs and the perturbed potential $V(r)$ can be expressed in the form (35). This result shows that the change of the potential due to the introduction of an impurity atom is very nearly proportional to $\Delta Z = Z_i - Z$, at least for $-2 \leq \Delta Z \leq +2$. In a certain sense, this result is what we may expect from the beginning, provided that the change of the potential is small compared with the potential itself and may be treated as a small perturbation to the potential of the pure metal. In fact, our potential $u(x, y, z)$ is determined by the equation (1) valid throughout the crystal under the boundary conditions (3a) and (3b) near the lattice points as stated in § 2.

On the other hand, the potential U of pure matrix metal satisfies the following condition.

$$\left. \begin{aligned} \nabla^2 U &= \alpha U^{3/2} && \text{throughout the crystal} \\ U &\sim Ze/|\mathbf{r} - \mathbf{R}| + \cdots && \text{near the lattice point } \mathbf{R} \end{aligned} \right\} \quad (37)$$

Now, if the change due to the impurity is small, we should be allowed to treat f defined by $u = U + f$ as a small quantity compared with U . Thus the differential equation satisfied by f is found to be

$$\nabla^2 f = \frac{3}{2} \cdot \alpha \sqrt{U} \cdot f \quad (38)$$

and the conditions at the lattice points are

$$f \sim \begin{cases} (\Delta Z)e/r + \cdots & \text{at } \mathbf{r} \sim \mathbf{R}_0 \\ \text{finite} & \text{at all other } \mathbf{R}_n \end{cases} \quad (39)$$

Taking into account that the differential equation (38) is linear, we can see quite easily that if $f^{(1)}$ is the solution of (38) with the conditions (39) for $\Delta Z = 1$, $f = (\Delta Z)f^{(1)}$ satisfies all the conditions for f in the general case. Hence the solution has the form:

$$f = (\Delta Z) \cdot f^{(1)} \quad (40)$$

where $f^{(1)}$ does not depend on ΔZ .

The above argument does not make use of

the cellular method. If we use the cellular method, however, $u - U$ in each cell is proportional to ΔZ :

$$\left. \begin{aligned} u_0 - U &= (\Delta Z) \cdot F_1(r) && \text{in } S_0 \\ u_n - U &= (\Delta Z) \cdot F_2(r) && \text{in } S_n \end{aligned} \right\} \quad (41)$$

In our calculation, we employed the linearized equation (38) only in the atomic sphere of m -atom and we solved the equation numerically. The results shows, however, that we might make use of the linearized equation (38), even in the impurity cell itself.

(iv) As to the case of $\Delta Z > 0$, the potential falls off more rapidly than those obtained in the previous work advancing from D_4 to D_1 as is shown in Fig. 4. It indicates that the screening radius becomes smaller and smaller in accordance with the case advancing from D_4 to D_1 . They are also found from Table III concerning the remaining charge which is not screened off.

As was found from our previous investigations, these results seem to diminish the disagreement between the calculated and experimental values of residual electric resistance of binary alloys.

The perturbed potential $-(\Delta Z/r)e^2 \cdot \exp(-qr)$ which was obtained by Mott from linearized T.F. equation, is also proportional to ΔZ , but, our present one (33) falls off more rapidly as is shown in Fig. 4. March et al.¹⁰⁾ have found that the potential obtained from numerical integration is represented by the asymptotic form $-(\Delta Z/r)e^2 \cdot A \cdot \exp(-qr)$ at some distance from the origin for the case of $\Delta Z > 0$. And Alfred and March¹¹⁾ also obtained the values of A for the cases of negative ΔZ . Their results were that the obtained values of A were larger than those corresponding to positive ΔZ (same $|\Delta Z|$), show that the screening of the excess charge $(\Delta Z)e$ is weak for the negative ΔZ in comparison with that for the cases of positive ΔZ .

As stated before, our present calculations show that the obtained potential (35) for the cases of $\Delta Z = -2$ or -1 coincides almost exactly with that of $\Delta Z = +2$ or $+1$ respectively.

But, due to the experimental results of the residual electric resistances which are related directly to the dimensions of the potentials, of binary alloys, the resistances for the cases of $\Delta Z < 0$ are comparatively larger than the corresponding values for $\Delta Z > 0$.

Therefore, there remains some ambiguity in our results for the cases of $4Z < 0$, and we hope to solve this point in our further investigations by using our improved model stated in the following sentence.

(v) As stated in the latter part of § 1, our present model is not completely satisfactory, since T.F. method cannot account for the shell structure of electrons in atoms.

We are now taking into account, in our model of this problem, the distribution of core electrons by the use of Hartree or Hartree-Fock fields and treating the electrons outside these cores by T.F. method. We are now proceeding this way and we hope to report the results in a near future.

§ 8. Acknowledgements

The author wishes to express his sincere thanks to Prof. Masao Kotani of University of Tokyo for his continued guidance and encouragements throughout this work and to Professors N. H. March, F. J. Blatt and K. Umeda, and Dr. S. Kobayashi for their kind interests and discussions. The author's appreciations are to Director S. Fujisawa and Dr. B. Okazaki of Fuji Photographic Film Co. Ltd. at Odawara for their kind permissions to use their electronic computer "Fujic" and especially to Mr. S. Tatsuoka who kindly operated the "Fujic" to make the tables of the solutions of T.F. equation. He further appreciates the valuable and kind assistance of Mrs. H. Komuro in the numerical work and the analysis of Fujic's data.

He is also indebted to the Ministry of Edu-

cation and the members of Kotani Laboratory of University of Tokyo for their financial aids and his thanks are also due to Professors M. Suzuki and S. Matsumoto of Hiroshima University for their kind interests.

Calculation of the Energy Band Structure of the β -SiC Crystal by the Orthogonalized Plane Wave Method

By Syoiti KOBAYASI

*Department of Physics, Faculty of Science, Hiroshima University
Hiroshima, Japan*

(Received December 7, 1957)

The energy band structure of the β - (zincblende-type) SiC crystal is worked by the orthogonalized plane wave (OPW) method. Since this crystal will be the typical one of the IV-IV compounds, the results of calculation for its electronic structure will be useful for systematic understanding of the transitions of the electron-behavior from the group-IV valence-crystals to the III-V compounds etc.. Our results show that the conduction band-minima occur at X -point or its immediate neighbor, while the valence band-maximum perhaps at Γ -point. Hence the indirect interband-transitions in the long wave limit will be expected to occur between these two states with the energy difference of 2.2 ev, and the direct interband-transitions at X -point will take place at a photon energy of 6.3 ev. Further the approximate charge-distribution in the crystal is worked by making use of the obtained Γ -valence eigenfunctions, which result seems to show that the electrons in its $\vec{k}=0$ levels of the β -SiC will be approximately a covalent-like distribution as far as Γ -eigenfunctions do concern. Finally, an idea is proposed to improve the slow-convergence of the OPW method for conduction bands of insulators. Its practical application is now in progress for the β -SiC.

§ 1. Introduction

Recently, many efforts have been made to calculate the detailed energy-band structures for the diamond-type group-IV valence-crystals (diamond, silicon, and germanium)^{1,2,3)}. Following these investigations, the speculation of rough features of the energy band structure in zincblende-type crystals has been attempted by Herman⁴⁾ on the basis of his own treatment of diamond and germanium¹⁾, and recently the elaborate programs for InSb⁵⁾, ZnS⁶⁾ and others⁶⁾ have already been started by some workers.

There would be two appreciable differences, however, between the general nature of the energy band structure for Ge-group and InSb-group, for the following reasons. In the first place, the space group of the latter⁷⁾ is referred to as the point space group T_d^2 , while that of the former, O_h^7 , is not a point space group. Secondly, for binding property, the latter may be supposed to be of partly ionic and partly covalent character, while the former will naturally be pure homopolar.

Between these two groups, there seems to lie IV-IV compounds, in which the typical one will be the β - (zincblende-type) SiC

crystal. The β -SiC has a similar symmetry property to that of InSb-group, while the former crystal seems to have close resemblance to the Ge-group rather than the InSb-group, for the reason that the constituent atoms belong to the group-IV and have the similar electron configuration.

Thus, a knowledge of the electronic structure of the IV-IV compounds will be useful for the systematic understanding of the transitions of the behavior of electrons from the monatomic crystals of diamond-type to the zincblende-type compounds.

In a preliminary investigation⁸⁾, we have already computed the rather rough picture of the band structure in the β -SiC by the tight-binding method. The main results were as follows. The minimum separation between the valence and the conduction bands occurred at $\vec{k}=0$, and was about 6 ev. The valence bands were divided into two branches with the minimum separation of 10 ev, at the Brillouin zone-edge along $[1, 0, 0]$, and hence in the preceding paper we conjectured that this fact would be the characteristic difference between the valence band-shape of the zincblende-type compounds and that of diamond-

type monatomic crystals, the valence bands of the latter giving no separation^{1,2,3)}.

Of course, the mentioned results of the tight-binding computation were not sufficient quantitatively, especially in the conduction bands which became very flat compared with the valence bands, probably because of the too much simplified assumptions in which no excited Bloch wave function was included and all energy-integrals were neglected except for those between the neighboring two kinds of atoms of the crystal.

Next we have attempted to go a step further by making use of the orthogonalized plane wave (OPW) method⁹⁾. As well known, the OPW method has already been applied successfully to the several metals¹⁰⁾ and to the nonmetallic diamond-type valence crystals mentioned above^{1,2)}. This is the reason why the OPW method was adopted in our present computation.

According to the present results of the β -SiC given in Sec. 2, the conduction band-minima occur at X -point ($\vec{k}=(2\pi/a) [1, 0, 0]$) or its immediate neighbor; a is the edge length of the cube which contains four unit cells, and the valence band-maximum perhaps at Γ -point ($\vec{k}=0$). Hence the indirect inter-band transitions in the long wave limit will be expected to appear near the band edge, its energy difference being 2.2 eV corresponding to the transition from the valence Γ_{15} -state to the conduction X_3 - (or its neighboring-) state. Besides, the direct transitions connected with the energy difference of 6.3 eV may be anticipated to occur at the X -point. Regarding these aspects of the absorption spectra of the β -SiC, Herman^{4,6)} and Choyke and Patrick¹¹⁾ have so far given some similar speculations.

Further, as shown in Sec. 3, we have estimated the charge distribution corresponding to $\vec{k}=0$ levels of the valence bands by making use of the four computed Γ -eigenfunctions of the valence bands. The results show that the electrons in the $\vec{k}=0$ levels of the β -SiC is approximately of covalent-like character.

It is well-known that in nature there are the two distinct crystalline-species of silicon carbide; i.e., the cubic one named as a β -type with which we now concern, and the hexagonal varieties, grouped as an α -type which is

so called carborundum. Many experimental investigations of the actual SiC crystals have been made so far, regarding the electronic conductivity^{12,13)}, the Hall effect¹²⁾, the injected light emission¹⁴⁾, the radiation damage¹⁵⁾, and the ultraviolet absorption of light near the band-edge^{11,16)}. But every specimen used for these experiments was the " α " one, probably because of the reason that rather large size of the α -type single crystal could be synthesized far more easily than that of the β -type one¹⁷⁾. In view of the above situations, the experimental studies on the β -type specimen in place of the ordinary α ones, are highly required in order to compare with our results.

Finally, concerning one of the computational difficulties; i.e., of the slow-convergence problem in the OPW method when applied to non-metals, a revised procedure will be proposed in Sec. 4 which may be useful for computing the conduction bands of such valence crystals and insulators.

§ 2. Potential Construction and the Obtained Energy Band Structure

The primitive translation vectors in the reciprocal lattice (Fig. 1 (i)) are given by

Fig. 1. Dimensions of the β (zincblende-type) SiC crystal. (i) The primitive translation in reciprocal lattice. $a=4.348\text{\AA}=8.217a_H$ (a_H =Bohr radius). (ii) The first Brillouin zone.

$$\vec{b}_1=(1/a)[-1, 1, 1], \quad \vec{b}_2=(1/a)[1, -1, 1], \quad \vec{b}_3=(1/a)[1, 1, -1], \quad (1)$$

where a denotes the edge length of the cube which contains four unit cells, being $a=4.348\text{\AA}=8.217a_H$ ¹⁸⁾ (a_H =Bohr radius). From (1) $\vec{K}$ -vectors are defined as

$$\vec{K}_m=2\pi \sum_{i=1}^3 m_i \vec{b}_i. \quad (2)$$

The first Brillouin zone can be taken as a truncated octahedron shown in Fig. 1 (ii) toge-

Si-atom). Hence, concerning the tail-parts of both the atomic-functions, there are considerable unbalances, as anticipated in advance. For this reason, we used a sort of the cut-off procedure of the tail-parts of $P(r)$'s, in order to avoid the unfavorable part of the mentioned unbalances.

In this connection, Woodruff²⁾ has recently proposed a procedure regarding the construction of potential and the corresponding determination of ion-cores, and has obtained the Γ -solutions with very rapid convergence for silicon crystal. Further, Herman⁶⁾ has proposed to form the crystal potential by try-and-error method through comparing with the X-ray term values. At any rate, the mentioned difficulty in the construction of crystal potential remains unsettled yet, in spite of its decisive importance in the calculation of the energy band structure.

Thus the energy band structure of the β -SiC has been calculated. The wave functions associated with the irreducible representations of the wave-vector group of a given symmetry point in $\vec{k}$ -space may be easily obtained in the same manner as in the case of symmetry-molecules²³⁾ by making use of Parmenter's group-theoretical consideration⁷⁾.

Thus we have computed the energy values on the following several symmetry-points and lines; Γ , [0, 0, 0]; X , [1, 0, 0] (in the unit of $2\pi/a$, and so forth); W , [1, 0, 1/2]; L , [1/2, 1/2, 1/2]; a point along the Σ -axis, [1/2, 1/2, 0]; among which the energy values of the Σ -point have been less precise than those at the other points. The reason for this result is that Σ has rather low symmetry compared with the others, hence we are forced to include only small number of the OPW-terms for this point as far as the desk-calculator is

Fig. 2. Energy band structure of the β -SiC crystal obtained in the present OPW-calculation. The numbers at the upperside of the figure represent those of the OPW-terms involved.

at our disposal. (Further, the lowest valence-levels for the mid-points along the A - and A -axes; i.e., for [1/2, 0, 0] and [1/4, 1/4, 1/4], have been calculated. These values are also written in Fig. 2, though they seem to be not in good convergence owing to the same reason as in Σ .)

Hence, we could not fully investigate the convergence of the eigenvalues, especially for the lower-symmetry points and lines. The obtained energy contours are shown in

Fig. 2, together with the convergence behaviors for X and Σ in Figs. 3 and 4, respectively. The numbers at the upperside of the Fig. 2 represent those of the OPW-terms involved. The spin-orbit coupling effect is neglected in view of the present degree of approximation. The terminology of BSW²⁴⁾ is used to denote the group representation and the points and lines of symmetry.

As mentioned in Sec. 1, the present results seem to show that in the β -SiC the conduc-

tion band minima occur at the X -point or in its vicinity, and the valence band maximum perhaps at the zone-center (Γ -point), so that the indirect interband transitions in the long wave limit will be expected from the valence band-top (Γ_{15}) to the conduction band bottom (X_3) with a photon energy of 2.2 eV, while the direct transitions connected with the smallest energy 6.3 eV will occur from X_5 of the valence band to X_3 of the conduction band, within the accuracy of the present computation. These results seem approximately to agree with Herman's^{4,6)} and Choyke and Patrick's¹¹⁾ speculations.

§ 3. Additional Numerical Computation

Since the convergence of the eigenvalues for each symmetry point in $\vec{k}$ -space may be supposed to be not sufficient enough as seen from Figs. 3 and 4, then we have further attempted to solve the secular equation for Γ involving 27 OPW-terms. The convergence-behaviors are shown in Fig. 5. (But, in Fig. 2, we have chosen the Γ -eigenvalues corresponding to 15 terms rather than to 27 terms, in order to keep balance in the whole contour of the energy bands.) The noticeable facts in Fig. 5 will be as follows. First, the convergence in the lowest valence band Γ_1 seems

Fig. 3. Convergence-behaviors of the X -eigenvalues, showing comparatively good convergence.

Fig. 4. Convergence-behaviors of the Σ -eigenvalues. (The example of insufficient convergence.)

Fig. 5. Further examination of convergence-behaviors of Γ -eigenvalues when 27 OPW-terms are involved. The convergence in the lowest valence band (Γ_1) seems to be extremely sufficient. The two lowest conduction bands, Γ_{15} (triplet) and Γ_1 (singlet) are reversed with each other in this case.

to be extremely sufficient, and secondly, the two lowest conduction bands Γ_{15} (triplet) and Γ_1 (singlet) are reversed with each other and Γ_1 is turned down to be the lowest as shown in Fig. 5. In diamond¹⁾ and silicon²⁾ the lowest conduction bands in Γ are both the triplet Γ_{15} , while in germanium¹⁾ it is the singlet Γ_2' (it corresponds to Γ_1 of zincblende-type crystal⁷⁾). Since the β -SiC is a compound of silicon and carbon, it would be natural to suppose that the lowest conduction bands in Γ would be triplet. But carrying through the computation beyond the present one will be prohibitibly laborious without automatic machines.

Fig. 6. Charge density according to the lowest valence-eigenfunction $\psi^{val}(\Gamma_1)$ normalized in the unit cell. (i) The component along the line connecting Si- and C-sites ([1,1,1] direction). (ii) The component along [1,0,0] direction through Si-sites alone. (iii) The same as (ii) but through C-sites alone. In (ii) and (iii) of this figure the charge distributions along [0,1,0] or [0,0,1] directions are quite same as that for [1,0,0].

Fig. 7. The similar figure as in Fig. 6, for $|\psi_x^{val}(\Gamma_{15})|^2$. (i), (ii), and (iii) of this figure correspond to (i), (ii), and (iii) of Fig. 6, respectively. The components along both [0,1,0] and [0,0,1] directions through Si- or C-site vanish. The situations are quite similar for $|\psi_y^{val}(\Gamma_{15})|^2$ and $|\psi_z^{val}(\Gamma_{15})|^2$.

Next, in order to obtain some knowledge of the behaviors of crystal electrons, for illustration, the charge density of Γ -electrons has been worked by making use of the obtained valence-electron wave functions. These wave functions are $\psi^{val}(\Gamma_1)$, $\psi_x^{val}(\Gamma_{15})$, $\psi_y^{val}(\Gamma_{15})$, and $\psi_z^{val}(\Gamma_{15})$, normalized in the unit cell. The behaviors of $|\psi^{val}(\Gamma_1)|^2$ in the unit cell is drawn in Fig. 6 (i), (ii) and (iii). And $|\psi_x^{val}(\Gamma_{15})|^2$ are shown in Fig. 7 (i), (ii) and (iii), along the similar directions as in Fig. 6. The apparent difference between $|\psi^{val}(\Gamma_1)|^2$ and $|\psi_x^{val}(\Gamma_{15})|^2$ is that the former is *s*-like, while the latter is *p*-like. The situations are quite similar for the cases of $|\psi_y^{val}(\Gamma_{15})|^2$ and $|\psi_z^{val}(\Gamma_{15})|^2$. Thus we have

$$|\psi_{\Gamma}^{val}|^2 = |\psi^{val}(\Gamma_1)|^2 + |\psi_x^{val}(\Gamma_{15})|^2 + |\psi_y^{val}(\Gamma_{15})|^2 + |\psi_z^{val}(\Gamma_{15})|^2, \quad (9)$$

which represents the charge distribution of Γ electrons. The [1, 1, 1] component of (9) is drawn in Fig. 8, which seems to show that the charge density in the space region between the Si- and the C-site as well as in

Fig. 8. The component along [1,1,1] direction of the charge density according to the total distribution belonging to $|\psi^{val}(\Gamma_1)|^2 + |\psi_x^{val}(\Gamma_{15})|^2 + |\psi_y^{val}(\Gamma_{15})|^2 + |\psi_z^{val}(\Gamma_{15})|^2$.

the vicinity of both the atoms will be considerably large compared with the other parts, representing the covalent-like distribution. However, if (9) or Fig. 8 is looked over from the standpoint of ionicity, the rather rough estimation shows that the charges corresponding to the Γ -valence electrons around the Si- and the C-position seem to be approximately $-3e$ and $-5e$, respectively, in spite of the present starting potential corresponding to $-4e$ and $-4e$, respectively. Then, in the ionic-viewpoint, β -SiC may be considered to be described approximately by $\text{Si}^{+3}\text{C}^{-5}$,

where $x \sim 1$. This result seems to agree with the semi-empirical values of electronegativity²⁵⁾: 1.8 and 2.5 for Si and C, respectively. But, after all, it will be rather right to imagine that the charge distribution in Fig. 8 is covalent-like, for the reason of the large charge-density in the mid-parts between the nearest Si and C.

At any rate, in order to obtain the binding mechanism of the β -SiC crystal, it is essentially required to work the total charge distribution of valence electrons which is given by $\sum_{\vec{k}} |\psi^{val}(\vec{k}, \vec{r})|^2$, and which calculation is now in progress.

In the present paper, we omitted the minor details of the calculation. These will be described in the Journal of Science of Hiroshima University, Ser. A, later on.

§ 4. A Revising Method of the OPW Approximation for the Conduction Bands of Insulators

In this section we shall propose a new procedure for obtaining the better variation functions for conduction bands of insulators.

For simplicity, let us now consider a crystal whose unit cell contains only one atom. $u_s(\vec{r} - \vec{R}_n)$ are the ion-core atomic-orbitals which belong to the n -th atom and the corresponding Bloch sums are written as

$$\phi_s(\vec{k}, \vec{r}) = N^{-1/2} \sum_n \exp(i\vec{k} \cdot \vec{R}_n) u_s(\vec{r} - \vec{R}_n),$$

$$s=1, 2, \dots, m, \quad (10)$$

where m is the number of the so called ion-cores, and N is the number of the unit cells in the crystal. Then the variation functions (OPW-terms) for the valence bands, which are orthogonalized to all the ion-cores (10), are

$$Y(\vec{k}, \vec{r}) = (N\Omega)^{-1/2} \exp(i\vec{k} \cdot \vec{r})$$

$$- N^{-1/2} \sum_s \sum_n \exp(i\vec{k} \cdot \vec{R}_n)$$

$$\cdot A_s(\vec{k}) u_s(\vec{r} - \vec{R}_n), \quad (11)$$

of which the valence-band eigenfunctions are made up as

$$\psi^{val}(\vec{k}, \vec{r}) = \sum_i \beta(\vec{k} + \vec{K}_i) Y(\vec{k} + \vec{K}_i, \vec{r}), \quad (12)$$

$\beta(\vec{k} + \vec{K}_i)$ being determined by group-theoretical consideration and by solving corresponding secular equations.

Then, the Wannier functions²⁶⁾ of the valence bands will be constructed from the Bloch orbitals (12) as follows:

$$a^{val}(\vec{k}, \vec{r} - \vec{R}_n)$$

$$= N^{-1/2} \sum_{\vec{k}} \exp(-i\vec{k} \cdot \vec{R}_n) \psi^{val}(\vec{k}, \vec{r}). \quad (13)$$

The Fourier transforms of (13); i.e., $\psi^{val}(\vec{k}, \vec{r})$ are represented by

$$\psi^{val}(\vec{k}', \vec{r})$$

$$= N^{-1/2} \sum_n \exp(i\vec{k}' \cdot \vec{R}_n) a^{val}(\vec{k}', \vec{r} - \vec{R}_n). \quad (14)$$

Now we suppose that $\psi^{val}(\vec{k}, \vec{r})$ have been obtained by applying the usual OPW method. $\psi^{val}(\vec{k}, \vec{r})$, of course, are orthogonal to all the $\phi_s(\vec{k}, \vec{r})$ in (10). Hence, $a^{val}(\vec{k}, \vec{r} - \vec{R}_n)$ for the valence bands play a similar role as those of the atomic orbitals in the lower ion-core bands. Then, the variation functions (OPW-terms) for the conduction bands can be constructed by including the Wannier-functions of the valence bands in addition to the usual atomic orbitals belonging to the ion-core levels:

$$Y(\vec{k}, \vec{r}) = (N\Omega)^{-1/2} \exp(i\vec{k} \cdot \vec{r})$$

$$- N^{-1/2} \sum_s \sum_n \exp(i\vec{k} \cdot \vec{R}_n) A_s(\vec{k}) u_s(\vec{r} - \vec{R}_n)$$

$$- N^{-1/2} \sum_t \sum_n \exp(i\vec{k} \cdot \vec{R}_n) A_t^{val}(\vec{k})$$

$$\cdot a_t^{val}(\vec{k}, \vec{r} - \vec{R}_n). \quad (15)$$

In the conventional OPW method, the valence bands and conduction bands of insulators have been solved at the same time, so that the convergence in the upper-lying conduction bands may be in general anticipated to be insufficient compared with that of the lower-lying valence bands, because the solutions for the higher energy levels can not be obtained until the secular determinants of rather high-order are solved. This fact is shown in Fig. 3 and 4. Then, we now propose that in the first step, the valence bands are calculated on the basis of (11) by the usual OPW method, secondly, the Wannier functions (13) of the valence bands are set up through the Fourier transform of the obtained $\psi^{val}(\vec{k}, \vec{r})$, and in the final step, the conduction bands are computed on the basis of (15), instead of (11); by the usual OPW method. Then, this procedure would lead to more rapid conver-

gence for the conduction bands than usual.

After all, according to the present proposition, the labor for solving the higher-order secular-equation is replaced by that for getting the Wannier functions of the valence bands. For practical application, it is necessary that the labor for obtaining these Wannier functions must be rather simple and easy in the actual problem. Application of this method to the conduction bands of the β -SiC crystal is now in progress.

The Crystallographic Aspect of the Mechanical Twinning in Ti and α -U

By Hiroshi KIH0

Department of Physics, Kyogyo-bu, University of Kyoto

(Received November 15, 1957)

A crystallographic study on the mechanical twinning in Ti and α -U is made by a method similar to that in a previous paper, allowing more kinds of atom movements, and the twin elements, K_1 , K_2 , η_1 and η_2 , are determined. It is found that $\{11\bar{2}2\}$ and $\{11\bar{2}4\}$ twins in Ti are reciprocal to each other and that the elements of $\{11\bar{2}1\}$ twin are in agreement with Hall's result. It is also found that a general result that a plane having the smallest shear S is liable to twin in order nearly holds in Ti and α -U.

§ 1. Introduction

In a previous paper¹⁾, the present author carried out, the crystallographic calculations on the atom movements of mechanical twinning, under several assumptions, and the twin elements, K_1 , K_2 , η_1 and η_2 , have been determined. There η_1 was denoted by $[uvw]$ and η_2 by $[m_0n_0p_0]$. It has thus been shown that the observed twins have the smallest shear S among crystallographically possible twins.

Recently, the same problem was treated, independently of the present author, by M. A. Jaswon and D. B. Dove^{2,10)}, who introduced the concept of homogeneous shear for a simple lattice and semi-homogeneous shear for a multiple lattice, and determined the atom movements. They used the inequality theorem in order to find a plane having the smaller twinning shear, thus obtaining the results similar to those of the present author. But, twins in Ti and Zr were not accounted for by them.

The assumptions used in the previous paper cited above are as follows:

I. There are only a few atom movements, U , and these appear alternatively when the twin boundary moves;

II. The atom which comes in a twin lattice site is at the nearest matrix lattice site to it. This is justified by the fact that the twin dislocation is movable;

III. An atom movement U consists of the Burgers vector b of a twinning dislocation and a shuffle. Since the two parts divided by the path of the twinning dislocation shift each

other by b on an average, the vector sum of the shuffles diminishes to zero.

Now, the i th lattice site is denoted by $R_i = m\mathbf{a}_1 + n\mathbf{a}_2 + p\mathbf{a}_3$, where $\mathbf{a}_1$, $\mathbf{a}_2$ and $\mathbf{a}_3$ are primary lattice vectors. If atoms at the origin (000) as well as at $(m_0n_0p_0)$ undergo the same movement U , so that the atom at $(m_0n_0p_0)$ comes to the twin origin (0'0'0') and the atom at (000) comes to $(m'_0n'_0p'_0)$ of the twin lattice, we may have

$$m_0 = m'_0, \quad n_0 = n'_0, \quad p_0 = p'_0, \quad (1)$$

where $(m_0n_0p_0)$ belongs to the same Bravais lattice as (000). By Eq. (6) in the previous paper, $[m_0n_0p_0]$ is equal to η_2 .

The atom movements are conveniently investigated in the modified lattice in which the twin shear magnitude or b of the twin dislocation diminishes to zero. Using the above assumptions, it can be determined how apart $(m_0n_0p_0)$ is from (000). Twin planes are classified into three types as follows:

Type I: All atom movements are equal to b and shuffles are zero.

Type II: There are two atom movements, $U_{\perp}$, in which shuffles are perpendicular to the twin plane, which are of the same magnitude but opposite to each other.

Type III: In addition to Type II, there are two more atom movements, $U_{\parallel}$, in which shuffles are parallel to the twin plane, so that the number of the atom movements is four in all*.

* Type I corresponds to the homogeneous shear in Jaswon and Dove's treatment, while Types II and III correspond respectively to Y and X modes of the semi-homogeneous shear.

Based upon this method, mechanical twins of Ti and α -U are examined, and to this end it becomes necessary that more atom movements are to be allowed.

§ 2. General Treatment

In the previous paper, it was considered that when the distances between (hkl) planes parallel to a twin plane are all equal, each plane is quite equivalent as for the atom movement, and the atom movement is only of one kind (Type I). As will be shown below, the observed twin planes of Ti and Zr come under this case, but in applying the atom movement of Type I, the assumption II is not satisfied. Thus, also in the case where the distances between (hkl) planes are all equal in a multiple lattice, the twinning is allowed to have a few atom movements (i.e., Type II or III). Then, in the case in which $f=1/2$ is contained in Type II, while the case in which $f=0$ or $f=1/2$ is contained in Type III, fd being the minor fractional distance between (hkl) planes.

Types IV. In the above treatment, the number of atom movements is only four. But, twinning types having more movements are possible geometrically and one way to obtain them stepwise is as follows.

If, in Type II, there is $(m_f n_f p_f)$, nearer to $(0'0'0')$ than $(m_0 n_0 p_0)$, on the (hkl) plane apart from $(m_0 n_0 p_0)$ by fd , this Type II is converted

to Type III by the assumption II. Again, similarly, when, in Type III, $(m_g n_g p_g)$ is on the (hkl) plane apart from $(m_0 n_0 p_0)$ by fd , it happens that

$$|T_g + b| < |U_\perp|, \quad (2)$$

where $U_\perp$ and $T_g + b$ are respectively the displacements from $(m_0 n_0 p_0)$ and $(m_g n_g p_g)$ to $(0'0'0')$, and T_g is the component of R_g parallel to the (hkl) plane. Then, an atom at $(m_g n_g p_g)$, instead of that at $(m_0 n_0 p_0)$, should come to $(0'0'0')$. Since $(m_g n_g p_g)$ does not belong to the same Bravais lattice as (000) , $(m_g n_g p_g)$ does not take the same atom movement U as that of (000) and the new $(m_0 n_0 p_0)$ lies on the sixth double plane. Then, if N denotes a unit vector normal to the twin plane, we have, as shown in Fig. 1,

$$\left. \begin{aligned} U_\perp &= b \pm fdN, \\ U_{||} &= b \pm (T_f + b), \\ U_{||}' &= b \pm (T_g + 2b), \\ b &= -T_0/3. \end{aligned} \right\} \quad (3)^*$$

Here, when $(m_0 n_0 p_0)$ on the sixth double plane is not the nearest neighbour to $(0'0'0')$, the atom movement U of $(m_0 n_0 p_0)$ is not equal to U of (000) as in the above and Type IV is converted to another type, and so on. However, the twin origin $(0'0'0')$, to which an atom at $(m_0 n_0 p_0)$ comes, has the mirror-image relation with the matrix origin (000) , so that it is not likely that $(m_0 n_0 p_0)$ is far distant from (000) . Thus, only Type IV is taken up in addition to Types I, II and III.

When $(m_f n_f p_f)$ or $(m_g n_g p_g)$ does not lie on the plane apart from $(m_0 n_0 p_0)$ by fd , the atom movements are not of the above types, but are rather complex. However, these can be obtained similarly.

Reciprocal twin. The modified lattices of a twin and its reciprocal one are identical with each other and the atom movement of the latter is similar to the former, excepting the case where the assumption II does not hold for the reciprocal twin, because their shear directions are perpendicular to each other. A pair of $\{hkl\}$ planes of the same magnitude

Fig. 1. The atom movement of Type IV. ($f=0$)

* b is reasonably the smallest one and does not always mean the Burgers vector of a real twin dislocation, because it is possible for dislocations of b to be combined, in consequence of alternative appearance of the different structures of the twin boundary.

as shown in Fig. 2 are reciprocal to each other, while the reciprocal of a single {hkl} plane in it is the {hkl} plane itself, or it cannot exist.

§ 3. Applications

Case of Ti and Zr

The mechanical twins in Ti (h.c.p.) were reported by C. J. McHargue and J. P. Hammond³⁾, J. D. Rosi et al.⁴⁾, and A. T. Churchman⁵⁾, while those in Zr (h.c.p.) were reported by E. J. Rapperport⁶⁾. The observed twins are {10 $\bar{1}2$ }, {11 $\bar{2}1$ }, {11 $\bar{2}2$ }, {11 $\bar{2}3$ } and {11 $\bar{2}4$ }. These, except for {10 $\bar{1}2$ }, are not contained in Table V in the previous paper*.

Table I. Twin elements in Ti and Zr
(r_0 being the distance between the nearest neighbours)

K_1	K_2	η_1	η_2	S	b/r_0	Type
{10 $\bar{1}2$ }	{10 $\bar{1}2$ }	[$\bar{1}011$]	[10 $\bar{1}1$]	0.175	0.10	III
{11 $\bar{2}1$ }	{0001}	[$\bar{1}126$]	[11 $\bar{2}0$]	0.630	0.31	II
{11 $\bar{2}2$ }	{11 $\bar{2}4$ }	[11 $\bar{2}3$]	[22 $\bar{4}3$]	0.218	0.094	IV
{11 $\bar{2}3$ }†	...	...	...	...	...	...
{11 $\bar{2}4$ }	{11 $\bar{2}2$ }	[22 $\bar{4}3$]	[11 $\bar{2}3$]	0.218	0.069	IV

† When another complex type of the atom movement is considered, the elements of {11 $\bar{2}3$ } twin, for which the assumption II holds, are K_1 =({11 $\bar{2}3$ }), K_2 =({11 $\bar{2}2$ }), η_1 =([11 $\bar{2}2$]), η_2 =([11 $\bar{2}3$]) and S =0.514, and its reciprocal twin cannot exist.

* K_1 =({112}), K_2 =({30 $\bar{2}$ }) in Table V in the previous paper must be abandoned, because ($m_0 n_0 p_0$) does not belong to the same Bravais lattice as (000).

The twin elements as determined by the above method are given in Table I and the geometrically possible twins are shown in Fig. 2. The {11 $\bar{2}3$ } twin rarely observed cannot twin and is exceptional in the present treatment. The {11 $\bar{2}2$ } and {11 $\bar{2}4$ } twins are reciprocal to each other, in contradiction to E. O. Hall's results that both of these twins are reciprocal to themselves respectively. It may be thought that the former is more liable to twin, since its shear magnitude S is smaller.

Next, the twin elements determine the stress in favour of twinning. Since the values of η_1 of {11 $\bar{2}4$ } are [22 $\bar{4}3$] and [$\bar{2}243$] respectively, they have different orientation dependence: the {11 $\bar{2}4$ } twin having η_1 =[22 $\bar{4}3$] is operative in the case where the axis of extension is nearly parallel to the basal plane, while the {11 $\bar{2}4$ } twin having η_1 =[$\bar{2}243$] is operative in the case where the said axis is nearly perpendicular to the basal plane. Referring to the experimental result⁴⁾, which shows the {11 $\bar{2}4$ } twin for extension of {11 $\bar{2}0$ } pole, the former may be profitable for twin element, in spite of the absence of direct determination of twin element by measuring the tilt of twin surface. Elements of the {11 $\bar{2}1$ } twin coincide for both treatments, and do not contradict to the observed orientation to twin⁴⁾. Experimental data about the orientation dependence of the {11 $\bar{2}2$ } twin are not only scanty but also scattered^{3,4,5)}, so that they are not sufficient to discuss its reciprocity to {11 $\bar{2}4$ }.

Case of α-U.

As already pointed out by many authors, the crystal structure of α-U resembles to that of h.c.p., so that probable twin planes is α-U also resemble to those in h.c.p. However, the difference of the crystal structure reveals that, as shown in Fig. 2, the order of shear magnitude S of some planes does not agree with each other. The results for the twin elements of {130}, {112} and '{172}' agree with those of Cahn⁸⁾ and Hall⁷⁾, while the results for the twin elements of '{176}' agree with Lloyd and Chiswick's results⁹⁾. Our results agree also with those obtained by Jaswon and Dove in their recent paper¹⁰⁾. However, the {121} twin as reported by Cahn, which was not observed by Lloyd and Chiswick, is not conceivable in the present treatment.

It was pointed out in the previous paper that the observed twins have the smallest S in order. Such a result holds also in the cases of α -U and Ti, and, as shown in Fig. 2, the shear S of the observed twins is small enough. However, the twinning is not so simple that the present crystallographic analysis cannot be considered to be conclusive, and probably the dislocation theory of twin nucleation and the evaluation of the energy of the twin boundary should be necessary for the complete explanation of the twin phenomena.

In conclusion, the author expresses his cordial thanks to Professor Kenzo Tanaka, University of Kyōto, for his encouragement and discussions. The author is also indebted to Mr. Saiyu Maruyama, Osaka Women's University, for his useful discussions.

Ferroelectricity of NaNH_4 -Tartrate

By Yutaka TAKAGI and Yasuharu MAKITA

Tokyo Institute of Technology, Oh-okayama, Tokyo

(Received December 6, 1957)

Below the transition point 109°K a crystal plate of NaNH_4 -tartrate shows a domain structure under a polarizing microscope if viewed in the direction parallel to the b axis. The polarization in each domain lies parallel to $+b$ or $-b$ axis, and can be reversed by shearing stress. The spontaneous polarization is $0.21\mu\text{Coul/cm}^2$ at 92°K and it is probably constant below the transition temperature.

§ 1. Introduction

As known well NaNH_4 -tartrate and its isomorph NaK -tartrate can form a continuous series of solution. The series were investigated first by Kurtschatow *et al.*¹⁾ and afterward by Melmed *et al.*²⁾. Substitution of very small amount of NaNH_4 -tartrate reduces the temperature range of ferroelectric activity in NaK -tartrate very rapidly. Substitution of about two per cent eliminates the spontaneous polarization entirely. The ferroelectric activity, however, reappears in the crystals containing more than about eighteen per cent of NaNH_4 -tartrate. These mixed crystals show a single Curie point at low temperatures, the

exact position of the transition depending upon the concentration. The Curie point-composition curve goes down linearly from about twenty per cent to about sixty per cent and then bends downward steeply at about eighty per cent. NaNH_4 -tartrate thus seems to have no Curie point or, if any, one at extremely low temperature. In fact, Kurtschatow *et al.* reported that NaNH_4 -tartrate did not reveal any dielectric anomaly from room temperature down to 83°K .

However, Jona and Pepinsky³⁾ have recently found that NaNH_4 -tartrate shows a small anomaly in the dielectric constants at 109°K , so small that there is no wonder why Kurt-

schatow *et al.* overlooked it. The anomaly was detected along its three crystallographic principal axes. The Curie-Weiss law does not hold in any of these axes. The dc biasing field of 10 Kv/cm super-imposed on an ac field of 10 v/cm does not change the value of dielectric constant. All these characters are very peculiar if compared with the well established properties of the NaK-tartrate and of the mixed ferroelectric crystals derived from them. Hoping to make clear the nature of the above mentioned transition in $\text{NaNH}_4\text{-tartrate}$, we have made a pyroelectric test of this crystal along its three principal axes and found that this crystal yields a pyroelectric charge along its crystallographic b axis. The details will be given in the following sections.

§ 2. Pyroelectric Study

Pyroelectric charge developed on the crystal surface during the temperature variation through the transition point has been measured by means of a Shimizu type electrometer⁴⁾. The sensitivity of about 5×10^{-11} Coul/division can easily be attained by this device.

Fig. 1. Pyroelectric charge developed on the crystal surface cut perpendicularly to the b axis.

It has been observed that an electric charge occurs abruptly on the crystal surface cut perpendicularly to the b axis just when the crystal passes through the transition point. The charge remains constant below the transition point. One example is shown in Fig. 1. The amount of the charge turned out to be different from specimen to specimen, covering the range 2.5 to 15×10^{-10} Coul/cm². Moreover the charge developed on the same surface of the same specimen varied after various treatments. The effect of field cooling is clearly demonstrated in Fig. 2. Prior to each run of the measurements, the specimen was

cooled from 118°K to 85°K under various dc field strength. At 85°K the electrodes were short-circuited for a few seconds and then immediately connected to the electrometer. Then the temperature was raised very slowly.

The figures beside each curve denote the dc field strength. Plus or minus sign means that the field was applied in the direction parallel or inverse to the sign of the charge observed in the virgin state. The figures in the circles denote the order of experiments.

Fig. 2. Effect of field cooling on the pyroelectric charge. The number enclosed in the circle denotes the order of the experiment. The figures beside each curve denote the field strength under which the crystal was cooled from 118° to 85°K.

The diversity of the amount of charge suggests strongly that the crystal is made up of many tiny domains, each being polarized parallel to the $+b$ or the $-b$ direction. It is to be noted, moreover, that the crystal has a self bias; a slightly positive charge was observed in the second run even after a strong negative field had been applied throughout the cooling period. The specimens cut perpendicularly to the a or the c axis did not show any trace of pyroelectricity at their passage through the transition point.

§ 3. Observation of Domain Structure

Above the transition point $\text{NaNH}_4\text{-tartrate}$ belongs to the orthorhombic symmetry class $P2_12_12$ and is therefore optically biaxial. The acute bisectrix is the c axis, the plane of the optic axes is (100) plane, and the crystal is optically negative. This fixes the position of the indicatrix with respect to the crystallographic axes:

$$a_{\text{ortho}}=Y, b_{\text{ortho}}=Z, c_{\text{ortho}}=X,$$

where X , Y and Z are the indicatrix axes. A b -plate therefore shows straight extinction, and the extinction positions correspond to the axes X and Y of the indicatrix.

If it is true that the crystal below the transition point polarizes spontaneously in the direction of the orthorhombic b axis, the symmetry must become monoclinic $P2_1$ owing to the spontaneous shear strain z_x° . This means that in a single domain crystal one of the monoclinic axes deviates from the original orthorhombic axis by an angle equal to z_x° . Of course this angle itself may be very small, but it is probable, as is so in the case of Rochelle salt, that the indicatrix axes rotates by an angle far larger than z_x° , for neither X nor Y is required to coincide with the monoclinic c or a axis. Only one condition necessary for this crystal symmetry is the coincidence of the b_{mono} axis with Z_{mono} (Fig.

Fig. 3. The relation between the crystallographic axes and the optical indicatrix axes (schematic). Left, Orthorhombic phase; Right, Monoclinic phase.

Fig. 4. The angle between the extinction positions of neighboring domains.

3). If the angle between the c_{mono} axis and the X_{mono} axis happens to be sufficiently large, the domains will be observed through a polarizing microscope, if viewed in the direction parallel to the b axis (Fig. 3).

Fortunately this turned out to be the case. Parallel stripes with alternately bright and dark appearance were actually observed if the b plate was kept below the transition temperature. The stripes were long in the direction of the c axis, and the width of them was about a few hundred microns. The angle between the extinction positions of the neighboring domains is constant below the transition point (Fig. 4).

§ 4. Hysteresis Curve Induced by Shearing Stress

We tried many times in vain to get the electric displacement *vs.* electric field hysteresis loops characteristic of normal ferroelectric crystals, though all the evidences thus far obtained indicate unambiguously that there exists spontaneous polarization along the b axis below the transition point of $\text{NaNH}_4\text{-tartrate}$. The D - E relation was linear up to the maximum electric field of 20Kv/cm which we could apply without destroying the crystal.

There remains however another way of influencing the polarization, for the crystal is strongly piezoelectric. The shear stress Z_x can as well affect the electric polarization as the electric field can. We made a 45° -cut of the crystal of which one edge bisects the a and the c axes and thickness of the plate lies along the b axis. The slab was set between the cross nicols of a polarizing microscope, and a normal stress P was applied on one pair of narrow surfaces. The result of observation is shown in Fig. 5. As the stress is increased, the fractional area of bright stripes decreases, until the whole area becomes dark at the pressure of about 95 Kg/cm². As the stress is reduced, bright stripes reappear in most cases, but in a few cases the crystal remains dark even after the external stress is completely removed. The fractional decrease of bright stripes roughly estimated from two sets of photographs is shown in Fig. 6.

If these stripes really represent the $+b$ or the $-b$ domains, the cycle of the area frac-

Fig. 5. Photographs showing the effect of shearing stress. (at 98.4°K).
a: Pressure=0, b: Pressure=62.5 Kg/cm², c: Pressure=98.7 Kg/cm².

tion such as shown in Fig. 6 should be accompanied by a cycle of the net polarization of the crystal slab. It turned out to be the case as shown in Fig. 7. The stress was increased and decreased step by step and the charge developed on the crystal surface was measured by the electrometer. Each pair of points connected by a short vertical line shows

the value of charge immediately after the respective stress was applied and the value of charge when the electrometer deflection attained a steady value after a few minutes had elapsed under the constant stress. As known well in NaK-tartrate, we have here also the two components of electric polarization, one of which responds very slowly. It took 44 minutes to perform the stress cycle shown in the figure.

Fig. 6. Decrease in bright area *vs.* mechanical stress. Circles: at 98.4°K, Triangles: at 96.0°K, Hollow marks: for increasing stress. Solid marks: for decreasing stress.

Fig. 7. Polarization *vs.* mechanical stress. Circles: at 92°K. Squares: at 126°K. Hollow marks: for increasing stress. Solid marks: for decreasing stress.

The same experiment was carried out at 126°K, above the transition point. The coincidence within the limit of accuracy of the measurements of the back and forth branches obtained in the stress cycle which took as long a time as 26 minutes assures that there is no appreciable leakage of electricity through the specimen and the measuring apparatus. The large hysteresis observed at 92°K is, therefore, a real effect due to the domain re-orientations. The spontaneous polarization estimated from this curve is 21×10^{-8} Coul/cm². The spontaneous polarization may perhaps be temperature independent as the pyroelectric charge remains constant below the transition point.

§ 5. Discussion and Conclusion

As is generally accepted, the mere existence of a spontaneous polarization is by itself insufficient to justify one in calling a certain crystal ferroelectric. Besides, we must have at least one way of reversing the direction of the spontaneous polarization. Of course the ferroelectricity is usually tested by applying the electric field, but in a wider sense of terminology the ferroelectricity may be tested by any means which can affect the electrical polarization. We feel, therefore, we are justified to call NaNH₄tartrate a ferroelectric crystal with its spontaneous polarization along

through the piezoelectric constant d_{25} and the dielectric susceptibility κ_2 . But the maximum stress at which the crystal breaks mechanically does not necessarily coincide with the maximum field strength at which the crystal breaks down electrically. There is, at least in a fortunate case, a possibility to give a stronger influence by mechanical means than by electrical means without destroying the specimen. After the experiment performed along this line proved to be successful, we came to realize that our original idea was an over-simplification. In fact, if translated into the electric field necessary to induce the same polarization, the pressure of about 100 Kg/cm² on a 45°-cut slab should be equivalent to the electric field of about 14 Kv/cm, far less than the maximum amplitude which we applied of 20 Kv/cm. The situation must be analysed in more details.

We have for a piezoelectric crystal the equations,

$$\begin{aligned} Z_x &= c_{55}Z_x + f_{25}P_y \\ E &= f_{25}Z_x + \chi_2 P_y \end{aligned}$$

We need therefore a plane to represent a given state of the crystal since there are two independent variables. For the electric field experiment, we have the solutions

$$Z_x = 0, \quad Z_x = -\frac{f_{25}}{c_{55}}P_y,$$

Fig. 8. Dielectric constants in the direction of three crystallographic axes.

the b axis, in spite of its very peculiar behaviors as compared with other normal ferroelectrics. The most striking feature from the theoretical point of view is surely the failure of the Curie-Weiss law above the transition point (Fig. 8).

When we took up the stress experiment we were led by the following reasoning. The shear stress is related with the electric field

Fig. 9. The two different paths on which the crystal proceeds. a: the electric field experiment, b: the shearing stress experiment. The curves are obtained by using the Mason's values⁷⁾: $d_{25} = -95.0 \times 10^{-8}$ e.s.u., $s_{55} = 33 \times 10^{-12}$ c.g.s., $\epsilon_y = 8.9$.

and

$$E_y = \left(\chi_2 - \frac{f_{25}}{c_{55}} \right) P_y,$$

and similarly for the stress experiment, we have the solutions

$$E_y = 0, \quad z_x = -\frac{\chi_2}{f_{25}} P_y,$$

and

$$Z_x = \left(f_{25} - \frac{c_{55}\chi_2}{f_{25}} \right) P_y.$$

As clearly shown by the second relations of the above two sets of solutions, the crystal proceeds on the different paths in the above two experiments (Fig. 9). That is, if we had translated into the electric field necessary to produce the same strain, instead of polarization, the same pressure of about 100 Kg/cm² should have been found equivalent to an electric field of about 500 Kv/cm. This situation may be the reason why we have observed different coercivities.

It is of some interest to note here that, below their transition points, $\text{LiNH}_4\text{-tartrate monohydrate}^{6)}$ has its spontaneous polarization

along the b axis while $\text{LiTi-tartrate monohydrate}^{6)}$ has its spontaneous polarization along the a axis, though they are isomorphous above the transition temperature.

Finally we wish to thank Professor H. Takahasi for his invaluable advice and Mr. H. Maniwa for his helpfull discussions. This work was partly supported by the Scientific Research Fund of the Ministry of Education.

On the Temperature Diffuse Scattering of Electrons

I. Derivation of General Formulae

By Satio TAKAGI

*Institute of Physics, College of General Education,
University of Tokyo
Komaba, Meguro-ku, Tokyo*

(Received September 7, 1957)

The perturbation theory of the temperature diffuse scattering of electrons is presented taking account of the fact that each of the primary and secondary waves in the crystal consists of many plane waves. Formulae for the intensity of the diffuse scattering from a monatomic crystal forming a primitive lattice are obtained for each of the perturbation potentials due to Bloch and to Nordheim. When each of the primary and secondary waves does not excite any Bragg reflexions and can be given by a plane wave, the Nordheim potential gives the same result and the Bloch potential gives practically the same result as that of the current X-ray diffraction theory applied to electron diffraction. The result may be applied to explain the formation of the Kikuchi pattern by the temperature diffuse scattering and the anomalous intensity variation of the diffuse spot from some single crystals.

§ 1. Introduction

According to the dynamical theory of electron diffraction developed by Bethe,¹⁾ the position of diffraction spots formed by reflexion from a perfectly smooth surface of a stationary crystal is determined completely by the surface lattice of the crystal. Miyake, Kohra and Takagi²⁾ have pointed out that circular arrays of sharp spots which appear in the reflexion patterns from cleavage faces of crystals (Fig. 1, a, b) arise from this dynamical effect, although previously several authors ascribed them to the two-dimensional diffraction from uppermost layer of the crystal on account of strong absorption of electrons.³⁾⁴⁾⁶⁾

Besides these sharp spots there appear

Fig. 1. (a)

Fig. 1. (b).

Fig. 1. (a) Electron diffraction pattern from a cleavage face of zincblende. Incident beam, nearly parallel to [111]. (b) The sketch of the pattern. Broken circles indicate that the sharp spots lie on circles. Small hatched circles show the diffuse spots.

actually a number of diffuse spots at positions which are approximately in accordance with the conditions of ordinary three-dimensional diffraction. Co-existence of diffuse spots and arrays of sharp spots is observed on many kinds of crystals and is regarded as a general phenomenon not peculiar to a particular kind of crystal. As the reflexion pattern from a smooth surface of a perfect crystal should be composed of only these arrays of spots

besides the patterns resulting from the secondary scattering such as Kikuchi patterns, the origin of the diffuse spots may be attributed to some kinds of lattice distortion. Miyake⁶⁾ has pointed out that they may be the temperature diffuse scattering.

The present paper treats the theory of the temperature diffuse scattering taking account of the dynamical effects. There are some experimental evidence that Kikuchi patterns, which are believed to be due to the inelastic collision of an electron with lattice electrons⁷⁾⁸⁾⁹⁾, may be partly attributable to the temperature scattering. According to the investigations of Watanabe¹⁰⁾ and Hashimoto, Yoda and Maeda,¹¹⁾ the energy spectrum of Kikuchi patterns contained parts corresponding to electrons with energy loss of less than 1~2 eV. They have pointed out that these electrons cannot be considered as ones inelastically scattered.* The theory of the temperature diffuse scattering may also be necessary for the detailed explanation of Kikuchi patterns.

§ 2. Basic Formulation of the Theory

The quantum mechanical theory of the temperature diffuse scattering of X-rays was developed by Born and Sarginson¹²⁾ and Born¹³⁾. The result is practically the same as that of the classical theories of Waller¹⁴⁾, Laval¹⁵⁾ and James.¹⁶⁾ In these theories each of the incident and thermally scattered waves is assumed to be a single plane wave. So far as this assumption holds, the result of the theory can also be applied to the case of electron diffraction with appropriate substitution of the atomic scattering factor. When dynamical effects are observed, however, many plane waves having wave vectors related by

$$\mathbf{k}_h = \mathbf{k}_0 + \mathbf{b}_h \quad (1)$$

are excited with a definite phase relationship, where $\mathbf{k}_h$ and $\mathbf{k}_0$ are wave vectors and $\mathbf{b}_h$ is a reciprocal lattice vector. These co-existing waves should be taken into account.

A solution of the Schrödinger equation for an electron in a periodic potential is given by a Bloch function

$$\psi_{\mathbf{k}} = \frac{1}{\sqrt{\Omega}} \sum_{\mathbf{h}} c_{\mathbf{k},\mathbf{h}} \exp(2\pi i \mathbf{k}_h \cdot \mathbf{r}), \quad (2)$$

where Ω is the volume of the crystal and the summation is over all the reciprocal lattice points. For convenience, $c_{\mathbf{k},\mathbf{h}}$ is normalized in the whole crystal, i.e.

$$\sum_{\mathbf{h}} |c_{\mathbf{k},\mathbf{h}}|^2 = 1. \quad (3)$$

Putting (2) into the Schrödinger equation, we obtain an infinite set of linear homogeneous equations or the fundamental equations of the dynamical theory.⁷⁾⁸⁾¹⁷⁾ In practical calculations, only a finite number of component wave with appreciable amplitude are considered, so that the number of equations becomes finite. Possible values of $\mathbf{k}_0$ are obtained by solving the secular equation and are designated by $\mathbf{k}_0^{(i)}$. The wave field in the crystal is expressed by a linear combination of (2).

$$\psi_c = \frac{1}{\sqrt{\Omega}} \sum_i \alpha_i \sum_{\mathbf{h}} c_{\mathbf{k},\mathbf{h}} \exp(2\pi i \mathbf{k}_r^{(i)} \cdot \mathbf{r}) \quad (4)$$

which satisfies appropriate boundary conditions. Each of the vacuum waves outside the crystal has a wave vector with tangential component coinciding with that of one of the component waves in (4). These vacuum waves are the only waves observed so long as the atoms are at rest. However, when the crystal is set in thermal motions, the electron in the state (4) will make transitions to other states. The vacuum waves having the tangential component of the wave vectors corresponding to the end states constitute the temperature diffuse scattering.

§ 3. Interaction Between an Electron and Lattice Vibrations

In the ordinary perturbation theory of the interaction between an electron and lattice vibrations, the perturbation potential is assumed to be the difference between the potential energy of an electron in the vibrating crystal $V(\mathbf{r})$ and that in the stationary crystal $V_s(\mathbf{r})$ ¹⁸⁾. However, a better approximation will be obtained by replacing $V_s(\mathbf{r})$ with the time average of $V(\mathbf{r})$, so that the perturbation potential $U(\mathbf{r})$ is put as

$$U(\mathbf{r}) = V(\mathbf{r}) - \langle V(\mathbf{r}) \rangle, \quad (5)$$

where $\langle \rangle$ means the time average.

There are several methods of getting $V(\mathbf{r})$. One, originally due to Bloch,¹⁹⁾ assumes

$$V(\mathbf{r}) = V_s(\mathbf{r} - \mathbf{u}(\mathbf{r})), \quad (6)$$

* In this paper the term "inelastic scattering" means the scattering accompanied by a change in the electronic state of the scatterer.

where $\mathbf{u}(\mathbf{r})$ is a continuous function whose value at the position of an atom describes the displacement of the atom as the result of lattice vibration. Another, due to Nordheim,²⁰⁾ replaces (6) with

$$V(\mathbf{r}) = \sum_n v_n(\mathbf{r} - (\mathbf{r}_n + \mathbf{u}_n)), \quad (7)$$

where $v_n(\mathbf{r})$ signifies the contribution of the n th atom to the potential energy of an electron at distance $\mathbf{r}$ from the centre of the atom, and $\mathbf{r}_n$ and $\mathbf{u}_n$, the mean position and the displacement of the atom, respectively. As it is not easy to decide which of the approximations is more appropriate for the present purpose, we shall first adopt (6) which is simpler and treat (7) in the appendix.

$V_s(\mathbf{r})$ can be expanded in a three-dimen-

sional Fourier series

$$V_s(\mathbf{r}) = \sum_g V_g \exp(2\pi i \mathbf{b}_g \cdot \mathbf{r}), \quad (8)$$

where $\mathbf{b}_g$ is the reciprocal lattice vector. Substituting (8) into (6) and using the relation¹²⁾²¹⁾

$$\langle \exp(2\pi i \mathbf{b}_g \cdot \mathbf{u}) \rangle = \exp(-2\pi^2 \langle (\mathbf{b}_g \cdot \mathbf{u})^2 \rangle),$$

we obtain

$$\langle V(\mathbf{r}) \rangle = \sum_g V_g' \exp(2\pi i \mathbf{b}_g \cdot \mathbf{r}), \quad (9)$$

where

$$V_g' = V_g \exp(-M), \quad (10)$$

and M is the Debye temperature factor given by

$$M = 2\pi^2 \langle (\mathbf{b}_g \cdot \mathbf{u})^2 \rangle = 2\pi^2 |\mathbf{b}_g|^2 \langle u_g^2 \rangle, \quad (11)$$

u_g being the component of $\mathbf{u}$ along $\mathbf{b}_g$. Thus we obtain as the first approximation

$$\begin{aligned} U(\mathbf{r}) &= \sum_g V_g' \exp(2\pi i \mathbf{b}_g \cdot \mathbf{r}) [\exp(-2\pi i \mathbf{b}_g \cdot \mathbf{u} + 2\pi^2 \langle (\mathbf{b}_g \cdot \mathbf{u})^2 \rangle) - 1] \\ &= -2\pi i \sum_g (\mathbf{b}_g \cdot \mathbf{u}) V_g' \exp(2\pi i \mathbf{b}_g \cdot \mathbf{r})^* \end{aligned} \quad (12)$$

$$= -(\mathbf{u} \cdot \text{grad} \langle V(\mathbf{r}) \rangle). \quad (12')$$

§ 4. The Transition Probability

For the sake of simplicity, let us assume a monatomic crystal composed of N unit cells, each of which contains only one atom. The displacement of an atom $\mathbf{u}_n$ can be expressed by the normal coordinate as¹⁸⁾

$$\mathbf{u}_n = \frac{1}{\sqrt{m_a N}} \sum_{\mathbf{q}, t} \mathbf{e}_{\mathbf{q}, t} \{a_{\mathbf{q}, t} \exp(2\pi i \mathbf{q} \cdot \mathbf{r}_n) + a_{\mathbf{q}, t}^* \exp(-2\pi i \mathbf{q} \cdot \mathbf{r}_n)\}, \quad (13)$$

where m_a is the mass of the atom, $\mathbf{q}$, the wave vector of a lattice wave, $t (=1, 2, 3)$ distinguishes directions of polarizations, $\mathbf{e}_{\mathbf{q}, t}$, a polarization vector for the mode $(\mathbf{q}, t)$ and $a_{\mathbf{q}, t}$, the normal coordinate. The magnitude of $\mathbf{q}$ is restricted within the first Brillouin zone. Substituting (13) into (12), we get

$$U(\mathbf{r}) = -\frac{2\pi i}{\sqrt{m_a N}} \sum_{\mathbf{q}, t} V_t' \exp(2\pi i (\mathbf{b}_t + \mathbf{q}) \cdot \mathbf{r}) \{a_{\mathbf{q}, t} \exp(2\pi i (\mathbf{b}_t + \mathbf{q}) \cdot \mathbf{r}) + a_{\mathbf{q}, t}^* \exp(2\pi i (\mathbf{b}_t - \mathbf{q}) \cdot \mathbf{r})\}, \quad (14)$$

where $(\mathbf{b}_t)_{\mathbf{q}, t}$ is the component of $\mathbf{b}_t$ along $\mathbf{e}_{\mathbf{q}, t}$.

The Schrödinger equation for the unperturbed state of electrons is written as

$$\Delta \phi_k + \frac{8\pi^2 m}{h^2} (E_k - \langle V(\mathbf{r}) \rangle) \phi_k = 0, \quad (15)$$

where E_k , m and h have usual meanings and ϕ_k is given by the Bloch function (2). We now calculate the transition probability from the state $(\phi_k, N_{\mathbf{q}, t})$ to the state $(\phi_{k'}, N'_{\mathbf{q}, t})$ where $\mathbf{k}'$ signifies the wave number vector of the electron in the final state, $N_{\mathbf{q}, t}$ and $N'_{\mathbf{q}, t}$, the quantum numbers of the vibrational mode in the initial and final states, respectively. If only the first power term in $\mathbf{u}(\mathbf{r})$ is retained, the transition probability has non-zero value only when the quantum number of one vibrational mode changes by 1 or -1 , those of the other modes being constant. The matrix element of $U(\mathbf{r})$ is then written as

* Within the limit of the approximation (12), we can replace V_g' in (12) by V_g so that $\langle V(\mathbf{r}) \rangle$ in (12') by $V_s(\mathbf{r})$. We, however, adopt (12') in order to compare the result with that of X-ray diffraction theory. The adoption of $\langle V(\mathbf{r}) \rangle$ instead of $V_s(\mathbf{r})$ as the unperturbed potential in (5) is significant for the calculation of unperturbed wave functions.

$$\begin{aligned}
 & \langle \mathbf{k}', N'_{qt} | U(\mathbf{r}) | \mathbf{k}, N_{qt} \rangle \\
 &= \left\{ \begin{aligned} & -\frac{2\pi i}{\sqrt{m_a N}} \sum_l V_l'(\mathbf{b}_l)_{qt} \left\{ \int \psi_{\mathbf{k}'}^* \psi_{\mathbf{k}} \exp(2\pi i (\mathbf{b}_l + \mathbf{q}) \cdot \mathbf{r}) d\mathbf{r} \right\} \sqrt{\frac{h}{8\pi^2 \nu_t(\mathbf{q})}} N_{qt}, \\ & \text{when } N'_{qt} = N_{qt} - 1 \\ & -\frac{2\pi i}{\sqrt{m_a N}} \sum_l V_l'(\mathbf{b}_l)_{qt} \left\{ \int \psi_{\mathbf{k}'}^* \psi_{\mathbf{k}} \exp(2\pi i (\mathbf{b}_l - \mathbf{q}) \cdot \mathbf{r}) d\mathbf{r} \right\} \sqrt{\frac{h}{8\pi^2 \nu_t(\mathbf{q})}} (N_{qt} + 1), \\ & \text{when } N'_{qt} = N_{qt} + 1 \end{aligned} \right\} \quad (16)
 \end{aligned}$$

where $\nu_t(\mathbf{q})$ is the frequency of the mode $(\mathbf{q}, t)$. The integral in (16) which is over the whole crystal is given by

$$\begin{aligned}
 \int \psi_{\mathbf{k}'}^* \psi_{\mathbf{k}} \exp(2\pi i (\mathbf{b}_l \pm \mathbf{q}) \cdot \mathbf{r}) d\mathbf{r} &= \frac{1}{\Omega} \sum_{\mathbf{h}'} \sum_{\mathbf{h}} c_{\mathbf{k}'\mathbf{h}'}^* c_{\mathbf{kh}} \int \exp(2\pi i (-\mathbf{k}_0' + \mathbf{k}_0 - \mathbf{b}_{\mathbf{h}'} + \mathbf{b}_{\mathbf{h}} + \mathbf{b}_l \pm \mathbf{q}) \cdot \mathbf{r}) d\mathbf{r} \\
 &= \sum_{\mathbf{h}'} \sum_{\mathbf{h}} c_{\mathbf{k}'\mathbf{h}'}^* c_{\mathbf{kh}} \delta_{\mathbf{k}'_0, \mathbf{k}_0 + \mathbf{b}_g \pm \mathbf{q}},
 \end{aligned}$$

where $\mathbf{g} = -\mathbf{h}' + \mathbf{h} + \mathbf{l}$. When $\mathbf{k}_0'$ and $\mathbf{k}_0$ are given, the reciprocal lattice vector $\mathbf{b}_g$ which satisfies $\mathbf{k}_0' = \mathbf{k}_0 + \mathbf{b}_g \pm \mathbf{q}$ is uniquely determined, as the magnitude of $\mathbf{q}$ is restricted in the first Brillouin zone. So, in the summation over $\mathbf{l}$ in eq. (16), only a term remains which satisfies $\mathbf{l} = \mathbf{g} + \mathbf{h}' - \mathbf{h}$, and (16) becomes

$$\begin{aligned}
 & \langle \mathbf{k}', N'_{qt} | U(\mathbf{r}) | \mathbf{k}, N_{qt} \rangle \\
 &= \left\{ \begin{aligned} & -\frac{i}{\sqrt{m_a N}} \sqrt{\frac{h}{2\nu_t(\mathbf{q})}} N_{qt} \sum_{\mathbf{h}'} \sum_{\mathbf{h}} c_{\mathbf{k}'\mathbf{h}'}^* c_{\mathbf{hk}} (\mathbf{b}_{\mathbf{g}+\mathbf{h}'-\mathbf{h}})_{qt} V_{\mathbf{g}+\mathbf{h}'-\mathbf{h}}, \\ & \text{when } N'_{qt} = N_{qt} - 1 \text{ and } \mathbf{k}_0' = \mathbf{k}_0 + \mathbf{b}_g + \mathbf{q} \\ & -\frac{i}{\sqrt{m_a N}} \sqrt{\frac{h}{2\nu_t(\mathbf{q})}} (N_{qt} + 1) \sum_{\mathbf{h}'} \sum_{\mathbf{h}} c_{\mathbf{k}'\mathbf{h}'}^* c_{\mathbf{hk}} (\mathbf{b}_{\mathbf{g}+\mathbf{h}'-\mathbf{h}})_{qt} V'_{\mathbf{g}+\mathbf{h}'-\mathbf{h}}, \\ & \text{when } N'_{qt} = N_{qt} + 1 \text{ and } \mathbf{k}_0' = \mathbf{k}_0 + \mathbf{b}_g - \mathbf{q} \\ & 0 \text{ otherwise.} \end{aligned} \right\} \quad (17)
 \end{aligned}$$

The probability per unit time of the transition is then given by

$$\frac{1}{\hbar^2} |\langle \mathbf{k}', N'_{qt} | U(\mathbf{r}) | \mathbf{k}, N_{qt} \rangle|^2 \frac{\partial}{\partial t} \left(\frac{\sin \xi t}{\xi} \right)^2, \quad (18)$$

where

$$\xi = \frac{1}{2\hbar} \{ E_{\mathbf{k}'} - E_{\mathbf{k}} + (N'_{qt} - N_{qt}) \hbar \nu_t(\mathbf{q}) \},$$

$E_{\mathbf{k}}$ being the energy of electron in the state $\mathbf{k}$. Integrating (18) over the end states, as in the ordinary procedure,²²⁾ we get

$$\begin{aligned}
 & \frac{\Omega}{\hbar^2} d\omega |\langle \mathbf{k}', N'_{qt} | U(\mathbf{r}) | \mathbf{k}, N_{qt} \rangle|^2 \frac{\partial}{\partial t} \int_0^\infty \left(\frac{\sin \xi t}{\xi} \right)^2 k'^2 dk' \\
 &= \frac{2\pi\Omega}{\hbar} d\omega |\langle \mathbf{k}', N'_{qt} | U(\mathbf{r}) | \mathbf{k}, N_{qt} \rangle|^2 k'^2 \left/ \frac{\partial E_{\mathbf{k}'}}{\partial k'} \right. . \quad (19)
 \end{aligned}$$

We can assume, for fast electrons,

$$E_{\mathbf{k}'} = \frac{\hbar^2}{2m} k'^2.$$

The probability (19) then turns out to be

$$\frac{m\Omega k' d\omega}{2\pi\hbar^3} |\langle \mathbf{k}', N'_{qt} | U(\mathbf{r}) | \mathbf{k}, N_{qt} \rangle|^2.$$

Since $E_k \gg h\nu_t(\mathbf{q})$, the electrons scattered by the transitions

$$(\mathbf{k}, N_{\mathbf{qt}}) \longrightarrow (\mathbf{k} + \mathbf{b}_g + \mathbf{q}, N_{\mathbf{qt}} - 1)$$

and

$$(\mathbf{k}, N_{-\mathbf{qt}}) \longrightarrow (\mathbf{k} + \mathbf{b}_g - (-\mathbf{q}), N_{-\mathbf{qt}} + 1)$$

which differ in energy by the amount $2h\nu_t(\mathbf{q})$ can not be practically distinguished. Summing up for these two transitions and also for t , and considering that $\nu_t(\mathbf{q}) = \nu_t(-\mathbf{q})$ and $\langle N_{\mathbf{qt}} \rangle = \langle N_{-\mathbf{qt}} \rangle = \{\exp(h\nu_t(\mathbf{q})/kT) - 1\}^{-1}$, we obtain the transition probability per unit time $P_{\mathbf{k}', \mathbf{k}} d\omega$ for which the wave vector of the scattered electron lies in the solid angle $d\omega$ in the direction of $\mathbf{k}'$ as

$$\begin{aligned} P_{\mathbf{k}', \mathbf{k}} d\omega &= \frac{m\Omega}{2\pi\hbar^3} k' \frac{1}{m_a N} \sum_t \frac{h}{2\nu_t(\mathbf{q})} \{2\langle N_{\mathbf{qt}} \rangle + 1\} \left| \sum_{\mathbf{h}'} \sum_{\mathbf{h}} c_{\mathbf{k}'\mathbf{h}'}^* c_{\mathbf{k}\mathbf{h}} (\mathbf{b}_{\mathbf{g}+\mathbf{h}'-\mathbf{h}})_{\mathbf{qt}} V'_{\mathbf{g}+\mathbf{h}'-\mathbf{h}} \right|^2 d\omega \\ &= \frac{m\Omega_0}{\hbar^2 m_a} k' \sum_t \left| \sum_{\mathbf{h}'} \sum_{\mathbf{h}} c_{\mathbf{k}'\mathbf{h}'}^* c_{\mathbf{k}\mathbf{h}} (\mathbf{b}_{\mathbf{g}+\mathbf{h}'-\mathbf{h}})_{\mathbf{qt}} V'_{\mathbf{g}+\mathbf{h}'-\mathbf{h}} \right|^2 \frac{1}{\nu_t(\mathbf{q})} \left\{ \frac{1}{\exp(h\nu_t(\mathbf{q})/kT) - 1} + \frac{1}{2} \right\} d\omega, \end{aligned} \quad (20)$$

where $\Omega_0 \equiv \Omega/N$ is the volume of the unit cell.

§ 5. The Intensity Formulae for the Diffuse Scattering

Let us calculate the intensity of the diffuse scattering when the primary wave in the crystal is given by a single Bloch function (2). When the intensity of the incident electron is designated by J_0 , its density ρ is given by²³⁾

$$\rho = J_0/v = J_0 m/hK_0,$$

where v is the velocity of the incident electron and K_0 is its wave number in vacuum. In the calculation of the preceding section, the wave function of the primary wave is normalized in the whole crystal so that the electron density is $1/\Omega$. The intensity $J_{s, \mathbf{h}'}$ of the component plane wave of the secondary wave in vacuum having the wave vector $\mathbf{K}'_{\mathbf{h}'}$ is consequently given by

$$J_{s, \mathbf{h}'} = (P_{\mathbf{k}', \mathbf{k}} |c_{\mathbf{k}'\mathbf{h}'}|^2 / R^2) \{ (J_0 m/hK_0) / (1/\Omega) \} \tau \frac{d\omega}{d\omega_0} \quad (21)$$

where R is the distance from the crystal to the point of measurement, τ is the transmissivity of electrons at the exit surface, and $d\omega/d\omega_0$ indicate the effect of refraction at the exit surface, where the solid angle $d\omega$ of the secondary ray in crystal changes into $d\omega_0$ in vacuum on passing the surface, as shown schematically in Fig. 2. Substituting (20) into (21) and remembering that $k' \approx K$, we obtain

$$\begin{aligned} J_{s, \mathbf{h}'} &= \frac{J_0}{R^2} \frac{N}{m_a} |c_{\mathbf{k}'\mathbf{h}'}|^2 \sum_t \left| \sum_{\mathbf{h}'} \sum_{\mathbf{h}} c_{\mathbf{k}'\mathbf{h}'}^* c_{\mathbf{k}\mathbf{h}} (\mathbf{b}_{\mathbf{g}+\mathbf{h}'-\mathbf{h}})_{\mathbf{qt}} f'_{\mathbf{e}, \mathbf{g}+\mathbf{h}'-\mathbf{h}} \right|^2 \\ &\quad \times \frac{h}{\nu_t(\mathbf{q})} \left\{ \frac{1}{\exp(h\nu_t(\mathbf{q})/kT) - 1} + \frac{1}{2} \right\} \tau \frac{d\omega}{d\omega_0}, \end{aligned} \quad (22)$$

where

$$f'_{\mathbf{e}, \mathbf{h}} = f_{\mathbf{e}, \mathbf{h}} \exp(-M), \quad f_{\mathbf{e}, \mathbf{h}} = -\frac{m\Omega_0}{2\pi\hbar^2} V_{\mathbf{h}}. \quad (23)$$

If the electron distribution around each atom is the same as for free atoms, $V_{\mathbf{h}}$ is given by

$$V_{\mathbf{h}} = -e^2(Z - f_{x, \mathbf{h}}) / \pi\Omega_0 |\mathbf{b}_{\mathbf{h}}|^2, \quad (24)$$

where Z is the atomic number, $f_{x, \mathbf{h}}$, the atomic scattering factor for X-rays and e , the electronic charge. Putting (24) into (23), we get

$$f_{\mathbf{e}, \mathbf{h}} = \frac{2e^2 m}{\hbar^2 |\mathbf{b}_{\mathbf{h}}|^2} (Z - f_{x, \mathbf{h}}), \quad (25)$$

which states that f_e is the atomic scattering factor for electrons.

If Nordheim's potential (7) is assumed instead of Bloch's (6), we obtain following intensity formula of the temperature diffuse scattering (see Appendix).

$$J_{s,h'} = \frac{J_0}{R^2} \frac{N}{m_a} |c_{k'h'}|^2 \sum_i \left| \sum_{h'} \sum_h c_{kh'}^* c_{kh} (b_{g+h'-h} + q)_{qt} f'_e (b_{g+h'-h} + q) \right|^2 \times \frac{h}{\nu_i(q)} \left\{ \frac{1}{\exp(h\nu_i(q)/kT) - 1} + \frac{1}{2} \right\} \tau \frac{d\omega}{d\omega_0}. \quad (26)$$

Fig. 2. (a) Showing the effect of reflexion and refraction at the exit surface. (b) Illustrating the relation between $d\omega$ and $d\omega_0$ in terms of the dispersion surface. H is the reciprocal lattice point, d_1 and d_2 , two branches of the dispersion surface, S_H , a sphere of radius K_0 with H as centre. $\vec{AH}$ and $\vec{A'H}$ are the wave vectors of the crystal waves, $\vec{A_0H}$ and $\vec{A_0'H}$, those of the vacuum waves. $\vec{AA_0}$ and $\vec{A'A_0}$ are perpendicular to the surface.

The difference between (22) and (26) is that the reciprocal lattice vector $b_{g+h'-h}$ and the atomic scattering factor $f_{e,g+h'-h}$ in (22) is replaced by $b_{g+h'-h} + q$ and $f'_e(b_{g+h'-h} + q)$, respectively, in (26). The difference is unimportant when $|q|$ is negligible compared with $|b_{g+h'-h}|$.

In general, the primary wave in the crystal is given by the combination of Bloch functions (4) where $k_0^{(i)}$ ($i=1, 2, \dots$) has the same tangential component as that of the in-

Fig. 3. Showing the relation between the wave vectors of crystal, vacuum and lattice waves. b_h is the reciprocal lattice vector. K 's, k 's and q 's are the wave vectors of crystal, vacuum and lattice waves, respectively. Those with dash refer to the secondary or scattered waves, and without dash to primary or incident waves.

cident wave, and many Bloch functions with the wave vectors having the equal tangential component can be connected to a single vacuum wave $\exp(2\pi i K' \cdot r)$. So, in calculating the intensity of the vacuum wave, we should take account of many transitions $\phi_k^{(i)} \rightarrow \phi_k^{(j)}$ ($i, j=1, 2, \dots$). As these transitions are related to different modes of vibrations which are mutually independent, the intensity of the vacuum wave is given by the sum of the intensities of the component wave resulting from each of the transitions,

$$J_{s,h'} = \sum_i \sum_j |\alpha_i|^2 J_{s,h'}^{ij}, \quad (27)$$

where i and j are the suffices for Bloch functions in the primary and secondary waves, α_i is the coefficient of the component Bloch functions in the primary wave (4), and $J_{s,h^{ij}}$ is given by (22) with $\mathbf{q}$ replaced by $\mathbf{q}_{ij}$ which is given by

$$\mathbf{q}_{ij} = \mathbf{k}_0^{(j)} - \mathbf{k}_0^{(i)} - \mathbf{b}_g. \quad (28)$$

The relation between the wave vectors of crystal, vacuum and lattice waves is shown in Fig. 3, where the case that each of the primary and secondary waves is given by the sum of two Bloch functions and that $\mathbf{b}_g = 0$

is illustrated.

§ 6. Case of Plane Waves

When each of the primary and secondary waves in the crystal does not excite any Bragg reflexions, each wave is given by a single plane wave, i.e.

$$c_{\mathbf{k},\mathbf{h}} = \delta_{\mathbf{h},0} \quad \text{and} \quad c_{\mathbf{k}',\mathbf{h}'} = \delta_{\mathbf{h}',0}.$$

Let us further assume that the effect of reflexion and refraction at the exit surface can be neglected, i.e. $\tau d\omega/d\omega_0 = 1$. Then (26) becomes

$$J_{s,0} = \frac{J_0}{R^2} \frac{N}{m_a} \sum_i (\mathbf{b}_g + \mathbf{q})^2_{a,i} f'_{e,g}(\mathbf{b}_g + \mathbf{q}) \frac{h}{\nu_i(\mathbf{q})} \left\{ \frac{1}{\exp(h\nu_i(\mathbf{q})/kT) - 1} + \frac{1}{2} \right\},$$

$$J_{s,h'} = 0 \quad (\mathbf{h}' \neq 0). \quad (29)$$

This is exactly the same result as that of the current theory of the temperature diffuse scattering.¹⁰⁾ On the other hand, (22) gives

$$J_{s,0} = \frac{J_0}{R^2} \frac{N}{m_a} \sum_i (\mathbf{b}_g)^2_{a,i} f'_{e,g} \frac{h}{\nu_k(\mathbf{q})} \left\{ \frac{1}{\exp(h\nu_i(\mathbf{q})/kT) - 1} + \frac{1}{2} \right\},$$

$$J_{s,h'} = 0 \quad (\mathbf{h}' \neq 0). \quad (30)$$

which will be obtained by replacing $\mathbf{b}_g + \mathbf{q}$ and $f'_e(\mathbf{b}_g + \mathbf{q})$ in (29) by $\mathbf{b}_g$ and $f'_{e,g}$, respectively. This difference is caused by the adoption of different perturbation potentials. In Nordheim's method, it is assumed that each atom vibrate with the electron cloud rigidly fixed to the nucleus, as in the current theory.

§ 7. Discussions

In this paper we have treated the temperature diffuse scattering of electrons by the perturbation theory. The treatment is kinematical so far as the diffuse scattering is concerned, since we have neglected the double diffuse scattering. On the other hand, we have taken account of the Bragg reflexion by the dynamical theory. The influence of the Bragg reflexion on the temperature diffuse scattering may be important when the Bragg reflexion is much more intense than the diffuse scattering. Eq. (22) and (26) shows, however, that in general the intensity of the diffuse scattering is the same, at least in *order of magnitude* whether the primary or secondary waves in the crystal satisfies the Bragg condition or not. In the latter case which we have treated in the preseding section,

the ratio of the intensity of the diffuse scattering to that of the Bragg reflexion is the same as for X-rays for which, as is well known, this ratio is very small.

The diffuse scattering obtained in the present study is only the first order diffuse scattering produced by the emission or the absorption of one quantum of a vibrational mode. This result is obtained by the adoption of the perturbation potential (12) in which we have neglected the higher power terms in $u(\mathbf{r})$. If we take account of higher terms, we shall have higher order diffuse scatterings which result from the transitions accompanied by simultaneous emission or /and absorption of more than one quantum of vibrational modes, even if we neglect the double diffuse scattering. Higher order diffuse scattering of X-rays has been studied by Laval.¹⁶⁾ According to his result it is important at large scattering angles and at high temperatures.²⁴⁾ This may be also valid for electron diffraction.

It is worth noticing that there is a slight difference between the intensity formulae given by Nordheim's potential and by Bloch's potential. In the case of a single plane wave these formulae are given by (29) and (30). The iso-diffusion surfaces around a reciprocal

lattice point have centre of symmetry at the reciprocal lattice point for (30), but not for (29). Lack of centre of symmetry in the case of the X-ray diffuse scattering from sylvine has been demonstrated by Laval.²⁶⁾ It is possible to decide which of the perturbation potentials (6) or (7) is more appropriate for the present purpose by careful measurement of the intensity, provided that the relatively high background caused by the inelastical scattering and by the scattering at lattice imperfections could be eliminated. However, this elimination especially the elimination of the scattering at lattice imperfections may be difficult in the present stage of development. In this connection it must be noted that in detailed comparison of the calculated and measured intensities, the effect of weak waves must be taken into account which we have neglected in deriving (29) and (30).

We have assumed in this paper that the crystal is monatomic and a unit cell contains only one atom. When the unit cell contains more than one atom, a similar treatment holds for scatterings near a reciprocal lattice

point which constitute most part of the temperature scattering at low and moderate temperatures. Because for these scatterings for which long lattice waves are concerned the acoustical mode is significant, since the frequency of the acoustical mode is much smaller than that of the optical mode for long waves. The result in the preceding sections are valid for long acoustical waves, if we replace the mass of an atom by the mass of a unit cell, since for long waves atoms in a unit cell oscillate almost in phase.

Application of the present theory to some simple cases of practical importance will be given in the next paper.

The author wishes to express his thanks to Prof. S. Miyake for his valuable discussions. The work was partly supported by a research grant of the Ministry of Education.

Appendix

Intensity Formula Derived from Nordheims's Potential

If Nordheim's potential is assumed, the perturbation potential becomes

$$U(\mathbf{r}) = -2\pi i \int \sum_n (\mathbf{b} \cdot \mathbf{u}_n) u'(\mathbf{b}) \exp(2\pi i \mathbf{b} \cdot (\mathbf{r} - \mathbf{r}_n)) d\mathbf{b}, \quad (31)$$

for monatomic crystals, where $\mathbf{b}$ is a vector in the reciprocal space and

$$u'(\mathbf{b}) = u(\mathbf{b}) \exp(-M) = u(\mathbf{b}) \exp(-2\pi^2 \langle (\mathbf{b} \cdot \mathbf{u}_n)^2 \rangle),$$

$u(\mathbf{b})$ being the Fourier transform of $v(\mathbf{r})$ defined by

$$u(\mathbf{b}) = \int v(\mathbf{r}) \exp(-2\pi i \mathbf{b} \cdot \mathbf{r}) d\mathbf{r}.$$

Substituting (13) into (31), we obtain an expression for $U(\mathbf{r})$ and the matrix element becomes

$$\begin{aligned} & (\mathbf{k}', N'_{qt} | U(\mathbf{r}) | \mathbf{k}, N_{qt}) \\ &= -\frac{2\pi i}{\sqrt{m_a N}} \int u'(\mathbf{b}) (\mathbf{b})_{qt} \sum_n \exp(-2\pi i (\mathbf{b} - \mathbf{q}) \cdot \mathbf{r}_n) \left\{ \int \phi_{\mathbf{k}'}^*(\mathbf{r}) \phi_{\mathbf{k}}(\mathbf{r}) \exp(2\pi i \mathbf{b} \cdot \mathbf{r}) d\mathbf{r} \right\} d\mathbf{b} \sqrt{\frac{\hbar}{8\pi^2 \nu_t(\mathbf{q})} N_{qt}}, \\ & \text{when} \quad N'_{qt} = N_{qt} - 1. \end{aligned} \quad (32)$$

Replacing $-\mathbf{q}$ and N_{qt} by $\mathbf{q}$ and $N_{qt} + 1$, respectively, we get the expression for $N'_{qt} = N_{qt} + 1$. The summation over n has non-zero value N , only when $\mathbf{b} - \mathbf{q} = \mathbf{b}_g$, where $\mathbf{b}_g$ is a reciprocal lattice vector. The second integral in (32), over the whole crystal, becomes

$$\int \phi_{\mathbf{k}'}^*(\mathbf{r}) \phi_{\mathbf{k}}(\mathbf{r}) \exp(2\pi i \mathbf{b} \cdot \mathbf{r}) d\mathbf{r} = \frac{1}{\Omega} \sum_{\mathbf{k}'} \sum_{\mathbf{k}} c_{\mathbf{k}'\mathbf{h}}^* c_{\mathbf{k}\mathbf{h}} \delta(\mathbf{b} - (\mathbf{k}' - \mathbf{k})),$$

Thus the matrix element turns out to be

$$\begin{aligned}
 & (k', N'_{qt} | U(r) | k, N_{qt}) \\
 & = \left\{ \begin{aligned} & -\frac{i}{\Omega_0 \sqrt{m_a N}} \sqrt{\frac{\hbar}{2\nu_t(q)}} N_{qt} \sum_{h'} \sum_h c_{k'h'}^* c_{kh} (b_{g+h'-h} + q)_{qt} u'(b_{g+h'-h} + q), \\ & \text{when } N'_{qt} = N_{qt} - 1 \text{ and } k'_0 = k_0 + b_g + q, \\ & -\frac{i}{\Omega_0 \sqrt{m_a N}} \sqrt{\frac{\hbar}{2\nu_t(q)}} (N_{qt} + 1) \sum_{h'} \sum_h c_{k'h'}^* c_{kh} (b_{g+h'-h} + q)_{qt} u'(b_{g+h'-h} + q), \\ & \text{when } N'_{qt} = N_{qt} + 1 \text{ and } k'_0 = k_0 + b_g - q. \end{aligned} \right. \quad (33)
 \end{aligned}$$

It is easily shown that

$$f_e(b) = -\frac{2\pi m}{\hbar^2} u(b)$$

is the atomic scattering factor for electrons. Putting $f'_e = f_e \exp(-M)$ and using (33) in the derivation of the intensity formula, we obtain (26).

On the Temperature Diffuse Scattering of Electrons

II. Applications to Practical Problems

By Satio TAKAGI

*Institute of Physics, College of General Education,
University of Tokyo
Komaba, Meguro-ku, Tokyo*

(Received November 16, 1957)

The results of the perturbation theory of the temperature diffuse scattering of electrons developed in the preceding paper are applied to practical problems with the assumption of two plane waves.

It is shown that the intensity of the diffuse scattering does not become infinite at a reciprocal lattice point as it does in the current theory but remains finite, that the temperature diffuse scattering gives rise to Kikuchi patterns, and that the intensity of diffuse spots changes abruptly when the incident wave excites a Bragg reflexion. The anomalous intensity variation of the diffuse spots from the surface of some single crystals may be due to this effect. In the Bragg case the direction of the diffuse scattering can be obtained by the modified Ewald construction which replaces the Ewald sphere by the equi-energy surface in the reciprocal space.

The possibility of treating the Kikuchi pattern due to the inelastic collision of incident electrons with lattice electrons by the present method is also discussed.

1. Introduction

In part I of the present paper^{1)*} we have developed a perturbation theory of the temperature diffuse scattering of electrons and have derived the intensity formulae taking into account the circumstance that each of the primary and secondary waves** may excite Bragg reflexions. The general formulae for the intensity of the first order temperature diffuse scattering from monatomic crystals are given by (27-I)* with $J_{s,h}^{ij}$ given by (22-I) or by (26-I), respectively, according as the Bloch or the Nordheim perturbation potentials are assumed. The formulae will now be applied to some simple cases of practical importance. The simplest case is that each of the primary and secondary waves does not excite any Bragg reflexions and is given by

a single plane wave, as has been treated in Section 6-I. In this case the same result as that of the current X-ray diffraction theory applied to electron diffraction was obtained by the Nordheim potential, and also by the Bloch potential with a sufficient approximation except for small scattering angles.

In the following we consider the case in which each of the primary and secondary waves is given by a combination of at most two plane waves, disregarding the simultaneous Bragg reflexions and the effect of weak waves.

2. Application to the Laue Case

Let us consider the case of transmission through a thin crystal bounded by two parallel planes and assume that each of the wave vectors of the waves contained in the primary and secondary waves makes a small angle with the surface normal. In this case the effect of reflexion and refraction at the entrance and exit surfaces can be neglected. The parameter W introduced by Bethe²⁾ (Selektionsfehler) describing the deviation from the Bragg condition is then given by (see Appendix I)

* In the following, Part I is referred to as [I]. Equations, sections and figures in Part I are cited by adding I, such as (27-I), Section 6-I etc.

** In this paper the primary or the secondary wave means the wave expressed by a Bloch function (2-I) and not a single plane wave contained in this function. The primary wave gives rise to the secondary wave by the process of temperature scattering.

$$W = -\frac{(\mathbf{K} + \mathbf{b}_h/2) \cdot \mathbf{b}_h}{|v_h'|}, \quad (1)$$

where $\mathbf{b}_h$ is the reciprocal lattice vector and

$$v_h' = (2m/h^2) V_h', \quad (2)$$

V_h' being the Fourier coefficient of $\langle V(\mathbf{r}) \rangle$ or the time mean of the potential energy of an electron in the crystal. $\mathbf{K}$ is the wave vector of the primary wave in the mean potential V_0 . The magnitude of $\mathbf{K}$ is given by

$$K^2 = K_0^2 - v_0, \quad (3)$$

where v_0 is given by $v_0 = (2m/h^2) V_0$, the tangential component being equal to that of the incident wave.

Subject to these assumptions, the ratio of the amplitude of the two component waves

is given by

$$c_{k,h}^{(i)} / c_{k,o}^{(i)} = W \pm \sqrt{W^2 + 1} \quad (4)$$

(+ for $i=1$, - for $i=2$),

where the superscript i ($=1, 2$) indicates the branch of the dispersion surface on which the wave point lies. If we put

$$W = \cot \beta, \quad 0 \leq \beta \leq \pi, \quad (5)$$

we have $W + \sqrt{W^2 + 1} = \cot(\beta/2)$, $W - \sqrt{W^2 + 1} = -\tan(\beta/2)$, and since c 's are normalized by (3-I), we get

$$\left. \begin{aligned} c_{k,o}^{(1)} &= \sin(\beta/2), & c_{k,h}^{(1)} &= \cos(\beta/2), \\ c_{k,o}^{(2)} &= \cos(\beta/2), & c_{k,h}^{(2)} &= -\sin(\beta/2). \end{aligned} \right\} \quad (6)$$

α 's in (4-I) then become

$$\alpha_1 = \sin(\beta/2), \quad \alpha_2 = \cos(\beta/2),$$

and the wave function of the primary wave is given by

$$\begin{aligned} \psi_{\mathbf{k}} = & (1/\sqrt{Q}) \{ \sin(\beta/2) \{ \sin(\beta/2) \exp(2\pi i \mathbf{k}_0^{(1)} \cdot \mathbf{r}) + \cos(\beta/2) \exp(2\pi i \mathbf{k}_h^{(1)} \cdot \mathbf{r}) \} \\ & + \cos(\beta/2) \{ \cos(\beta/2) \exp(2\pi i \mathbf{k}_0^{(2)} \cdot \mathbf{r}) - \sin(\beta/2) \exp(2\pi i \mathbf{k}_h^{(2)} \cdot \mathbf{r}) \} \} \end{aligned}$$

which is to be connected to the incident wave of electron density $1/\Omega$. We now consider the transition to the state designated by W' . Putting $W' = \cot \beta'$ ($0 \leq \beta' \leq \pi$), we get similar expressions as (6) for the secondary waves and obtain from (27-I) and (22-I)

$$\begin{aligned} J_{s,h} &= \sin^2 \frac{\beta}{2} (J_{s,h}^{11} + J_{s,h}^{12}) + \cos^2 \frac{\beta}{2} (J_{s,h}^{21} + J_{s,h}^{22}), \\ J_{s,h}^{11} &= \frac{J_0}{R^2} \frac{N}{m_a} \cos^2 \frac{\beta'}{2} \sum_t \left\{ \cos \left(\frac{\beta}{2} - \frac{\beta'}{2} \right) (\mathbf{b}_g)_{\mathbf{q},t} f'_{e,g} \right. \\ &\quad \left. + \sin \frac{\beta'}{2} \cos \frac{\beta}{2} (\mathbf{b}_{g-h})_{\mathbf{q},t} f'_{e,g-h} + \cos \frac{\beta'}{2} \sin \frac{\beta}{2} (\mathbf{b}_{g+h})_{\mathbf{q},t} f'_{e,g+h} \right\}^2 \frac{Q_t(q_{11})}{\nu_t^2(q_{11})}, \\ J_{s,h}^{12} &= \frac{J_0}{R^2} \frac{N}{m_a} \sin^2 \frac{\beta'}{2} \sum_t \left\{ \sin \left(\frac{\beta}{2} - \frac{\beta'}{2} \right) (\mathbf{b}_g)_{\mathbf{q},t} f'_{e,g} \right. \\ &\quad \left. + \cos \frac{\beta'}{2} \cos \frac{\beta}{2} (\mathbf{b}_{g-h})_{\mathbf{q},t} f'_{e,g-h} - \sin \frac{\beta'}{2} \sin \frac{\beta}{2} (\mathbf{b}_{g+h})_{\mathbf{q},t} f'_{e,g+h} \right\}^2 \frac{Q_t(q_{12})}{\nu_t^2(q_{12})}, \\ J_{s,h}^{21} &= \frac{J_0}{R^2} \frac{N}{m_a} \cos^2 \frac{\beta'}{2} \sum_t \left\{ -\sin \left(\frac{\beta}{2} - \frac{\beta'}{2} \right) (\mathbf{b}_g)_{\mathbf{q},t} f'_{e,g} \right. \\ &\quad \left. - \sin \frac{\beta'}{2} \sin \frac{\beta}{2} (\mathbf{b}_{g-h})_{\mathbf{q},t} f'_{e,g-h} + \cos \frac{\beta'}{2} \cos \frac{\beta}{2} (\mathbf{b}_{g+h})_{\mathbf{q},t} f'_{e,g+h} \right\}^2 \frac{Q_t(q_{21})}{\nu_t^2(q_{21})}, \\ J_{s,h}^{22} &= \frac{J_0}{R^2} \frac{N}{m_a} \sin^2 \frac{\beta'}{2} \sum_t \left\{ \cos \left(\frac{\beta}{2} - \frac{\beta'}{2} \right) (\mathbf{b}_g)_{\mathbf{q},t} f'_{e,g} \right. \\ &\quad \left. - \cos \frac{\beta'}{2} \sin \frac{\beta}{2} (\mathbf{b}_{g-h})_{\mathbf{q},t} f'_{e,g-h} - \sin \frac{\beta'}{2} \cos \frac{\beta}{2} (\mathbf{b}_{g+h})_{\mathbf{q},t} f'_{e,g+h} \right\}^2 \frac{Q_t(q_{22})}{\nu_t^2(q_{22})}, \end{aligned} \quad (7)$$

* Bethe's first approximation is used throughout this paper. i.e. we put $V_{11} = V_{22} = 0$, $V_{12} = v_h$ in Bethe's notations (Reference 2, p. 78).

** v_h is real and negative. See (24-I)

where

$$Q_t(q) = h\nu_t(q) \left\{ \frac{1}{\exp(h\nu_t(q)/kT) - 1} + \frac{1}{2} \right\}$$

and $J_{s,h}$ is the intensity of the scattered wave in vacuum which is connected to the waves $\exp(2\pi i \mathbf{k}_h^{(1)} \cdot \mathbf{r})$ and $\exp(2\pi i \mathbf{k}_h^{(2)} \cdot \mathbf{r})$ in the crystal at the surface. $\mathbf{k}_h^{(j)}$ is given by

$$\begin{aligned} \mathbf{k}_h^{(j)} &= \mathbf{k}_0^{(j)} + \mathbf{b}_h \\ &= \mathbf{k}_0^{(1)} + \mathbf{b}_{g+h} + \mathbf{q}_{ij} \quad (i, j=1, 2). \end{aligned} \tag{8}$$

The relation between $\mathbf{q}$'s, $\mathbf{k}$'s and $\mathbf{k}'$'s, in the case that $\mathbf{b}_g=0$, is illustrated in Fig. 3-1.

3. Intensity of the Temperature Diffuse Scattering Extremely Near a Reciprocal Lattice Point

We assume now that the Ewald sphere passes near the reciprocal lattice point designated by H. The primary wave then satisfies closely the Bragg condition concerning H, and we can obtain the intensity of the diffuse scattering around H by putting $\mathbf{b}_g=0$ in (7). Particularly interesting is the case when

$$\beta = \pi/2 (W=0) \text{ and } \beta' \rightarrow \pi/2 (W' \rightarrow 0). \tag{9}$$

Then (7) gives the intensity of the diffuse scattering extremely near the Bragg spot when the incident wave exactly satisfies the Bragg condition. According to the current theory the intensity tends to infinity at the reciprocal lattice point³⁾, while the present theory gives a finite value as is shown below.

For the sake of simplicity, the reciprocal lattice vector $\mathbf{b}_h$ is assumed to be parallel to the surface. In this case, (9) means that

$$\mathbf{q}_{11}, \mathbf{q}_{22} \rightarrow 0 \text{ and } \mathbf{q}_{12}, -\mathbf{q}_{21} \rightarrow \mathbf{q}_0, \tag{10}$$

where $\mathbf{q}_0$ is the vector in the reciprocal space drawn from the vertex of a branch of the

Fig. 1. Showing the relation between the wave vectors q_{ij} concerned in one transition. The reciprocal lattice vector $\mathbf{b}_h$ is parallel to the surface. A_1 and A_2 are the wave points of the primary waves and A_1' and A_2' are those of the secondary waves. Dotted lines are normal to the surface.

dispersion surface d_2 to that of d_1 (Fig. 1). Since the magnitude of $\mathbf{q}$'s are sufficiently small, we can put

$$Q_i(\mathbf{q}_{ij}) = kT \tag{11}$$

and

$$\nu_i(\mathbf{q}_{ij}) = c_i q_{ij}, \tag{12}$$

where $c_i (i=1, 2, 3)$ are the velocities of elastic waves in the crystal. Putting (9), (10), (11), (12) and $\mathbf{b}_g=0$ into (7), we obtain

$$\begin{aligned} J_{s,h}^{11} &= \frac{1}{2} \frac{J_0}{R^2} \frac{N}{m_a} f_{e,h}^2 kT \cos^2 \frac{\beta'}{2} \frac{1 - \sin \beta'}{q_{11}^3} \\ &\times \sum_i \frac{(\mathbf{b}_h \cdot \mathbf{q}_{i1})^2}{c_i^2} \text{ etc.} \end{aligned} \tag{13}$$

Fig. 2. Showing the relation between $\mathbf{k}_0$, $\mathbf{b}_h$ and $\mathbf{q}$ in the case that $\mathbf{b}_h$ is parallel to the surface. O and H are the origin and the point of the reciprocal lattice, respectively and M is the middle point of $\overline{OH}$.

When $\beta = \pi/2$ and $\mathbf{q}$'s are very small, $\mathbf{q}_{11}$ and $\mathbf{q}_{22}$ are nearly parallel to, and $\mathbf{q}_{12}$ and $\mathbf{q}_{21}$ are nearly perpendicular to $\mathbf{b}_h$. We see by Fig. 2 that

$$W' = -(\mathbf{K}' + \mathbf{b}_h/2) \cdot \mathbf{b}_h / |\mathbf{v}_h'| = \pm |\mathbf{q}_{11}| |\mathbf{b}_h| / |\mathbf{v}_h'| \tag{14}$$

and we obtain

$$\frac{1 - \sin \beta'}{q_{11}^2} = \frac{W'^2}{2q_{11}^2} = \frac{|\mathbf{b}_h|^2}{2|\mathbf{v}_h'|^2}.$$

We now further assume that the crystal is elastically isotropic so that three vibrational modes associated with a wave vector are a longitudinal and two transverse waves. Then we get

$$\begin{aligned}
 J_{s,h} &= \frac{1}{2} (J_{s,h}^{11} + J_{s,h}^{12} + J_{s,h}^{21} + J_{s,h}^{22}) \\
 &= \frac{1}{2} \frac{J_0}{R^2} \frac{N}{m_a} |b_h|^2 f'_{e,h}{}^2 kT \\
 &\quad \times \left\{ \frac{1}{4} \frac{|b_h|^2}{|v_h'|^2 c_1^2} + \frac{1}{q_0^2 c_{tr}^2} \right\}, \quad (15)
 \end{aligned}$$

where c_1 and c_{tr} are the velocities of the longitudinal and transverse waves, respectively. The result of the dynamical theory gives $q_0 = |v_h'|/K^*$ and since $b_h/K = 2 \sin \theta$, where θ is the Bragg angle, is of the order of 1/100 in ordinary conditions, the first term in the curly bracket of (15) can be neglected. (15) then becomes

$$J_{s,h} = \frac{1}{2} \frac{J_0}{R^2} \frac{N}{m_a} f'_{e,h}{}^2 |b_h|^2 kT / c_{tr}^2 |q_0|^2 \quad (16)$$

$$J_{s,h} = J_{s,h}^{21} + J_{s,h}^{22}$$

$$\begin{aligned}
 J_{s,h}^{21} &= \frac{J_0}{R^2} \frac{N}{m_a} \sum_t \left\{ \cos^2 \frac{\beta'}{2} \sin^2 \frac{\beta'}{2} (b_g)_{q,t}^2 f'_{e,g}{}^2 + \cos^4 \frac{\beta'}{2} (b_{g+h})_{q,t}^2 f'_{e,g+h}{}^2 \right. \\
 &\quad \left. + 2 \sin \frac{\beta'}{2} \cos^3 \frac{\beta'}{2} (b_g)_{q,t} (b_{g+h})_{q,t} f'_{e,g} f'_{e,g+h} \right\} \frac{Q_t(q_{21})}{\nu_t^2(q_{21})} \\
 J_{s,h}^{22} &= \frac{J_0}{R^2} \frac{N}{m_a} \sum_t \left\{ \cos^2 \frac{\beta'}{2} \sin^2 \frac{\beta'}{2} (b_g)_{q,t}^2 f'_{e,g}{}^2 + \sin^4 \frac{\beta'}{2} (b_{g+h})_{q,t}^2 f'_{e,g+h}{}^2 \right. \\
 &\quad \left. - 2 \sin^3 \frac{\beta'}{2} \cos \frac{\beta'}{2} (b_g)_{q,t} (b_{g+h})_{q,t} f'_{e,g} f'_{e,g+h} \right\} \frac{Q_t(q_{22})}{\nu_t^2(q_{22})}.
 \end{aligned}$$

Since q_0 , the distance between the vertices of the dispersion surface, is very small ($\sim 10^{-4}$ A $^{-1}$, for $V_h=1$ volt and $\lambda=0.06$ A), we can put $q_{21}=q_{22}=q$, when q 's are not too small. Then we get a more simple expression

$$\begin{aligned}
 J_{s,h} &= \frac{J_0}{R^2} \frac{N}{m_a} \left\{ \sum_t (b_{g+h})_{q,t}^2 f'_{e,g+h}{}^2 \frac{Q_t(q)}{\nu_t^2(q)} + \frac{1}{2(W'^2+1)} \sum_t [(b_g)_{q,t}^2 f'_{e,g}{}^2 - (b_{g+h})_{q,t}^2 f'_{e,g+h}{}^2] \frac{Q_t(q)}{\nu_t^2(q)} \right. \\
 &\quad \left. + \frac{W'}{W'^2+1} \sum_t (b_g)_{q,t} (b_{g+h})_{q,t} f'_{e,g} f'_{e,g+h} \frac{Q_t(q)}{\nu_t^2(q)} \right\} \quad (17)
 \end{aligned}$$

by utilizing the relations $2 \cos^2(\beta'/2) \sin^2(\beta'/2) = 1/2(W'^2+1)$, $\cos^4(\beta'/2) + \sin^4(\beta'/2) = 1 - 1/2(W'^2+1)$ and $2 \sin(\beta'/2) \cos^3(\beta'/2) - 2 \sin^3(\beta'/2) \cos(\beta'/2) = W'/(W'^2+1)$. When (11) and (12) hold, (17) becomes

$$\begin{aligned}
 J_{s,h} &= \frac{J_0}{R^2} \frac{N}{m_a} \frac{kT}{q^2} \left\{ |b_{g+h}|^2 f'_{e,g+h}{}^2 \sum_t \frac{\cos^2 \vartheta_{g+h,q,t}}{c_t^2} + \frac{1}{2(W'^2+1)} \left[|b_g|^2 f'_{e,g}{}^2 \sum_t \frac{\cos \vartheta_{g,q,t}}{c_t^2} \right. \right. \\
 &\quad \left. \left. - |b_{g+h}|^2 f'_{e,g+h}{}^2 \sum_t \frac{\cos^2 \vartheta_{g+h,q,t}}{c_t^2} \right] + \frac{W'}{W'^2+1} |b_g| |b_{g+h}| f'_{e,g} f'_{e,g+h} \sum_t \frac{\cos \vartheta_{g,q,t} \cos \vartheta_{g+h,q,t}}{c_t^2} \right\} \quad (18)
 \end{aligned}$$

where $\vartheta_{g,q,t}$ is the angle between b_g and e_{qt} . $J_{s,h}$ in (17) and (18) signifies the intensity of the diffuse scattering in the direction kh'

(16) means that the transition probability to the state on the same branch of the dispersion surface as that of the initial state is negligible compared with that to the different branch and that the intensity corresponding to the latter is equal to a half of the intensity, calculated by the current theory, at the vector distance q_0 from the reciprocal lattice point H. This conclusion is also valid for the Nordheim potential (see Appendix II).

4. Kikuchi Patterns

We now consider the case when $\beta \rightarrow 0$: i.e. when the primary wave does not excite any Bragg reflexion and the secondary wave does excite a Bragg reflexion (h). In this case (7) becomes

which is given by (8)**. The relation between the wave vectors of the primary, the secondary and the lattice wave is shown in Fig. 3.

* See footnote * on p. 288.

** The difference of kh' 's designated by the superscript (i) is insignificant in the present case.

This result is analogous to that of Kainuma's theory⁴⁾ which treat the Kikuchi pattern as the result of the inelastic scattering*. The variation of the functions $1/2(W'^2+1)$ and $W'/(W'^2+1)$ in (17) or (18) with W' is shown in Fig. 4. The first term in the curly bracket of (17) or (18) correspond to the ordinary temperature diffuse scattering, the second term to the Kikuchi line and the third term to the Kikuchi band. The Kikuchi line is black or white according as the coefficient of $1/2(W'^2+1)$ is positive or negative, which is the intensity of the ordinary temperature diffuse scattering in the direction $\mathbf{k}_g'$ minus that in the direction $\mathbf{k}'_{g+h}$. The factor $|\mathbf{b}_g|^2 \cdot f_{o,g}'^2$ which is important in determining the intensity of the temperature diffuse scattering is shown in Fig. 5.

Fig. 4.

Fig. 3. Showing the relation between the wave vector of the primary wave $\mathbf{k}_o$, those of the secondary wave $\mathbf{k}_o'$ and $\mathbf{k}_h'$, that of lattice wave $\mathbf{q}$ and reciprocal lattice vectors. The direction of the Kikuchi line is also shown.

Fig. 5. $b=2 \sin \theta/\lambda$.
 $f_o(b)$: atomic scattering factor for electrons.

The intensity given by (17) or (18) will contribute to the intensity of the Kikuchi pattern actually observed. However, the intensity distribution is considerably different from the total intensity of the ordinary Kikuchi pattern. $J_{s,h}$ given by (18) is inversely proportional to q^2 , so that it has a significant value only when q is small or only at points close to the reciprocal lattice point $(\mathbf{g}+\mathbf{h})$. The same is valid for $J_{s,h}$ given by (17). Thus the first order temperature scattering contributes to the intensity of the Kikuchi line only at points near a diffuse spot. The remaining part of the line is due to the other kind of scattering, mostly to the inelastic scattering. The intensity of some Kikuchi line is actually enhanced when they pass near a diffuse spot. The first order temperature scattering may actually contribute to the enhanced part. In

* See footnote * on p. 279 of [I].

this connection, it must be noted that Hashimoto and his collaborators⁵⁾ have studied the energy loss of diffracted electrons, from molybdenite, forming Kikuchi patterns and Kossel-Möllenstedt (K-M) patterns, by eliminating electrons with energy loss of more than a certain value, Δv , and observing the fading away of the patterns. On decreasing Δv , they observed that a part of Kikuchi lines far from the K-M pattern faded away, but a part near a K-M pattern remained even for $\Delta v = 2\text{ev}$. This observation is consistent with the present result. This point may be further clarified by measuring the energy loss of electrons along a Kikuchi line.

Higher order temperature diffuse scattering which we have not treated in the present papers may also contribute to Kikuchi patterns. According to the approximate calculation for X-rays⁶⁾, the intensity of the second

order scattering is inversely proportional to q instead of q^2 in the case of the first order scattering. Higher order temperature scatterings are less dependent on q . The intensity variation of the Kikuchi pattern with q may be slower for the higher order scattering than for the first order scattering.

5. Variation of the Intensity of Diffuse Spots with Change of the Direction of the Incident Wave

In this section, we shall treat the inverse case of the preceding section: i.e. the case when the primary wave excites a Bragg reflexion and the secondary wave does not, so that $\beta' \rightarrow 0$. The secondary wave is composed only of a plane wave with the wave vector $\mathbf{k}_0' = \mathbf{k}_0 + \mathbf{b}_g + \mathbf{q}$ and the intensity of this wave $J_{s,o}$ is obtained by exchanging $\sin^2(\beta'/2)$ and $\cos^2(\beta'/2)$ in (7) and putting $\beta' = 0$. The result is

$$\left. \begin{aligned} J_{s,o} &= \sin^2 \frac{\beta}{2} J_{s,o}^{12} + \cos^2 \frac{\beta}{2} J_{s,o}^{22} \\ J_{s,o}^{12} &= \frac{J_0}{R^2} \frac{N}{m_a} \sum_t \left\{ \sin \frac{\beta}{2} (\mathbf{b}_g)_{\mathbf{q},t} f'_{e,g} + \cos \frac{\beta}{2} (\mathbf{b}_{g-h})_{\mathbf{q},t} f'_{e,g-h} \right\}^2 \frac{Q_t(\mathbf{q}_{12})}{\nu_t^2(\mathbf{q}_{12})} \\ J_{s,o}^{22} &= \frac{J_0}{R^2} \frac{N}{m_a} \sum_t \left\{ \cos \frac{\beta}{2} (\mathbf{b}_g)_{\mathbf{q},t} f'_{e,g} - \sin \frac{\beta}{2} (\mathbf{b}_{g-h})_{\mathbf{q},t} f'_{e,g-h} \right\}^2 \frac{Q_t(\mathbf{q}_{22})}{\nu_t^2(\mathbf{q}_{22})} \end{aligned} \right\} \quad (19)$$

When $\mathbf{q}_{12}$ and $\mathbf{q}_{22}$ can be put equal as before, we get

$$\begin{aligned} J_{s,o} &= \frac{J_0}{R^2} \frac{N}{m_a} \left\{ \sum_t (\mathbf{b}_g)_{\mathbf{q},t}^2 f'_{e,g} \frac{Q_t(\mathbf{q})}{\nu_t^2(\mathbf{q})} + \frac{1}{2(W^2+1)} \sum_t [(\mathbf{b}_{g-h})_{\mathbf{q},t}^2 f'_{e,g-h} - (\mathbf{b}_g)_{\mathbf{q},t}^2 f'_{e,g}] \frac{Q_t(\mathbf{q})}{\nu_t^2(\mathbf{q})} \right. \\ &\quad \left. - \frac{W}{W^2+1} \sum_t (\mathbf{b}_{g-h})_{\mathbf{q},t} (\mathbf{b}_g)_{\mathbf{q},t} f'_{e,g-h} f'_{e,g} \frac{Q_t(\mathbf{q})}{\nu_t^2(\mathbf{q})} \right\}. \end{aligned} \quad (20)$$

The results (19) and (20) predict that when the primary wave excites a Bragg reflexion the intensity of the diffuse spots generally varies abruptly. The variation with the W -value of the primary wave is similar to the intensity variation across a Kikuchi pattern discussed in the previous section. This effect is not yet observed in the transmission experiment. However, Miyake⁷⁾ has pointed out that the intensity of the diffuse spots from a cleavage face of zincblende is enhanced when the specular reflexion spot or the regular reflexion of the incident beam by the surface comes on a Kikuchi line which implies the occurrence of a Bragg reflexion in the crystal, as has been pointed out by Miyake,

Kohra and Takagi⁸⁾. The enhanced diffuse spots are shown in Fig. 1-I. The effect is most remarkable when the reflected beam (Bragg reflexion) makes a small angle with the surface, the normal component of its wave vector being either positive (Laue case) or negative (Bragg case). This effect may be attributed to the same effect as predicted by (19) or (20), since the present argument in the case of normal incidence can also be applied with a slight modification at least to the Laue case with oblique incidence.

Particularly interesting is the case when the specular reflexion spot deviates slightly from the Kikuchi line. This case is shown in Fig. 6 a, b. The diffuse spots are more

intense in (a) than in (b), while the deviation of the specular reflexion spot from the Kikuchi line is equal in magnitude but opposite in direction. This may be explained by the third term in the curly bracket of (19) or (20). The problem of enhancement of the diffuse spot will be treated in more detail elsewhere.

(a)

(b)

Fig. 6. Electron diffraction patterns from a cleavage face (110) of zincblende. The incident beam satisfies closely the Bragg condition concerning (260). The azimuth of the incident beam is slightly different in the two photographs. The specular reflexion spots are indicated by arrows. The incident spots are not shown.

6. Comments on the Bragg Case

In the Laue case, when the primary wave can be expressed by a combination of two plane waves, the wave field in the crystal which is connected to the incident wave is composed of two primary waves. In the Bragg case, however, only one primary wave out of the two is permitted in the crystal when the crystal is sufficiently thick, so that the incident electrons can not penetrate

through the crystal. It is well known that in the range of selective reflexion, the crystal wave has a complex wave vector that it suffers absorption even if the crystal is non-absorbing in the ordinary sense. The absorption coefficient of one of the crystal waves is negative, i. e. the amplitude increases on penetrating into the crystal. The wave with negative absorption coefficient is not permitted in the crystal with sufficient thickness. Kohler⁹⁾ has pointed out that the same is valid for incidences outside the range of selective reflexion, if the true absorption is taken into account. In this case also, one of the primary wave has the negative absorption coefficient and it is not permitted even if the absorption is very weak, provided that μD is large, where μ is the absorption coefficient and D , the thickness of the crystal.

In the range of selective reflexion, the wave vector of the crystal wave is complex. These waves can not be treated by the present theory, because we have assumed that the wave field in the crystal can be expressed by a combination of plane waves with real wave vector. Outside this range, however, we can assume that the waves in the crystal have real wave vector (negligible absorption) but that there is only one primary wave permitted in the crystal. Then we can treat the problem in the Bragg case in the similar way as that given in the preceding sections. However, we shall not discuss the problem in detail but only comment some qualitative results.

(1) In deriving (17) and (18) for the intensity of the Kikuchi pattern, we have assumed that the primary wave in the crystal is a plane wave. (17) and (18) can therefore be applied to the Bragg case if the effect of reflexion and refraction at the entrance and exist surfaces is taken into account.

(2) The variation of the intensity of diffuse spots with change in the direction of the incident wave in the Laue case which is given by (19) or (20) is composed of two contributions from two primary waves. So, the variation in the Bragg case is different from that in the Laue case, though the variation itself will be observed in both cases.

(3) It is shown that in order to obtain the position of the diffuse spot, it is sufficient to consider only one transition from the state

represented by a wave point corresponding to a primary wave to the state represented by a wave point on the different branch of the dispersion surface from that of the initial state. The position of the diffuse spot is then obtained by the "modified Ewald construction" which replaces the Ewald sphere in the ordinary Ewald construction by an equi-energy surface which is the locus of the terminus of the wave vector of the crystal wave, drawn from a point, corresponding to the energy of the incident wave and which is congruent to and equally orientated as the dispersion surface. The detailed procedure is given in Appendix III and illustrated in Fig. 7. The position of the diffuse spots obtained by this method is approximately equal to that obtained by the ordinary Ewald construction [or by the kinematical theory,

Fig. 7. The modified Ewald construction.

while the position of the sharp spots (given by LH' in Fig. 7) is given by the dynamical theory and is such that they were produced by the two-dimensional diffraction from the surface lattice of the crystal, as has been pointed out by Bethe²⁾ and by Miyake, Kohra and Takagi⁸⁾.

7. Conclusions and Discussions

In this paper we have presented the results of the theory of the temperature diffuse scattering of electrons developed in [I] in some simple cases. The main results are the following.

(1) The intensity of the temperature diffuse scattering at a reciprocal lattice point is finite

and is equal to a half of the intensity, given by the current theory, at a point which is the vector distance q_0 apart from the reciprocal lattice point, where q_0 is the smallest vector distance between two branches of the dispersion surface.

(2) Temperature diffuse scatterings give rise to Kikuchi patterns. The characteristic intensity variation across the Kikuchi line or band is the same as that given by Kainuma's theory. However, the intensity varies considerably along a Kikuchi line. Observed Kikuchi line becomes intense when it passes near a diffuse spot. The increased portion of the intensity may be due to the temperature scattering.

(3) When the incident beam excites a Bragg reflexion, the intensity of a diffuse spot changes abruptly. The variation of the intensity with change in the W -value of the incident wave is similar to the intensity variation across a Kikuchi pattern. This result may explain the anomalous intensity variation of the diffuse spots from the surface of some single crystals observed by Miyake⁷⁾.

(4) In the Bragg case, the position of diffuse spots are different from that of the sharp spots which appear on circular arrays. The positions can be determined by the "modified Ewald construction" which replaces the Ewald sphere by the equi-energy surface in the reciprocal space. The position of the diffuse spots in vacuum is approximately equal to that obtained by the ordinary Ewald construction.

We have obtained the Kikuchi pattern by the perturbation method without the rather complicated notion of "reciprocal waves" used in the theories of von Laue and of Kainuma. The Kikuchi pattern resulting from inelastic scattering* may also be treated by this method. The interaction of an incident electron and a lattice electron has been treated by several authors in the theories of the secondary electron emission¹⁰⁾. The theory of the Kikuchi pattern may be developed along similar lines.

The author wishes to express his thanks to Prof. S. Miyake for his valuable discussions. This work was partly supported by a research grant of the Ministry of Education.

* See footnote * on p. 279 of [1].

Appendix I. “Selektionsfehler” W in the Case of the Transmission though a Parallel-sided Crystal

In the notation of the present paper, W is given by¹¹⁾

$$W = - \frac{K\zeta}{|v_h'| \sqrt{\cos \vartheta_2 / \cos \vartheta_1}}$$

Here v_h' and K is given by (2) and (3), respectively, ϑ_1 and ϑ_2 are the angle between the surface normal and k_o and k_h , the wave vectors of the component waves of the primary wave, and ζ is the “Resonanzfehler” defined by $\zeta = \overline{LO} - \overline{LH}$, where L is the Laue point, O and H are the origin and the point of the reciprocal lattice, respectively. As $LO = K$ and $LH = |K + b_h|$, we have

$$\zeta = K - |K + b_h| = -(K + b_h/2) \cdot b_h / K.$$

When ϑ_1 and ϑ_2 are small, $\cos \vartheta_2 / \cos \vartheta_1 \approx 1$, and we get Eq. (1).

Appendix II. Intensity of the Temperature Diffuse Scattering Extremely Near a Reciprocal lattice Point, in the Case of Nordheim’s Potential

Putting $b_g = 0$, $\beta = \pi/2$ and $\beta' \rightarrow \pi/2$ in (27-I) and (26-I), we get, in the case of two plane waves,

$$\begin{aligned} J_{s,h} &= \frac{1}{2} (J_{s,h}^{11} + J_{s,h}^{12} + J_{s,h}^{21} + J_{s,h}^{22}) \\ J_{s,h}^{11} &= J_{s,h}^{22} = \frac{1}{2} \frac{J_0}{R^2} \frac{N}{m_a} kT \\ &\quad \times \left\{ f_e'(0) - \frac{1}{2} \frac{b_h^2}{|v_h'|} f_e'(b_h) \right\}^2 / c_1^2 \\ J_{s,h}^{12} &= J_{s,h}^{21} = \frac{1}{2} \frac{J_0}{R^2} \frac{N}{m_a} b_h^2 f_{e,h}'^2 kT / q_0^2 c_{tr}^2 \end{aligned}$$

where we put

$$f_e'(b) = f_e'(b_h) = f_{e,h}', \quad (b = b_h \pm q_0),$$

since $|q_0|$ is small. This can also be written as

$$\begin{aligned} J_{s,h} &= \frac{J_0}{R^2} \frac{N}{m_a} b_h^2 f_{e,h}'^2 kT \\ &\quad \times \left\{ \frac{1}{2b_h^2} \left[\frac{f_e'(0)}{f_e'(b_h)} - \frac{1}{2} \frac{b_h^2}{|v_h'|} \right]^2 / c_1^2 \right. \\ &\quad \left. + \frac{1}{2q_0^2} / c_{tr}^2 \right\}. \end{aligned} \tag{21}$$

Values of $f_e(0)/f_e(b_h)$ and $b_h^2/|v_h|$ for Ni are listed in Table I. $f_e(0)/f_e(b_h)$ is at most of the same order of magnitude as, and in general

much smaller than $b_h^2/|v_h|$. So the first term in the curly bracket of (21) is at most of the same order of magnitude as the first term in the curly bracket of (15) which can be neglected. Thus (16) is also valid in the present case.

Table I.

hkl	$f_e(0)/f_e(b_h)$	$b_h^2/ v_h $
111	4.02	2.73
222	9.7	20.4
333	17.2	85.5
444	26	259

Values of v_h are obtained from the values of V_h given by Bethe²⁾. Values of $f_e(b_h)$ are obtained by interpolation from those given by Mott and Massey¹²⁾.

Appendix III. The “Modified Ewald Construction”

The procedure of obtaining the position of the diffuse spot by the modified Ewald construction is shown in Fig. 7. In this figure S is the equi-energy surface corresponding to the energy of the incident wave, L is its centre and O is the origin of the reciprocal lattice. The tangential component of $\vec{LO}$ is equal to that of the incident wave. $\vec{LO}$ gives the wave vector of the primary wave in the crystal and if S passes near a reciprocal lattice point H , the primary wave contains also a plane wave with wave vector $\vec{LH}$ which correspond to a sharp diffraction spot. The wave vector of the crystal wave corresponding to the centre of the diffuse spot is given by $\vec{LD}$, where D is the point on S being nearest to H or more exactly the point of contact of S with an iso-diffusion surface around H . The directions of the corresponding vacuum waves are given by $\vec{LH'}$ and $\vec{LD'}$ as in the ordinary procedure, where H' and D' lie on S' , a sphere of radius K drawn around L , $\vec{HH'}$ and $\vec{DD'}$ being normal to the surface.

Though the position of the diffuse spot obtained by the present method is approximately equal to that obtained by the ordinary method as is mentioned in the text, the directions of the diffuse scattering in the crystal obtained by the two methods are somewhat different from each other.

Optical and Electrical Properties of Tin Oxide Films

By Kozo ISHIGURO, Taizo SASAKI, Toshihiro ARAI
and Isamu IMAI

*Department of Physics, College of General Education;
Institute of Science and Technology,
University of Tokyo*

(Received June 29, 1957)

The electrical and optical properties of the transparent conducting tin oxide films were studied experimentally. The observed Hall effect and Seebeck effect show that the present specimens are *n*-type conductor whose carrier density is $10^{19} \sim 10^{20} \text{ cm}^{-3}$. The optical measurements made it clear that the fundamental energy gap was about 4 eV and the plasma frequency of the conducting carriers lied in the near infrared region. By comparing the observed optical transmission and reflection with the theoretical values which can be calculated with the electrically measured constants, the effective mass of the carriers was determined to be about 1/5 of the free electron mass. It will be discussed in conclusion that, to satisfy the thermoelectric power relation with this small effective mass, we must assume that the Coulomb scattering of impurity ions is the predominant scattering mechanism in the transparent conducting tin oxide films.

§1. Introduction

Since the interesting properties of transparent conducting coating on glass surface were discovered, a large number of experimental works in this field have been reported¹⁾. But these have been confined almost exclusively to the refinement of the method of preparation and very few papers have referred to the analysis of their physical properties. The object of the present paper is to report on the experimental results carried out in our laboratory to make clear the optical and electrical properties of the typical transparent conducting coating, tin oxide film. In particular, the contribution of the free carriers,

whose nature can be estimated from the electrical measurements, to the optical properties in the near infrared region will be discussed in some detail.

§2. Preparation of Samples

Among the various methods of preparation, the simplest one was adopted. Namely, one component solution of $\text{SnCl}_4 \cdot 5\text{H}_2\text{O}$ crystal or SnCl_4 liquid in distilled water or in ethyl alcohol was sprayed by a small atomizer on the glass, fused silica or rock salt plates. The effect of mixing the impurities of III or V valency according to Verwey's principle of controlled valency²⁾ will not be discussed in

the present paper.

As shown in Fig. 1, the substrate was held downward in a main cylindrical electric furnace and the solution was sprayed onto it from the underlying atomizer. After passing through the preheating furnace, the atomized fog of SnCl_4 was poured upon the heated substrate. The adequate temperature of the main furnace was $500\sim 600^\circ\text{C}$.

Fig. 1. Arrangement for preparing samples.

According to the electron diffraction observation, the main pattern coincides with that of SnO_2 and the rings are fairly sharp, indicating that the film is composed of crystallites not so small as to be interpreted as amorphous state.

§ 3. Electrical Properties

The experimental arrangement used for the conductivity measurement is shown schematically in Fig. 2. Knowing the film thickness, the conductivity of the sample can be calculated from the potential difference between the fixed points A and B, if a constant current is maintained in the sample from left to right in the figure. The potential difference was measured by the usual potentiometric method whose sensitivity was ca. 5 micro volts. To assure the ohmic contacts in the arrangement, careful pre-examinations had been repeated until the result was satisfactory. Table I summarizes the measured values for several different samples.

The Seebeck E.M.F. θ was also measured by giving a temperature difference of several degrees between the point contacts A and B.

Fig. 2. Schematic diagram of circuit used for measurements of electric properties.

Since the Seebeck E.M.F. of tin oxide is much larger than that of copper which was used as point contact probes, the direction of thermoelectric power directly suggests the type of the free carriers in tin oxide. The conclusion is that our specimens are *n*-type carriers in accordance with Aichison³⁾ and Bauer⁴⁾.

The temperature dependence of θ is given by the formula⁵⁾

$$\left. \begin{aligned} \theta &= -e \frac{d\theta}{dT} = \left(\frac{p}{6} + \frac{1}{2} \right) \pi^2 k / \xi \\ &\quad \text{(in the degenerate case)} \\ &= \left(\frac{p}{2} + \frac{5}{2} - \xi \right) k \\ &\quad \text{(in the non-degenerate case)} \end{aligned} \right\} \quad (1)$$

where

$$\xi = \zeta / kT,$$

$$\zeta = \text{Fermi energy},$$

p = scattering index defined from the proportionality of relaxation time τ to v^p .

p is an adjustable parameter chosen so as to give the best representation of τ . The limiting values of p are -1 and 3 . The former corresponds to the scattering by the acoustical lattice vibrations and the latter to the Coulomb scattering by ionized atoms. In our specimens, the number of free electrons is such that they cannot be treated as a non-degenerate gas and it is necessary to consider them a transition case from classical to quantum statistics.

The correct Fermi energy and effective

† It may be interesting to notice that $n \approx (1/l)^3$ in the present case.

mass of carriers may be estimated from (1) by appropriate interpolations. However, as it is generally admitted that the effective mass m^* determined from the Seebeck effect gives too small value, we did not adopt the calculated value itself but assumed that the upper and lower limits of the effective mass were the free electron mass m and 1/10 of it respec-

tively. The optical transmission and reflection calculated assuming these limiting values of the effective mass are compared with the measured values which are to be given in the next section.

The samples of relatively high electrical conductivity change their conductivity neither by temperature variation nor by evacuation

But the low conductivity samples were rather unstable and the results obtained were similar to those of G. Bauer⁴), who investigated the temperature dependence of conductivity, Seebeck E.M.F. and Hall coefficient of tin oxide films prepared by the oxidation of Sn films evaporated on fused quartz plates. Assuming that the temperature dependence of the low conductivity specimens is given by

$$\sigma = a \exp(-\varepsilon/kT),$$

the activation energy ε is estimated at 0.01~0.04 ev. By evacuation, however, the conductivity increases to about 10 times this value under the normal condition. It may be concluded, therefore, that the low conductivity samples are typical reduction type semiconductors, the excess Sn atoms supplying the conduction electrons.

A ceramic specimen with dimension $10 \times 2 \times 2$ mm showed the resistance of about 10^{11} ohms, which remained unchanged even after the bombardment with 2 Mev deuterons of ca. 10^{14} per cm^2 density generated by the cyclotron of Inst. of Science and Technology*. When the same specimen was evacuated, however, the resistance was found to decrease remarkably. This may be due to the escape of oxygen atoms from the surface layer.

The Hall constant R_H was obtained with some difficulties, since the effect was fairly small, especially for high conductivity samples whose constants were about $R_H = 0.075 \text{ cm}^3/\text{coul}$. The measured constants indicates that the specimens are n -type in accordance with the Seebeck effect measurement. From the Hall constant of the typical sample No. 15, we estimate the carrier concentration N and Hall mobility μ_H as follows:

$$N = 8.4 \times 10^{19} \text{ cm}^3$$

$$\mu_H = 32 \text{ cm}^2/\text{volt} \cdot \text{sec}.$$

§ 4. Optical Properties

The transmission and reflection in the wavelength region from 0.25 to 4.0μ were measured by a small quartz spectro-photometer, and the transmission of the longer wavelength region was recorded by a Parkin Elmer spectro-photometer and a rock salt double

monochrometer, Koken Type 301. As the substrates, fused quartz and rock salt plates were used. Fused quartz is superior than rock salt in the durability for the humidity and the mechanical impinging. Since it does not transparent for longer wavelength region than 4μ , however, we must use rock salt plate for the measurements in the region from 4μ to 15μ . Fig. 3 shows transmissivity

Fig. 3. Observed transmissivity and reflectivity of tin oxide films as a function of wavelength.

A: fused quartz substrate.

B: rock salt substrate.

— } represent different specimens
 --- }
 }

versus wavelength curves. The substrate of sample A was a fused quartz plate and that of sample B was a rock salt plate. The specimens sprayed on rock salt plate generally show very low D.C. conductivity. Microscopic observation revealed that many cracks are present on these specimens, however, and the A.C. measurement proved that the conductivity remarkably increased already at 10 k.c. Therefore, these low D.C. conductivity is not the intrinsic nature of the film on rock salt substrate but is caused only by a macroscopic boundary effect of the cracks. Then the apparent low D.C. conductivity will not have any important influence on optical properties, if the scattering loss of the incident light by these cracks is corrected to give a smooth transmission curve connecting the values for the quartz and rock salt substrates.

A general survey of the curves shows that the specimens are almost perfectly transparent in visible region and the fundamental absorption begins at about 0.3μ extending to shorter wave length. In the infrared region, the transmissivity decreases gradually whereas

* The bombardment was carried out by the courtesy of Prof. K. Ôno.

the reflectivity begins to increase*.

The absorption coefficients at the fundamental absorption edge are shown in Fig. 4. The correlation between the absorption coefficient and the D.C. conductivity was not detected.

The refractive index in the transparent region and the film thickness were obtained from the determination of the wavelengths corresponding to the interference maxima and minima and the reflectivities at these wavelengths. The film thickness was also checked by Tolansky's multiple beam interference method, and the refractive indices measurement was supplemented by Abelès' reflection method⁷⁾.

Fig. 4. Absorption coefficient at the fundamental absorption edge as a function of photon energy.

Some measurements were also made of the photo-conductivity. The photo current of about 1% of the dark current was observed when the specimen was exposed to light from a high pressure mercury lamp with a filter transmitting only ultra violet light. This observation confirms that the fundamental absorption edge corresponds to the energy gap between the valence band and the conduction band. But it should be noticed that the rise and decay time of photo-conductivity of

the present specimens are several minutes or more. Since the correction of the thermoelectric effect induced by the temperature rise of the specimen by illumination of intense light has been considered, these slow time response cannot be explained by the thermal effect. It is not clear at present why such slow time response should occur in the specimens with so many dark free carriers which will immediately fill up the holes made by photo electrons.

Fig. 5 (a), (b). Time dependency of photo-conduction.

* Aitchison reported that tin oxide was transparent from 0.2 to 14 microns³⁾. But our observations do not support his results. He adopted reflection method and the sensitivity of the reflection method is high only when the absorption is very large and this may explain the cause of his neglect of absorption.

§ 5. Unified Discussions of Electrical and Optical Properties⁹⁾

E. Kanai⁸⁾ proposed to adopt the well known optical theory of metals to explain the characteristics of tin oxide. He attributes the difference between the usual metals and tin oxide to the difference of the free carrier concentration. Though the plasma frequency of metals of high carrier concentration lies in the ultra violet region, that of tin oxide lies in the near infrared owing to the low carrier concentration. In his opinion, this is the cause of the optical transparency of tin oxide in spite of its metallic conduction. If this is the case, the measurements of optical properties may afford a supplemental method to determine effective mass and the scattering mechanism of free carriers even when the specimen is unstable for temperature change. This will be discussed below.

In germanium, the plasma frequency lies in the far infrared region owing to the low concentration of carriers, which makes its study very difficult. But in the case of semi metallic conductor such as tin oxide, we can investigate the optical anomalies expected at the plasma frequency without large experimental difficulty.

Let us suppose that the refractivity of tin oxide is caused by the combined effect of the intrinsic absorption continuum lying in the ultra violet region corresponding to the excitation of oxygen ions and the infrared absorption by the ohmic conduction of free carriers

and, therefore, that it is not necessary to consider the absorption by lattice vibration. The dispersion of refractive index, then, is given by the usual Drude-Krönig-Fujioka's formula

$$n^2-k^2=A_v-\frac{\nu_P^2}{\nu^2+\nu_A^2}$$
$$2nk=\frac{\nu_P^2\nu_A}{\nu^2+\nu_A^2}\frac{1}{\nu}+B_v\nu,$$

where

$n-ik$ =complex refractive index ,
 ν_P =plasma frequency
 $= (e^2N/m^*\pi)^{1/2}$
 $= (\sigma/\pi\tau)^{1/2}$,
 $\nu_A=1/2\pi\tau$,
 $A_v=\bar{\nu}_B^2/(\nu_B^2-\nu^2)$,
 $B_v=\bar{\nu}_B\nu_C/(\nu_B^2-\nu^2)^2$

and ν_B , $\bar{\nu}_B$, ν_C represent the mean effect of the fundamental electronic transitions in the ultra violet region.

For the longer wavelength region than the visible, one may put $B_v=0$, since the experiment shows that no absorption is present in the visible region. ν_B and $\bar{\nu}_B$ can be calculated from the observed refractive indices in the visible region, and ν_P and ν_A are determined from the electrical measurements. With these values, one can calculate the complex refractive index at any given frequency in the infrared region as shown in Table II.

If we assume that the film thickness is so large, say 10 μ , that the interference effect

may be neglected, then one can write the reflectivity R and transmissivity T

$$R = \frac{(n_2 - n)^2 + k^2}{(n_2 + n)^2 + k^2},$$
$$T = \frac{16n_0n_2(n^2 + k^2)}{\{(n + n_2)^2 + k^2\}\{(n + n_0)^2 + k^2\}} e^{-\alpha l},$$

where n_0 is the refractive index of the substrate and n_2 is that of the incident side medium. (Fig. 7)

Fig. 6. Transmissivity and reflectivity calculated as a function of wavelength with the assumed effective mass; $m^*=0.1m, 0.35m$ and m . (film thickness= 10μ).

Fig. 7. Schematic explanation of transmissivity and reflectivity of film.

The calculated values are shown in Fig. 6. It is expected from them that the reflection increases remarkably for wavelengths longer than the wavelength corresponding to plasma frequency, and that the transmission decreases rapidly at the same wavelength region¹⁸⁾. However, the actual specimens do not have such a large thickness and are only $0.1\sim0.3\mu$ thick. Then one cannot neglect the interference effect and must use the exact formula which involves the interference effect¹⁰⁾:

$$R = e^{-\alpha l} \left\{ \left(\frac{M_2}{N_2} \right)^2 e^{\alpha l} + \left(\frac{M_0}{N_0} \right)^2 e^{-\alpha l} - 2 \left(\frac{M_0 M_2}{N_0 N_2} \right) \cos (D + \Phi) \right\} |f|^2,$$

$$T = e^{-\alpha l} \frac{16n_0n_2(n^2 + k^2)}{\{(n + n_2)^2 + k^2\}\{(n + n_0)^2 + k^2\}} |f|^2,$$

and

$$|f|^2 = \frac{e^{\alpha l}}{\left\{ e^{\alpha l} + \left(\frac{M_0 M_2}{N_0 N_2} \right)^2 e^{-\alpha l} - 2 \left(\frac{M_0 M_2}{N_0 N_2} \right) \cos (D + \Psi) \right\}},$$

where

$$n_j - n_1 = M_j \exp i\phi_j \quad M_j^2 = (n_j - n)^2 + k^2$$
$$n_j + n_1 = N_j \exp i\theta_j \quad N_j^2 = (n_j + n)^2 + k^2$$

($j=0$ or 2)

$$(M_0 M_2 N_0 N_2) \cos \Phi = (n^2 + k^2)^2 + n_0^2 n_2^2 - (n_0^2 + n_2^2)(n^2 + k^2) + 4n_0 n_2 k^2$$
$$(M_0 M_2 N_0 N_2) \sin \Phi = 2k(n_0 - n_2)(n^2 + k^2 + n_0 n_2)$$
$$(M_0 M_2 N_0 N_2) \cos \Psi = (n^2 + k^2)^2 + n_0^2 n_2^2 - (n_0^2 + n_2^2)(n^2 + k^2) - 4n_0 n_2 k^2$$
$$(M_0 M_2 N_0 N_2) \sin \Psi = 2k(n_0 + n_2)(n^2 + k^2 - n_0 n_2).$$

In Fig. 8, the results of the calculations for the effective mass $m^*=0.1m, 0.35m$ and m are

Fig. 8. Comparison of the observed transmissivity and reflectivity of tin oxide film with the calculated values with the assumed effective mass of free carriers: $m^*=0.1m, 0.35m$ and m . Full line=calculation, Dotted line=observation (film thickness= 0.11μ).

Fig. 9. Calculated wavelength corresponding to transmissivity 70% of tin oxide film of 0.11μ thick as a function of m^*/m .

compared with the experimental values (No. 15) where m is the free electron mass. To make the calculated one coincide with the experimental value, one may be inclined to adopt $m^* \approx 0.15m$. (Fig. 9) Then, if the equation (1) is valid for the present case, the scattering index p must be 3 in order to give such effective mass in the degenerate case (Table I). Then it may be concluded that, in the present specimens, the Coulomb scattering by ionized atoms is the rather predominant scattering mechanism.

§ 6. Discussions

The electrical and optical properties of tin oxide films mentioned above don't have the remarkable differences from the other oxides such as In_2O_3 , CdO , ZnO etc., except the fact that the density of the free carriers are easily increased by the simple method and the films are strong and durable. Furthermore, it is reported by several authors¹¹⁾ that the transparent electrodes are also made by In_2O_3 and CdO films prepared by sputtering method in an atmosphere of the adequate oxygen pressure and the mobilities of electrons are also in the range of $1 \sim 100 \text{ cm}^2/\text{volt} \cdot \text{sec}$. When these oxides are heated above 200°C , complex irreversible change due to adsorption, dissociation and diffusion of oxygen occurs and the interpretation of conductivity versus temperature curves must be cautions of these effects and the details of our experimental results of conductivity change with temperature of SnO and SnO_2 films will be reported later in another paper. Considering these circumstances, one of the interesting points of the study of SnO_2 films is to determine the source of the free carriers of such large density and our conclusion that the impurity scattering of free carriers is the predominant process in the conduction mechanism may be suggestive. But it must be noticed that the conclusion was derived by applying the well known usual theory of metals and only the scattering of lattice vibration of the acoustical mode was considered and the effect of optical vibration was neglected. But if the ionic character of the binding of SnO_2 crystal is large, such approximation may not be allowed.

Percentage ionic character P of SnO bonding is given by¹²⁾

$$P = 16|x_{\text{Sn}} - x_0| + 3.5|x_{\text{Sn}} - x_0|^2$$

$$= 37.3\%$$

where $x_{\text{Sn}} \approx 1.8$ and $x_0 = 3.5$. This is fairly small comparing with the values of alkali halides. However, considering the fact that SnO_2 crystal is rutile type and Madelung constant is very large, the ionic character in bonding might be the considerable amount and the neglect of the interaction of the electron wave with the optical vibration of lattice may not be good approximation. On the other hand, however, the fact that the effective mass of our sample is small and same order with the homopolar crystals such as Ge and Si support the opposite stand point that the effect of optical mode is small. Because, with the increasing ionic character of the lattice, the free electron will be afforded the nature of polaron and the mass must be increased. The measurements of the absorption of infrared radiation in the residual ray region are desirable to make this problem clear. Finally, it will need some explanation that whereas the carrier density changed easily in order of 10^{19} by thermal treatment, the change by deuteron bombardment could not be detected. The number of the displaced atoms per unit volume from their regular sites by deuteron bombardment are given approximately by $\rho(Z/M)\sigma N$, where ρ , Z and M are density, atomic number and mass number respectively and σ is the cross section of collision of the atom with deuteron and N is the number of irradiating deuterons per cm^2 . In our experimental condition, if the carrier density change is proportional to the deficient number of oxygen atoms, it is anticipated that to obtain the positive results the cross section of collision must be larger than 0.1 barns. Our negative result may suggest smaller cross section of collision between oxygen atom and deuteron.

§ 6. Summary

The electrical and optical properties of tin oxide films prepared by the spraying method were studied. The experiments carried out so far show that tin oxide is a conductor with n -type carriers and the optical properties in the near infrared region is influenced strongly by the properties of free carriers. In order to unify the optical and electrical measurement, the effective mass of the carriers must be taken as $1/5 \sim 1/7$ of the free

electron mass and the scattering index of the carriers p equal to 3. Compared with metals, tin oxide has some advantages in investigating the electric conduction mechanism and optical properties of free carriers, since the samples are transparent for wide frequency region and the specimens with the different carrier concentration can be prepared easily.

The authors wish to express their thanks to Mr. Kin'ichi Nakamura of N.H.K. for the presentation of the problem, to Mr. T. Kurachi and Prof. K. Kudo for their help in the infra-red measurements, to Mr. M. Kuriyama and Prof. S. Takagi for the identification of the diffraction pattern and also to Prof. K. Takahashi for measurement of high resistance.

Furthermore, the authors wish to express their thanks to Dr. Hisao Miyazawa and Prof. Jiro Yamashita for their advices regarding several general properties of semiconductors.

Statistical Aspect in Accelerating Creep and Creep Fracture of OFHC Copper

By Takeo YOKOBORI

Department of Mechanical Engineering, Tohoku University, Sendai

and Hideharu OHARA

Central Research Lab., Hitachi Ltd., Kokubunji, Tokyo

(Received December 5, 1957)

A large number of creep rupture tests on OFHC copper wire have been carried out at stress levels of 24.0~25.0 Kg/mm² and temperatures of 8~40°C. The F-test was made for the differences in variance between time for initiation of accelerating creep and time for rupture measured from the initiation of accelerating creep, and the regression analysis between these times was carried out. The scatter observed for these times appears to be an inherent characteristic of the material itself associated with a Markoff process—dynamic statistical process—as a rate process.

§ 1. Introduction

The scatter of the time for creep fracture under assumedly identical conditions is much larger than has generally been believed¹⁾⁻³⁾. The recent studies indicate that the most of the scatter observed in creep life of metals appears to be an inherent characteristic of the material¹⁾⁻³⁾. The statistical variations were interpreted as a Markoff process—dynamic statistical process—which are explained as a kind of rate process^{1),2)}. In order to obtain more detailed knowledge on the problem, the creep fracture process was divided into the following two stages in the present study. These are Stage 1, from the instant of the application of the load till the initiation of accelerating creep, the period of which is denoted by t_1 ; and Stage 2, from the initiation of accelerating creep till fracture, the period of which is denoted by t_2 . In the preliminary study on commercial copper by one (T. Yokobori) of the authors, there was no correlation between t_1 and t_2 at the 10% level of significance at the stress of 28.8 Kg/mm² and 28°C. In the present paper, the authors have attempted to verify the validity of independency of t_2 on t_1 at any stress level and temperature, and the validity of interpreting the Markoff process—dynamic statistical process—as a kind of rate process. While in the previous study^{1),2)}, commercial copper wire as cold-drawn was used, in the present study the specimens of OFHC copper as annealed were tested.

§ 2. Material and Treatment

The OFHC copper was obtained by vacuum melting. It is spectroscopically fine having the chemical analysis as shown in Table I,

Table I. Result of gas analysis.

Element	Content (%)
O ₂	0.00033
H ₂	0.00003
N ₂	tr.

and was cold drawn to wire of 0.5 mm diameter from 10 mm diameter without intermediate annealing. The wire was cut into 130 specimens, the length between two chucks being kept at about 90 mm. The test specimens were annealed for 30 minutes at 300°C. The grains obtained are shown in Fig. 1.

§ 3. Procedures and Testing Equipment

The general arrangement of test equipment is shown in Fig. 2. The two similar equipments were used. The elongation of the test specimens was not magnified, but was recorded by a pen using a string. The ends of specimens were inserted into grooves of two chucks respectively, and tightened with small bolts. The temperature of atmosphere around the specimen did not vary throughout the test by more than $\pm 0.5^\circ\text{C}$ by regulating it at the room temperature. Applied stress and temperature are 24.0 Kg/mm², 24.5 Kg/mm², 25.0 Kg/mm² and 8°C, 20°C, 30°C, 40°C as shown

Table II. Summary of testd data*.

** Specimens of each group were chosen at random in respect of position in the original long wire.

Table II. Eight to twenty specimens were tested at each of stress levels and temperatures. The data of specimens which fractured near (at the distance less than 4 mm from) the chuck were excluded.

finding inflexion points. t_2 was obtained as $t_3 - t_1$. t_1 determined in this manner seems rather slightly arbitrary because of always involved visual effect. The results, however, obtained by several trials in one curve show

Fig. 1. Microstructure of OFHC copper. $\times 80$.

Fig. 3. Fractured area of the specimen. $\times 245$.

Fig. 2.

§ 4. Results

The type of fracture at the tested range of stress and temperature was necking type as shown in Fig. 3. The following notations are used in accordance with Fig. 4.

t_1 = the time period for the initiation of accelerating creep measured from the instant of load application,

t_2 = the time period for fracture measured from the instant of the initiation of accelerating creep, and

t_3 = the time period for fracture measured from the instant at load application, that is, $t_1 + t_2$.

t_1 , t_2 and t_3 were determined from automatically recorded strain versus time curve (creep curves). t_3 was determined from automatically recorded strain versus time diagrams (creep curves). In the case of short value of t_3 , the results were checked with stop-watch and the agreement was satisfactory. t_1 was determined from the same diagrams by trying to draw tangential straight lines to the curves and

Fig. 4. Definition of t_1 , t_2 and t_3 .

that the scatter (error) of t_1 determined in this way was smaller than 15% of t_1 of the curve. Since the coefficient of variation of t_1 itself was almost 100%, the following treatment and conclusions in this articles may not be affected seriously by this method of determination of t_1 , t_2 and t_3 . The rawtest data are summarized in Table II.

§ 5. Statistical Analysis

The scatters of t_1 and t_2 were very remarkable and the frequency distributions appear to be roughly exponential type in all cases. Examples of the histograms are presented in Fig. 5. The F-test was applied to determine whether the differences in variance for t_1 and t_2 are significant at the 5% level of confidence. The logarithms of t_1 and t_2 were used, since exponential distribution is approximated with

Fig. 5. Histogram of t_1 , t_2 and t_3 .

Table III. Summary of statistical analysis of test data.

Temperature °C	Stress Kg/mm ²	Number of specimens tested	An unbiased value of dispersion of log t_1	An unbiased value of dispersion of log t_2	Result of F test at 5% level	Result of regression analysis of t_1 and t_2
8	24.5	18	0.108	0.245	Not Significant	Not Significant ($\alpha=50\%$)
	25.0	19	0.161	0.156	Not Significant	Not Significant ($\alpha=5\%$)
20	24.0	17	0.448	0.042	Significant	Not Significant ($\alpha=60\%$)
	24.5	14	0.342	0.055	Significant	Not Significant ($\alpha=10\%$)
	25.0	16	0.183	0.124	Not Significant	Not Significant ($\alpha=0.5\%$)
30	24.0	10	0.115	0.191	Not Significant	Not Significant ($\alpha=50\%$)
	25.0	8	0.068	0.019	Not Significant	Not Significant ($\alpha=80\%$)
40	24.0	20	0.198	0.169	Not Significant	Not Significant ($\alpha=2.5\%$)
	24.5	16	0.147	0.176	Not Significant	Not Significant ($\alpha=1\%$)

* α =The level of significance.

log normal distribution. In all cases except two, the differences in variance for t_1 and t_2 are not significant at the 5% level of confidence as shown in sixth column of Table III. Hence we may be justified to conclude that the scatter of t_1 and t_2 are of the same order of magnitude and very large.

Next, the regression analysis⁴⁾ was applied to determine whether the period t_2 of Stage 2 is dependent on the period t_1 of Stage 1. The results of the analysis are summarized in Table III. An examples of corresponding values of t_1 and t_2 are presented in Fig. 6. In five cases of nine tested the t -values were within the critical region corresponding to the level of significance larger than 10% as shown in Table III.

Consequently it can be concluded that there is no correlation between t_1 and t_2 , and creep

fracture process may be assumed as at least two successive events of Stage 1 and Stage 2.

Fig. 6. Scatter diagram of t_1 and t_2 .

§ 6. Physical Interpretation of Statistical Nature of Creep Fracture

The problems of the initiation of fracture

or yielding appears to have been interpreted as a Markoff process—dynamic statistical process^{1), 2), 5), 6), 7), 8)}. Let us take this approach in the present case and consider the physical nature of the statistical aspect. Let us denote the probability that the accelerating creep will initiate in the next interval of time dt , provided it has not initiated already, as

$$\mu_1(t)dt \quad (1)$$

If $P_1(t)$ is the probability that the accelerating creep has not initiate at time t , the probability that it will initiate between times t and $t+dt$ is

$$P_1\mu_1dt = -dP_1. \quad (2)$$

P_1 can be obtained using the frequency distribution curve $q_1(t)dt$ or approximately by the relation

$$P_1 = 1 - \frac{\nu}{n+1} \quad (3)$$

Eq. (3) is the mean frequency of the ν th of n observed observations. When t_1 is plotted as abscissae and the logarithm of P_1 as ordinates, then μ_1 is given by negative tangent of $\log P_1 - t_1$ plot. On integrating Eq. (2) we get

$$P_1(t) = \exp\left(-\int_0^t \mu_1(t)dt\right). \quad (4)$$

If μ_1 is independent of time, Eq. (4) reduces to

$$P_1(t) = \exp(-\mu_1 t). \quad (5)$$

In this case the frequency distribution curve is written as:

$$q_1 dt = -\frac{dP_1}{dt} dt = \mu_1 \exp(-\mu_1 t) dt. \quad (6)$$

Next, let us take the same approach for Stage 2. The treatment is quite similar as for Stage 1 except the following notations instead of μ_1 , q_1 and P_1 respectively and time is measured from the initiation of the accelerating creep.

$\mu_2(t)dt$ = the probability that the crack will occur in the next interval of time dt , provided it has not occurred already, and
 $P_2(t)$ = the probability that the crack has not occurred at time t .

The same formulae are obtained as Eq. (1), (2), (3), (4), (5) and (6) with μ_2 , q_2 and P_2 instead of μ_1 , q_1 and P_1 respectively. Logarithms of P_1 and P_2 were plotted against t_1 and t_2 , respectively, for each applied stress and temperature. Examples of $\log P_1$ versus t_1 ,

and $\log P_2$ versus t_2 plots are presented in Fig. 7. In all cases, $\log P - t$ plots may be approximated with straight lines except the initial portion corresponding to larger value of P . The averaged value $\bar{\mu}_1$ and $\bar{\mu}_2$ of μ_1 and μ_2 over the range of scatter of t_1 and t_2 were deter-

(a)

(b)

(c)

Fig. 7. The curve of $\log P - t$.

○, ● and ● denote t_1 , t_2 and t_3 , respectively.
 P = the probability of non-fracture.

mined assuming the linearity of $\log P_1 - t_1$ and $\log P_2 - t_2$ plots respectively. The values of $\bar{\mu}_1$ and $\bar{\mu}_2$ obtained were plotted against reciprocal of absolute temperature T for each constant stresses as shown in Fig. 8. It appears that $\bar{\mu}_1$, $\bar{\mu}_2$ and T may be approximately related by:

$$\bar{\mu}_1 = C_1 \exp(-U_1/RT) \quad (7)$$

and

Fig. 8. The relation of $1/T$ to μ_1 and μ_2 .
 T =absolut temperature

$$\bar{\mu}_2 = C_2 \exp(-U_2/RT) \tag{8}$$

where R is gas constant, C_1 , C_2 , U_1 and U_2 are constants. Eqs. (7) and (8) are of the same type as the rate in rate process, and U_1 and U_2 are regarded as activation energy. U_1 and U_2 can be determined from the tangent of the straight line in Fig. 8. In the range

Fig. 9. The relation between activation energy U and stress level.

of 24.0 Kg/mm²~25.0 Kg/mm², U_1 and U_2 are 22.5~24.0 Kcal/mol. and 20~21 Kcal/mol. respectively. If U_1 and U_2 are plotted against stress as shown in Fig. 9, it appears that there is linearity between activation energy and stress. It is interesting that the straight lines can be extrapolated to pass through the value

of 39.4 Kcal/mol., which is nearly equal to the activation energy of the creep of the same material obtained by one (Ohara) of the authors⁹⁾, or of the other pure copper¹⁰⁾.

The same approach was also applied assuming a whole process including Stage 1 and 2 as a Markoff process—dynamic statistical process. In this case, μ , q and P are used instead of μ_1 (or μ_2), q_1 (or q_2) and P_1 (or P_2). $\log P-t$ plot appears also to be linear as shown in Fig. 7. $\bar{\mu}$ determined by the same procedure has also approximately the same type as the rate in rate process as shown in Fig. 10. That is, we get:

$$\bar{\mu} = C \exp(-U/RT) \tag{9}$$

where R , T , U and C have the same meaning as Eqs. (7) and (8). Hence it can be seen that a whole process may be at least formally well explained as a single rate process. This may be due to the fact that each of Stage 1 and 2 is a rate process and activation energies and stress dependence in both proprocess are almost equal respectively as seen from Fig. 9. If $\bar{\mu}$ is assumed to be approximately almost independent of time, then frequency distribution curve, qdt , of fracture time t_3 is given by the same type of equation as Eq. (6). On the other hand, Eq. (6) if approximated with log normal distribution function. In this sense, the scatter of creep fracture

time may assume log normal distribution. It can be seen from Eq. (9) that the scatter of time for fracture is smaller, the higher the temperature for constant stress and the higher

(6) Since in the present case activation energies and the stress dependence in both rate processes are almost equal respectively, the whole process can approximately be expressed by a single rate process with the same activation energy.

(7) The following characteristic of scatter in creep life may be explained.

(i) The scatter of creep fracture time is of a log normal type of distribution, and

(ii) the scatter of creep life becomes smaller, the higher the temperature for constant stress and the higher the stress for constant temperature.

Fig. 10. The relation of $1/T$ to $\bar{\mu}$.

the stress for constant temperature, since the variance D^2 of time for fracture is expressed by $1/\bar{\mu}^2$ in this case.

§ 7. Conclusion

Creep fracture tests on OFHC copper wire at 24.0 Kg/mm²~25.0 Kg/mm² and 8°C~40°C have been carried out and the results were statistically analysed. In the present case creep fracture process was divided into the following two stages: Stage 1, from the instant of load application to the initiation of accelerating creep, the period of which is denoted by t_1 ; and Stage 2, from the initiation of accelerating creep till fracture, the period of which is denoted by t_2 . Then,

(1) Both of Stage 1 and 2 appear to be of statistical nature.

(2) Creep fracture process may be assumed as statistically at least two successive events of Stages 1 and 2, each of which is regarded as a Markoff process—dynamic statistical process.

(3) Creep fracture is not accurately described as a single process as usually treated.

(4) Each of Stage 1 and 2 is considered as a kind of rate process.

(5) The scattering of t_1 and t_2 can be interpreted as associated with a Markoff process—dynamic statistical process which is identified with a rate process.

A Method for Measuring the Dynamic Viscosity & Dynamic Rigidity of Visco-elastic Liquids I.

Ali Abdel Kerim Ibrahim

*Physics department, Faculty of Science,
The University, Alexandria, Egypt*

(Received November 19, 1957)

Consider a viscoelastic liquid of dynamic viscosity η_D in gm. cm.⁻¹ sec.⁻¹ dynamic rigidity N in dyne cm.⁻² is filling the annular gap between two coaxial cylinders. The outer cylinder (of inner radius b incm.) is oscillating through very small angles about 1° at various frequencies n in sec.⁻¹, the inner cylinder (of radius a in cm., length of immersion L in cm. and moment of inertia I in gm. cm.²) is suspended by a delicate wire of torsion constant τ in gm. cm.² sec.⁻².

If θ_0 is the angle of deflection of inner cylinder and ϕ_0 is that of the outer, then¹⁾,

$$|\psi|^2 = \frac{e^{8d/R} |\gamma|^2}{e^{8d/R} |\gamma|^2 + 4\gamma^2 \omega^2 d^2 - 4dN[\gamma(1+3d/R) + \rho d]} \quad (1)$$

where,

$$|\gamma|^2 = \left(\frac{N}{\omega}\right)^2 + \eta_D^2$$

$$d = \frac{b-a}{2}$$

$$R = \frac{b+a}{2}$$

$$\omega = 2\pi n$$

$$\gamma = \frac{I\omega^2 - \tau}{K\omega^2}$$

$$K = 2\pi L a^3$$

and,

$$\psi = \theta_0 / \phi_0.$$

After some rearrangement equation (1) becomes,

$$e^{6d/R} [\psi^{-2} - 1] |\gamma|^2 = -4dN[\gamma(1+3d/R) + d\rho] + 4\gamma^2 \omega^2 d^2 \quad (2)$$

Then, if ω is kept constant while the dimensions of the apparatus were varied then, ψ also varies and two equations are obtained. From these two equations the dynamic rigidity and dynamic viscosity can be determined.

A calculation of data on the rheometer as used

for viscoelastic liquids follows. Using the symbols defined previously, the constants (Using Oldroyd apparatus and results (2)) have the following values.

i) First case apparatus dimensions.

$$R = 2.1462 \text{ cm.} \quad d = 0.025 \text{ cm.}$$

$$I = 2677 \text{ gm.cm.}^2$$

$$\gamma = 1.294 \text{ gm.cm.}^{-2} \quad n = 2.5 \text{ sec.}^{-1}$$

$$\tau = 2.79 \times 10^6 \text{ gm.cm.}^2 \text{ sec.}^{-2} \quad L = 25.4 \text{ cm.}$$

With a mixture of poly (methyl methacrylate) and pyridine at 25°C (density 0.98 gm./ml.) in the rheometer, the value of ψ is 0.91.

Now equation (2) becomes,

$$1.902|\gamma|^2 = 0.5853N + 19.87 \quad (3)$$

ii) Second case of apparatus dimensions.

$$R = 2.1207 \text{ cm.} \quad d = 0.0505 \text{ cm.}$$

$$I = 2468 \text{ gm.cm.}^2$$

$$\gamma = 1.2445 \text{ gm.cm.}^{-2} \quad n = 2.5 \text{ sec.}^{-1}$$

$$\tau = 2.79 \times 10^6 \text{ gm.cm.}^2 \text{ sec.}^{-2} \quad L = 25.4 \text{ cm.}$$

With the same liquid in the rheometer the value of ψ is 0.39 and that equation (2) becomes,

$$6.411|\gamma|^2 = 1.316N + 94.17 \quad (4)$$

From equations (3) & (4), the value of N & η_D can be determined, the results are,

$$N = 41.33 \text{ dyne cm.}^{-2}$$

$$\eta_D = 4.03 \text{ Poise.}$$

Table (I) gives the values of the dynamic viscosity and dynamic rigidity of a mixture of poly (methyl methacrylate) and pyridine at various frequencies.

Table I.

n in sec. ⁻¹	η_D in Poise	N in dyne cm. ⁻²
2.5	4.03	41.33
3	3.606	54.68
4	3.224	59.17
10	2.13	80.55

Magneto-resistance Effect in Cadmium Sulphide

By Shōji TANAKA and Taizō MASUMI

Department of Applied Physics
University of Tokyo, Tokyo, Japan

(Received December 27, 1957)

At present, a little knowledges¹⁻⁶⁾ have been given about the electronic energy band structures in cadmium sulphide single crystals, though the photoconductive properties have been largely investigated. Kroeger et al.^{1,5)} have measured the Hall effect in several impurity-doped conducting crystals and photoconducting crystals for the temperature range from 20°K to 700°K. The present work reported here is the measurement of magneto-resistance effect in impurity-doped cadmium sulphide single crystals at several temperatures.

The samples used for the experiment are the conducting flaky CdS single crystals doped with Ga or Cl or with excess-Cd that have hexagonal crystal structure being of Wurtzite lattice type. The *c*-axis of the crystal lies in the flaky surface and the surface is perpendicular to one of the three *a*-axes. The sizes of thin flake specimens are the order of 4 mm × 2 mm × 0.1 mm and the electrodes are indium-melted ones forming good ohmic con-

Fig. 1

Fig. 1. $(\Delta\rho)_H/\rho$ versus H in CdS-Ga at 160°K for the fixed direction of I $[0\bar{1}\bar{1}0]$ and H $[2\bar{1}\bar{1}0]$.

Fig. 2

Fig. 2. $(\Delta\rho)_H/\rho H^2$ versus θ in CdS-Ga at 160°K for the fixed direction of I $[0\bar{1}\bar{1}0]$ with $H=7500$ gauss.

tacts. Measurements have been made of relative changes of resistivity due to magnetic field H , $(\rho - \rho_0)/\rho_0 = (\Delta\rho)_H/\rho$, as a function of magnetic field strength H and the angle θ between the current I (or the direction of the fixed axis in some cases) and H at several temperatures. Some examples of the experimental results, the relation between $(\Delta\rho)_H/\rho$ and H for the I -direction $[0\bar{1}\bar{1}0]$ (perpendicular to the *a*-axis said above and also to *c*-axis) and H -direction $[2\bar{1}\bar{1}0]$ (parallel to the *a*-axis said above and perpendicular to *c*-axis) at 160°K and

the angular dependence of $(\Delta\rho)_H/\rho H^2$ upon θ at the same temperature, are illustrated in Fig. 1 and 2 for a Ga-doped crystal, where θ is the angle between the I -direction $[0\bar{1}\bar{1}0]$ and H -direction on the curve (a) in Fig. 2, while, on the curve (b), it is the angle between the direction $[0001]$ (parallel to *c*-axis) and H -direction with the rotation axis $[0\bar{1}\bar{1}0]$.

Fig. 3. $(\Delta\rho)_H/\rho H^2$ versus θ in CdS-Cd at 180°K for the fixed direction of I $[0001]$ with $H=4900$ gauss.

Similar example for the I -direction $[0001]$ in a crystal with excess-Cd at 180°K is shown in Fig. 3. No appreciable differences between the results obtained for the CdS-Cd crystals and those for the CdS-Ga and CdS-Cl crystals have been observed. The absolute values of $(\Delta\rho)_H/\rho H^2$ in this case are much smaller than those for the I -direction $[0\bar{1}\bar{1}0]$, and the angular dependence in Fig. 3 presents different appearances from that in Fig. 2 (a).

The general features of the $(\Delta\rho)_H/\rho$ versus H^2 relation shows good proportionality below 8×10^3 gauss in both cases. Temperature dependence of $(\Delta\rho)_H/\rho H^2$ for the fixed configuration and the results of Hall effect measurement⁶⁾ also support that the impurity scattering for electrons has not always a predominant effect in our observations. The angular dependences in Fig. 2 and 3 suggest the existence of anisotropic energy surfaces of conduction band in hexagonal cadmium sulphide although the correction of $(\Delta\rho)_H/\rho H^2$ for the transverse magneto-resistance effect in short samples⁷⁾ also must be considered in the case of the curve (b) in Fig. 2.

Further investigations are now in progress and they are likely to give some informations about the problem.

Absorption Lines in the Antiferromagnetic States of $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{MnBr}_2 \cdot 4\text{H}_2\text{O}$

By Ikuji TSUJIKAWA
*The Research Institute for Iron,
Steel and Other Metals
Tohoku University, Sendai*
(Received January 13, 1958)

When paramagnetic salts become antiferromagnetic, we can expect polarization and energy shift of the absorption spectrum. We have chosen the monoclinic crystals of $\text{MnCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{MnBr}_2 \cdot 4\text{H}_2\text{O}$ as the Néel temperatures of these salts are easily attainable (1.6°K and 2.2°K respectively^{1,2}).

Furthermore the Mn^{2+} ions have line shape absorptions. We measured the violet doublet absorption between 20°K and 1.4°K with a grating spectrograph with $2.5\text{\AA}$ per mm dispersion.

We ascertained that there is no phase change at T_N by observation with parallel light and crossed Nicols. In Table I, the relative intensities of V_1 and V_2 (designated from the longer wave length side) at different temperatures are shown. There are anisotropies in both salts, especially in bromide. In the case of L (incident light) $\parallel a$, E (electric vector of L) $\parallel c'(c' \perp a, b)$ and in the case of $L \parallel b$, $E \parallel c'$, we obtain similar polarization so that these absorptions are caused by electric dipole.

The measured oscillator strength is the order of 10^{-8} . Above and below T_N , we find remarkable

Table I. Relative intensities of V_1 and V_2 .

Salt	MnCl ₂ ·4H ₂ O						MnBr ₂ ·4H ₂ O					
Temp.	20°K		4,2°K		1,4°K		20°K		4,2°K		1,6°K	
Line	V ₁	V ₂	V ₁	V ₂	V ₁	V ₂	V ₁	V ₂	V ₁	V ₂	V ₁	V ₂
<i>L</i> <i>b</i> , <i>E</i> <i>a</i>	4	5	4	6	4	2	40	40	40	40	25	15
<i>L</i> <i>b</i> , <i>E</i> <i>c'</i>	5	6	5	4	10	3	9	10	10	8	20	2
<i>L</i> <i>a</i> , <i>E</i> <i>b</i>	3	5	3	4	4	6	2	6	4	6	5	0

changes of polarization. In the antiferromagnetic state V_2 becomes very weak relative to V_1 . This should not occur, if the excited state consists of two orbital components originating from $^4E^{(3)}$ and it is probable that these are the crystalline Stark components $\pm 3/2, \pm 1/2$ of ^4A . In Fig. 1, temperature dependence of the wave number of V_1 and V_2 is shown. Both lines shift to the shorter wave length when temperature lowers in the neighbourhood of T_N .

Below T_N , both the ground and excited states should be in the molecular field which causes the splitting of spin components in each state. Firstly we assume that the $\pm 3/2$ component is lower in the excited state and the g -value is 2. From Henry's magnetization data, the measured molecular field at 1.4°K in chloride is $9,000\phi$ and at 1.6°K in bromide is $16,500\phi$. These molecular fields cause splittings $0.84\text{ cm}^{-1}, 1.54\text{ cm}^{-1}$ respectively between two neighbour components $M_s, M_s \pm 1$. From these considerations, we can expect that V_1 and V_2 shift to shorter wave length by 0.84 cm^{-1} or 1.54 cm^{-1} . The measured shifts are in good accordance with such expectation. For the polarization, if we assume the b axis as the preferred axis and that transition moments do not

vary above and below T_N and take into consideration the electron population for each spin component, the calculated intensities qualitatively ex-

Fig. 1. Temperature dependence of wave number.

plain the experimental results in bromide but quantitatively there are some discrepancies.

The conclusion that the preferred axis is the b

axis is in accordance with the antiferromagnetic resonance experiments⁴⁾. However, in chloride, augmentation of intensity of V_2 at $1.4^\circ K$ in the case of $L//a$, $E//b$ is anomalous and we cannot explain this fact.

Magnetic After-Effect Due to Quenched-in Vacancies in Nickel

By Yoji NAKAMURA

Faculty of Science, Kyoto University

and Jin-ichi TAKAMURA

Department of Metallurgy, Kyoto University

(Received December 10, 1957)

The purpose of this note is to describe the contribution of non-equilibrium point defects to the magnetic property of metals. For detecting the effect, the magnetization intensity measurements were made with astatic magnetometer in the magnetic field corresponding to the range of initial permeability. In order to introduce point defects into a metal, quenching from high temperatures was done, since it has some merit in creating in abundance only one kind of point defects, i.e. vacancies. If the magnetic property is influenced by quenched-in vacancies, it may be expected that the magnetization intensity in the quenched specimen would change its magnitude in the recovery process which tends to maintain thermodynamical equilibrium by eliminating excess vacancies.

The specimen used for the experiment was nickel, which is most stress-sensitive due to its large magnetostriction. Quenching was done by the method of allowing the nickel wire (99.98% of purity, 2 mm dia) to drop into the iced-brine bath of $-10^\circ C$. Specimens were set in the earth magnetic field in such a way that the torque due to the quenched specimen was compensated by the torque of well annealed specimen. The change in the magnetization intensity of the quenched specimen was measured at room temperature.

Some of the results are shown in Fig. 1. The rate of the change is maximum initially, and then decreases with continued recovery. The change went to completion at room temperature in about ten days or more. With increasing the quenching

temperature, the amount of the change increased, as expected from the concentration of frozen-in vacancies.

The observed change of magnetization intensity with time runs in parallel to that of volume during the corresponding period (Fig. 2). The volume change is attributable to the disappearance of excess vacancies and it was deduced from the contraction in length¹⁾.

Fig. 1. Increase in magnetization intensity, ΔI , in Ni as a function of recovery time, after quenching. T_q is the quenching temperature, T_r the recovery temperature.

Fig. 2. Volume change as a function of recovery time in Ni, after quenching.

These effects could not be observed in well annealed specimens. Hence it may be safely said that the magnetic effect would be ascribed to the elimination of excess vacancies and not to the after-effect of thermal fluctuation²⁾. In conclusion, the large increase of the magnetization intensity we observed may not be understood by the change in intrinsic magnetization due to the volume change obtained during the recovery, but it is to be interpreted in terms of domain boundary displacements.

The authors wish to express their hearty thanks to Professor H. Takaki for his interest in this work and to Dr. N. Kawai who kindly lent them the astatic magnetometer and gave valuable discussions.

Electrical Properties of Ag_2Se

By Shin-ya MIYATANI

Department of Physics, Faculty of Science,
Niigata University

(Received December 11, 1957)

Ag_2Se has similar electrical properties to those of Ag_2S or Ag_2Te about which we have already reported^{1,2)}. Using the same experimental method with that described there, the electronic conductivity, σ_e , ionic conductivity, σ_i , Hall constant, R , thermoelectric power, Θ , and Nernst coefficient, Q , can be measured as functions of the e.m.f., E , of the galvanic cell $\text{Ag}|\text{AgI}|\text{Ag}_2\text{Se}|\text{Pt}$ or the deviation from the stoichiometric composition.

Now, Fig. 1 shows $\log \sigma_e$, $\log R\sigma_e$, Θ/k , and Q vs eE/kT in the $\alpha\text{-Ag}_2\text{Se}$ (stable above about 140°C). Since the values of eE represent the position of the Fermi level relative to that in an Ag-saturated composition, these plots can be compared with the theoretical curves; $\log F_r$, $\log (F_{2r-1/2}F_r^{-1})$, $(2+r)F_{r+1}(1+r)^{-1}F_r^{-1}-\eta$, and $ke^{-1}R\sigma_e((r+2)F_{r+1}(r+1)^{-1}F_r^{-1}-(2r+3/2)F_{2r+1/2}(2r+1/2)^{-1}F_{2r-1/2})$ vs $\eta^{3,4)}$ respectively, where η is the reduced Fermi energy and related to eE/kT by $\eta=\eta_s(T)-eE/kT$

($\eta_s(T)$ is η in Ag-saturated Ag_2Se), $F_r=\int_0^\infty x^r(1+\exp(x-\eta))^{-1}dx$, and the mean free path of conduction electron, l , is assumed to be expressed as $l=l_0(e/kT)^r$ (ϵ is the kinetic energy of conduction electron). Adjusting the origins of the experimental and theoretical graphs, the fitness between them is tested. Fig. 1 shows that the theoretical curves for $r=0$ fit fairly well with experimental plots except Θ . Thus, assuming $r=0$, we obtain l_0 and the effective mass of conduction electron as $244\text{\AA}$ and $0.174m$ at 170°C , $227\text{\AA}$ and $0.174m$ at 220°C , and $202\text{\AA}$ and $0.184m$ at 280°C respectively.

Further, the concentration of the excess Ag relative to a certain composition, N , is known from the quantity of electricity sent across the galvanic cell $\text{Ag}|\text{AgI}|\text{Ag}_2\text{Se}|\text{Pt}$. The R^{-1} vs eN plots show that they are related to each other by a simple equation; $R^{-1}=eN+\text{const}$. Adjusting the additive constant, we have $R^{-1}=eN_a$ where N_a can be regarded as the concentration of excess Ag over the stoichiometric composition. Since R^{-1} is equal to en (n : carrier concentration) in a highly degenerate case like the present one, we have $n=N_a$. The numbers added to the equi-Ag/Se ratio lines in Fig. 1 are such eN_a -values in C cm^{-3} . By the way, the contribution of hole is not too large even at the maximum of E where the evaporation of Se begins to take place.

On the other hand, the ionic conductivity, σ_i , is obtainable from the relaxation time, τ , of the io-

nic polarization effect with the use of the equation; $\sigma_i=L^2/(\pi^2\tau|dE/d(eN)|)^{2)}$ where L is the total length of the specimen. The measurements of τ show that σ_i is independent of the composition since $\tau dE/d(eN)$ is independent of E . Thus we obtain σ_i as $3.6\Omega^{-1}\text{cm}^{-1}$ at 220°C and this value slightly increases with increasing temperature.

Fig. 1. $\log \sigma_e$, $\log R\sigma_e$, Θ/k , and Q vs eE/kT in $\alpha\text{-Ag}_2\text{Se}$. The degeneracy is high as shown by the positions for $\eta=2$ on the upper abscissa.

Finally, in the $\beta\text{-Ag}_2\text{Se}$ (stable below about 130°C), $R\sigma_e$ decreases slightly with increasing E (it increases if $r=0$ and does not change if $r=1/2$), where the accuracy of E is poor since the σ_i 's in Ag_2Se and AgI are very small in this temperature range. Moreover the potential from the Nernst effect, V_N , is far smaller than that from the Righi-Leduc effect, V_R ($V_N/V_R \approx 1/2$ if $r=0$ and $V_N=0$ if $r=1/2$). These facts suggest that the scattering mechanism in the β phase is different from that in the α phase and r may be rather near to $1/2$ than to 0 . Assuming $r=1/2$, the mobility and effective mass of conduction electron are obtained as $810\text{ cm}^2\text{ sec}^{-1}\text{ volt}^{-1}$ and $0.11m$ at 130°C respectively. By the way, such a change of r at the α - β transition takes place also in Ag_2Te and will be reported in near future.

The Effect of G-P (1) and G-P (2) Aggregates on the Plastic Deformation of an Age-Hardenable Al-Cu 4% Alloy

By Keisuke MATSUURA,
Hokkaido Gakugei Univ.

Sôichi IZUMI and Shigeyasu KODA
Hokkaido Univ.

(Received December 3, 1957)

The authors previously reported that the effect of G-P (2) or G-P (1) aggregates on the plastic deformation was different from that of the precipitates of θ' phase according to the experiment on Al-Cu 4% alloys aged at 160°, 200° and 240°C, respectively¹⁾. To clarify the effect of G-P (1) and G-P (2) more particularly the authors have examined the stress-strain curves and slip patterns of the specimens aged at 130°C. At this temperature of ageing, the age-hardening occurs in two stages separated by a flat plateau of constant hardness. The initial rise and flat plateau are attributed to the formation of G-P (1) aggregates and the second rise is mainly due to the formation of G-P (2)²⁾. At the peak hardness, besides the G-P(2) aggregates, about 5-10% of the total possible θ' phase may be formed, however its contribution to the hardness seems to be negligible.

In the present experiment, polycrystalline wires of 1 mm. diameter for tensile testing, and strips of 1 mm. thickness for the observation of slip patterns were prepared. They were solution-treated for 30 min. at 530°C, air-quenched on a sheet of

iron and then aged at 130°C for various periods. To eliminate the effect of the formation of G-P (1) during plastic deformation³⁾, the tensile testing was carried on in liquid nitrogen (Fig. 1), however the specimens for the observation of slip patterns were stretched at room temperature (Photo. 1, 2 and 3).

In Fig. 1, the following characteristics are recognized. Although the yield strength increases appreciably with ageing, the rate of strain-hardening changes only a little during the second rise

Fig. 1. Variation of stress-strain curves at -196°C with Ageing at 130°C .

of hardness. Corresponding to this fact, there is no distinct difference in the slip patterns among the air-quenched specimen, the one aged for 12 hrs. which is hardened with G-P (1), and the one

Photo. 1. Air-quenched
($840\times 4/3$)

Photo. 2. Aged for 12
hours at 130°C ($840\times 4/3$)

Photo. 3. Aged for 9
days at 130° ($840\times 4/3$)

Photo. 1, 2, 3. Sliplines on polycrystalline Al-Cu 4% alloys after several % extension.

aged for 9 days which is hardened with G-P (2). However, the slip lines in the specimen aged for 9 days seem to be a little longer and straighter than those of the air-quenched specimen.

These results suggest that the mechanism of plastic deformation of the specimens hardened with G-P (1) or G-P (2) is almost the same as that of

the air-quenched one. Therefore, the average internal stress due to the formation of G-P zones, as proposed by Mott and Nabarro⁴⁾, is considered as an important cause of age-hardening, since the mode of plastic deformation is not necessarily affected by such hardening. This idea assumes that dislocations can pass through G-P (1) or G-P (2)

aggregates on the plastic deformation. From a calculation of Kelly and Fine⁵⁾, it seems that this assumption is reasonable.

Some Observations on Germanium Bi-crystals

Makoto KIKUCHI and Sigeru IIZIMA

Electrotechnical Laboratory, Tokyo, Japan

(Received January 11, 1958)

It has been tried to make germanium bi-crystals with two single crystal seeds. A pulled bi-crystal is shown in Fig. 1. In this case, the seeds are $[111]$ and $[100]$, one of whose $\langle 110 \rangle$ edges are arranged to be nearly parallel.

The crystal was sliced into wafers of 2 mm in thickness perpendicular to the axes. Fig. 2 and

Fig. 1. A pulled bi-crystal.

3 show the slices after being etched with superoxol. The same slices are shown in Fig. 2 and 3 with different angles of illumination, since it is not possible to make all regions to be apparent by only one illuminating condition. The slices from the top towards the bottom of the crystal correspond to the slices of upper-left to lower-right in the figures.

In the crystal illustrated, unexpected third crystal originated at the joint of the $[100]$ $[111]$ grain boundary and the crystal periphery, as shown in Fig. 4. Though the direction of this third crystal is

not yet defined, it is seen from the figures that this axis becomes predominant as the crystal is grown up and finally pushes out the $[100]$ region.

It has been observed in other $[100]$ $[111]$ bicrystals, that the relative predominance of $[100]$ and $[111]$ in the growth of bi-crystals depends on the relative orientation of these two crystal axes.

Fig. 2. Slices of bi-crystal.

Fig. 3. Slices of bi-crystal.

Fig. 4.

Fig. 5.

Fig. 6.

When $[111]$ and $[100]$ are contacting with $\langle 110 \rangle$ edge at the boundary, and the etched pattern is as shown in Fig. 5, $[111]$ crystal becomes predominant over $[100]$ as the crystal is grown. On the other hand, in the case of Fig. 6, ($[111]$ axis is rotated 180°) $[100]$ crystal becomes predominant over $[111]$.

The Consecutive Observations on the Twin Intersections

By Hiroshi KIH0

Department of Physics, Kyoyo-bu,
Kyoto University

and Saiyu MARUYAMA

Department of Physics,
Osaka Women's University

(Received December 7, 1957)

Differing from the intersections of slip lines, it is not easy to distinguish between the crossing and the crossed twins, because the misfits of the twin bands are not the direct result of the shear of the crossing twins. The interpretations of the intersections in α -U¹⁾, in Zn²⁾, in β -Sn³⁾ and in Ti⁴⁾ have all been made on the pictures already intersected. In our previous work³⁾, to decide between the crossing and the crossed twins and to determine the modes of strain accommodation, we took up all the possible cases of intersection satisfying our criterion, and classified the pictures into these cases. Here, instead of the said method, we carried out the consecutive observations on the course of twin intersections in Bi, and observing directly the crossing and the crossed twins, confirmed our criterion on the modes of strain accommodation.

The specimens were prepared in the form of a thin strip ($1 \times 1.5 \times 15$ mm) by cleaving off from mother Bi single crystals. Their axes were in the direction of $[1\bar{1}0]$. The twin lamellae developed consecutively by pressing the specimen on the outer surfaces of metal rings with varying curvatures, or by pressing the centre of the specimen by a screw keeping the ends fixed.

When a twin band (110) crosses another, (101), which was formed prior to (110), it sometimes splits into two secondary twins, (110)_t and (011)_t, in the crossed twin (101) (Plate 1). (Here subscript *t* means that the indices are referred to the crystal axes within the crossed twin.) The former (110)_t is a mirror-image of the crossing twin (110), and the trace of (110)_t coincides with that of the said crossing twin in the K_1 plane of the crossed. While the latter (011)_t is the other secondary twin, and the trace of which does not coincide with that of the crossing twin (110) in the K_1 plane of the crossed. Each of them contributes to the strain accommodation. It is understandable by adding the effect of the surface to our previous criterion³⁾.

Several facts were disclosed in addition by the consecutive observations on the cleavage surfaces. The following **A** and **B** show, respectively, the crossing and the crossed twins.

(1) When the angle between the crystal surface and **B** is acute (Plate 2, "X" region), **A** is stopped by **B** and it grows with tapering. The accommodation kink appears above the intersection line of **A** and **B**. This, together with the tapering of **A**, accommodates the strain. On the other hand, when the angle between them is obtuse (Plate 2, "Y" region), **A** broadens without tapering, the accommodation kinking does not occur because of the lack of the intersection line of **A** and **B** in "Y", but the secondary twin (110)_t and sometimes the secondary twin (011)_t and basal slip (111)_t appear in **B** to accommodate the residual strains (Plate 1).

Plate 1. $\times 200$ Plate 2. $\times 220$

←→ Specimen axis

Plate 3. $\times 240$ Plate 4. $\times 180$

(2) The broadness of the twin bands has nothing to do with the determination of **A** and **B**. In Plate 3, one might recognize the slender twin to be **A**, but the consecutive observations show it to be **B** having the secondary twins in it.

(3) The apparent penetration of **A** into **B** by a short distance is due to the result of the boundary movement of **B** after **A** has been stopped (Plate 2). This mechanism often results in the misfit of **B**.

(4) When the specimen is unbent in a reverse way, untwinning of **A** accompanies untwinning of the secondary twin, and untwinning of **B** does not accompany that of the secondary twin (Plate 4).

The authors express their cordial thanks to Prof. K. Tanaka, Kyoto University, for valuable advices and constant encouragement.

Microwave Spectrum of Hydrazine

By Takeshi KOJIMA

Department of Liberal Arts.

Toyama University, Toyama

Hiromasa HIRAKAWA and Takeshi OKA

Department of Physics, Tokyo University,
Tokyo

(Received January 16, 1958)

The microwave spectrum of hydrazine N_2H_4 was observed in the frequency range from 4.7 to 30 kMc/sec. About two hundred lines were found, all exhibiting quadratic Stark effects. Their fre-

quencies f and intensities I were listed in Table I. The spectrum is complicated by the internal rotation of one NH_2 group with respect to the other and further by the inversion of each NH_2 group similar to that occurring in ammonia and methylamine. For some lines the hyperfine structures due to the electric quadrupole coupling of two N nuclei with the overall and internal rotation of the molecule were found.

Stark effects were observed for stronger lines and the numbers of resolved components n are shown in the last column of Table I. Fairly large number of lines were found to show no splitting in spite of the Stark shift of about 10 Mc/sec at the electric field of 2000 volt/cm.

On the Low Lying Levels of Mn⁵⁵

By Sadaaki YANAGAWA

*Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo*

(Received December 24, 1957)

In this calculation of the low lying energy levels of Mn⁵⁵, the same treatment as in our previous note¹⁾ is extended from the standpoint of the configurational mixings. One assumes that the potential between nucleons is $V(r_{12})[1+a(\sigma_1 \cdot \sigma_2)]$: $V(r)=V_0 e^{-r^2/r_0^2}$, and the wave functions are the harmonic oscillator type due to Talmi²⁾. λ is the ratio of the potential range r_0 to $1/\sqrt{\nu}$ which determines the extension of the wave function. The values of a and λ are determined from the experimental data of the energy splittings of the $J=0, 2$ and 4 levels for Fe⁵⁶. And for these values of parameters, the competition of the low lying levels $J=7/2, 5/2$ and $3/2$ for Mn⁵⁵ is discussed.

§ 1. Introduction

In a previous note¹⁾, we have discussed about the difference of the ground state spin of Mn⁵⁵ and Ti⁴⁷. In this case, the important feature is the fact that the ratio of the energy splitting of the 1st to the 2nd excited state measured from the ground state for Fe⁵⁶ and Ti⁴⁸ are abnormally small. We have assumed that the ground configuration for protons of Fe⁵⁶ and for neutrons of Ti⁴⁸ are $(f_{7/2})^2$ and the states of neutrons of Fe⁵⁶ and of protons of Ti⁴⁸ are frozen to the $\{(j)^2: 0\}$ states. The configurations for protons of Mn⁵⁵ and for neutrons of Ti⁴⁷ are taken as $(f_{7/2})^3$. Other kinds of nucleon group can be handled similarly. As is shown in the reference (1) the $J=5/2$ state is the lowest one. But the fact that the $J=3/2$ state lies at the position just above $7/2$ level, is not in good agreement with the experiments. Some improvement is necessary.

It is questionable whether the freezing one kind of nucleon group in even-even nuclei to the seniority zero state is good or not. However, we have here tried to improve the results quantitatively from the standpoint of the configurational mixings, and examined to see how far this treatment is near the truth.

The method of the configurational mixing for Fe⁵⁶ is completely analogous to the one used in the calculation for Ca⁴² by Komoda and the author³⁾. We assume as in the reference (3) $V(r_{12})[1+a(\sigma_1 \cdot \sigma_2)]$ for the two body nuclear potential, where $V(r)$ is Gaussian potential $(=V_0 \times e^{-r^2/r_0^2})$, r_0 the potential range parameter). We used as before the harmonic

oscillator wave function for the nucleon state function, the radial part of which is defined by

$$R_{nl}(r) = N_{nl} e^{-(\nu/2)r^2} r^{l+1} L_{n+l+1/2}^{l+1/2}(\nu r^2).$$

N_{nl} is a normalization factor and L is an associated Laguerre polynomial. $\nu = \omega m / \hbar$ where m and ω are the constants contained in the Hamiltonian of the harmonic oscillator

$$\mathcal{H} = \frac{1}{2m} (p^2 + m^2 \omega^2 r^2).$$

The explicit expression for $L_{n+l+1/2}^{l+1/2}$ is given in Talmi's paper²⁾. The excitation energies of a single nucleon from $f_{7/2}$ to $f_{5/2}$ and $p_{3/2}$ are taken from the experimental values of the 1st and 2nd excited states of Co⁵⁷. They are 1.4 and 1.5 Mev. respectively.

§ 2. Calculation for Fe⁵⁶

For Fe⁵⁶ the proton configurations are assumed to be the mixings of $(f_{7/2})^2$, $(f_{7/2}f_{5/2})$ and $(f_{7/2}p_{3/2})$ configurations. Especially for $J=0$ state, $(f_{5/2})^2$ and $(p_{3/2})^2$ configurations are taken into account. And the part of neutrons are disregarded as in the previous note.

For several fixed values of parameters a and λ ($=r_0\sqrt{\nu}$), the secular equations are solved for $J=0, 2$ and 4 energy states for Fe⁵⁶, of which dimensions are all 3.

The ratio of the experimental energy value of $J=2$ state to that of $J=4$ for Fe⁵⁶ is about 2.46. We can determine the values of a and λ so as to make the theoretically calculated ratio coincide with the experimental one 2.46. For these special parameters a and λ , the pairing energy E_p is determined from the experimental energy value of $J=2$ state; 0.845

Mev. for Fe^{56} . The results out of our calculations which seem suitable are tabulated in Table I.

Table I.

α	λ	E_p
0.1	0.66	3.4
0.2	0.45	3.0

(E_p is the pairing energy in Mev.)

Fig. 1.

Fig. 2.

For $\alpha=0.1$ and 0.2 , the energy diagrams are plotted against λ in the figures. If α becomes large (for example $\alpha=0.3$), λ and E_p decrease ($\lambda \sim 0.3$, $E_p \sim 1.5$), and conversely as α becomes smaller than 0.1 (for example $\alpha=0$: Wigner force only), λ and E_p increase rapidly ($\lambda \sim 1.5$, $E_p \sim 9$).

§ 3. The Calculation for Mn^{55}

For Mn^{55} the proton configurations are assumed to be the mixings of $(f_{7/2})^3$, $(f_{7/2})^2 f_{5/2}$ and $(f_{7/2})^2 p_{3/2}$, and the group of neutrons are

frozen. The state functions are $\{(f_{7/2})^3; J\}$, $\{(f_{7/2})^2(J'), f_{5/2}; J\}$ and $\{(f_{7/2})^2(J'), p_{3/2}; J\}$, $J' = 0, 2, 4$ and 6 . Then the dimensions of secular equations for energy matrices are 6 for $J=7/2$ and $5/2$ and 5 for $3/2$. For the above parameter values, we have solved the equations by the usual perturbation method and obtained the lowest root of the secular equations. The results are tabulated in Table II.

Table II.

α	$E(7/2)$	$E(3/2)$
0.1	0.23	1.27
0.2	0.33	1.25

(measured from the ground state $J=5/2$ in Mev.)

§ 4. Discussions

As shown in the Table II the state $J=5/2$ is the lowest. The fact that the $J=3/2$ state lies at the position of about 1 Mev. above the ground state $5/2$, is the remarkable result, considering that among the present experimental data, there is no level up to about 1 Mev. from the ground except the $7/2$ level. The nucleus radius parameter R_0 is determined roughly from the equation $1/\sqrt{\nu} = 2.21 R_0$ by demanding that the root mean square radius of the nucleus Fe^{56} should agree with the usual formula $R = R_0 A^{1/3}$. In this way we obtain $R_0 = 1.41 \times 10^{-13}$ cm. for $\lambda=0.45$ and $R_0 = 0.96 \times 10^{-13}$ cm. for $\lambda=0.66$, if the parameter of potential range r_0 is taken as 1.4×10^{-13} cm. For the nucleus Ti^{47} too, we can treat completely in the same manner as for Mn^{55} .

Our fundamental assumption that the neutron's group is "frozen" to the lowest seniority state, might not be tenable in the theory of the shell model. Nevertheless, our calculation shows that the method of the configurational mixings gives fairly correct results. It would be of interest to see how far the results are improved by taking the higher seniority states into account.

Alpha Particles from the Interaction of 14.8-Mev Neutrons with Medium Weight Nuclei

By Isao KUMABE

Department of Physics, Faculty of Science, University of Kyoto

(Received December 25, 1957)

The angular and energy distributions of alpha particles resulting from $V^{51}(n, \alpha)Si^{48}$ and $S^{32}(n, \alpha)Si^{29}$ reactions induced by 14.8-Mev neutrons were measured with Ilford C2 nuclear plates. It was found that the angular distributions for the entire energy regions in the center-of-mass system are concave upward and approximately 90° symmetrical, and the energy distributions show that the alpha particles with energies below the Coulomb barrier are more emitted than expected. Also the curve on a semilog plot of the relative level density calculated from the energy distributions of the alpha particles fits a straight line which would correspond to Maxwellian distributions with the temperatures of about 0.9 Mev for Sc and about 1.5 Mev for Si.

The total cross sections of V and S are $126 \text{ mb} \pm 15\%$ and $109 \text{ mb} \pm 15\%$ respectively. Experimental data on (n, α) reaction so far obtained by us are summarized and discussed in detail.

§ 1. Introduction

The angular and energy distributions of the alpha particles emitted, when various nuclei are irradiated by fast neutrons, yield information concerning the basic mechanism of such interactions.

The activation cross sections were measured for many elements bombarded with 14.5-Mev neutrons by Paul and Clarke.¹⁾ They have shown that the (n, p) and (n, α) reaction cross sections for large mass number are too larger than those predicted by the evaporation theory, but the $(n, 2n)$ reaction cross sections are approximately in agreement with the theory. They suggested the existence of the non-compound process in the cases of (n, p) and (n, α) reactions. Experimental data of the angular and energy distributions on (n, α) reactions for various nuclei may give more reliable information on these problems.

Several experiments²⁻⁶⁾ have been performed to measure the density of energy levels on excitation energy. In those experiments, measurements were made of the energy distributions of neutrons and protons from reaction and inelastic scattering on various nuclei. The presence of non-compound-nucleus processes throws serious doubt on the interpretation of the results of those experiments and prompts a search for new experiments which might provide less ambiguous information about the energy level density. On the

other hand, experimental data (n, α) reactions may give more reliable information on the energy level density, since it seems improbable that alpha particles will be emitted by direct interaction.

Brady⁷⁾ has measured the angular and energy distributions of the alpha particles resulting from the (p, α) reactions for several elements at 18 Mev. However, the detailed data have not been reported.

Except for light nuclei, angular and energy distribution of the (n, α) reaction have been measured so far only for zirconium,⁸⁾ for which the angular distribution above 120° has not been measured and the energy distribution has not been reported in detail.

In previous papers⁹⁾¹⁰⁾, we have reported the angular and energy distributions of the alpha particles resulting from $Al^{27}(n, \alpha)Na^{24}$, $Co^{59}(n, \alpha)Mn^{56}$ and $Mn^{55}(n, \alpha)V^{52}$ reactions induced by 14.8-Mev neutrons. It has been found that the angular distributions for the entire energy region of particles are concave upward and approximately 90° symmetrical, and the energy distributions show that the alpha particles with energies below the Coulomb barrier are more emitted than has been expected by the evaporation theory.

In this paper the measurement extended to the target nuclei of vanadium and sulphur are reported. Since the target nuclei of the so far measured (n, α) reactions were Al^{27} ,

Co^{59} and Mn^{55} and resultant residual nuclei were limited to odd-odd, sulphur was chosen for the target element in spite of 95.06% abundance of S^{32} .

§ 2. Experimental Procedure

The experimental arrangement is shown schematically in Fig. 1. Neutrons were pro-

Fig. 1. Experimental arrangement. Al: aluminum backing holder (thickness 1 mm). Pt: platinum backing (thickness 60 mg/cm²). t: target. S: celluloid spacer (thickness 0.1 mm). E: Emulsion. G: Glass. T or T': tritium target. When the tritium target is placed in the position T, the emulsion detects alpha particles emitted in the forward direction, and when the tritium target is placed in the position T', the emulsion detects alpha particles emitted in the backward direction.

vided by the $d\text{-T}$ reaction, employing magnetically analyzed molecular deuterium of 220 Kev from a Cockcroft-Walton machine. The tritium target consisted of 0.5 curies absorbed in a 0.2 mg/cm² zirconium foil and was bombarded with a steady beam of about 100 μA . Neutron production was $\sim 5 \times 10^8$ neutrons/sec. Neutron flux was monitored by a modified Mc Kibben¹¹⁾ BF_3 proportional counter which had been calibrated by an argon-filled proportional counter counting the accompanying alpha particles from the $T(d, n)\alpha$ reaction. The argon-filled counter was placed at 90° direction with respect to the beam.

The targets of vanadium and sulphur were vacuum evaporated onto halves of platinum foil of thickness 60 mg/cm² which were used

to reduce the background. Target thicknesses used were 2.54 mg/cm² for V and 2.43 mg/cm² for S respectively. 1.5" $\times$ 1" Ilford C2 plates (thickness 200 μ) were used.

An incident angle of 45° for the neutrons was chosen. Advantages of incident angle 45° are as follows.

1. If neutron incidence is normal or parallel to the plane, on account of large absorption loss of particles emitted parallel to the plane, the errors arising from the correction of absorption loss increase near $\theta = 90^\circ$ or 0° and 180° , and then the uncertainty of the angular distribution increases. However, if an incident angle of 45° is chosen, the particles which are emitted parallel to the plane and suffer a large absorption loss distribute between $\theta = 45^\circ$ and 135° and then the errors arising from the correction are averaged and decrease.

2. There is a possibility that a part of tracks emitted in the direction normal to the plane may be missed in scanning, but in the case of the incident angle of 45° for the neutrons, these contribute to only a small part of the angular distribution near $\theta = 45^\circ$ or 135° .

3. The errors arising from the estimation of the shrinkage factor in the case of an incident angle of 45° is averaged over all angles and become smaller than in the case of parallel or normal incidence to the plane. The disadvantage of incident angle of 45° is that the complicated calculation is needed for the angular distribution.

In order to discriminate alpha particles from protons in the emulsion, the plates were processed by the temperature method¹²⁾ using low pH (6.6) amidol developer¹³⁾, and for the hot stage, we chose the values of 15 minutes and 18°C for the suitable time and temperature respectively after several trials. And the soaking of the emulsions in a glycerine solution to prevent their shrinkage after development significantly improved the accuracy in the measurement of the alpha tracks.

The processed emulsions were scanned using "Tiyoda" microscope and "Nippon Kogaku" microscope at magnification of 1350. Acceptance criteria required for tracks is to begin at the emulsion surface. The shrinkage factor (2.3) was obtained by measuring the horizontal and vertical components of the

lengths of Polonium alpha tracks. Data were obtained by two different observers, working in different areas of the plates. The data were analyzed separately and combined only after it was established that the two sets displayed the same general features. The background tracks were measured in the half without the target material of the emulsion. The range-energy relation in C2 plate used

was obtained from the range-energy curve of Rotblat¹⁴⁾ corrected with $Po-\alpha$.

§ 3. Results

The angular distributions in the center-of-mass system of the alpha particles from the interaction of 14.8-Mev neutrons with vanadium and sulphur for the entire energy region are shown in Fig. 2. The uncorrected

Fig. 2. Angular distributions of alpha particles from the $V^{51}(n, \alpha)Sc^{48}$ and $S^{32}(n, \alpha)Si^{29}$ reactions. The dashed lines show the observed angular distributions, while the solid lines show the corrected angular distributions.

angular distribution is divided into two energy regions, namely, a high-energy region (>6 Mev) and a low-energy region (<6 Mev), and it was found that the angular distributions for these two regions are nearly similar to each other. Therefore we assumed that the angular distributions for various energy regions are all the same. Thus the correction for the energy loss of alpha particles in the target material was carried out for the uncorrected energy distribution in Fig. 3, using the angular distribution. Then, making use of this corrected energy distribution, the cor-

rection for the absorption loss of alpha particles stopped in the target material was carried out for the uncorrected angular distribution. The final results obtained by the successive corrections are shown by the solid line in Fig. 2 and by the solid curve in Fig. 3. The procedures of the correction are presented in Appendix. The errors in Figs. 2 and 3 are the statistical errors derived from the track counts of the target and background data.

It is assumed that the relation between the measured alpha particle energy distributions

and the level densities of the residual nucleus is given by the following formula¹⁵⁾:

$$n(\varepsilon)d\varepsilon = \text{const.} \cdot \varepsilon \sigma_c(\varepsilon) \omega(\varepsilon_r) d\varepsilon,$$

where $n(\varepsilon)d\varepsilon$ = number of alpha particles emitted with energy between ε and $\varepsilon + d\varepsilon$, $\sigma_c(\varepsilon)$ ¹⁶⁾ is the cross section, including the effects of barrier penetration for a nuclear radius of $1.5 \times 10^{-13} A^{1/3}$ cm, for the formation of the compound nucleus in the same state of excitation by the reverse reaction, in which particles of energy ε strike the excited residual nucleus, and $\omega(\varepsilon_r)$ is the density of energy level of the residual nucleus at excitation $\varepsilon_r = \varepsilon_{\text{max}} - \varepsilon$. ε_{max} is the maximum energy which the emitted particle may have. Fig. 4 shows the results presented by plotting the measured energy spectra divided by $\varepsilon \sigma_c(\varepsilon)$. Except for low energy side, the data

fit a straight line which would correspond to a Maxwellian distribution with the temperatures of about 0.9 Mev for Sc and about 1.5 Mev for Si. The temperatures at the low energy side (7 Mev for Sc and 7 Mev for Si) are not included in the present discussion because of the contribution of the second alpha particles from $(n, n\alpha)$ events.

The total cross sections of V and S are 126 and 109 mb respectively. Combined systematic and statistical uncertainties are estimated to be roughly 15% in the total cross sections.

§ 4. Discussions

(1) Angular distributions

As in the cases of Al, Co and Mn, the angular distributions for the entire energy

Fig. 3. Energy distributions of alpha particles from the $V^{51}(n, \alpha) Sc^{48}$ and $S^{32}(n, \alpha) Si^{29}$ reactions. The histograms and dashed curves show the observed energy distributions, while the solid curves show the corrected energy distributions.

region in the cases V and S are also approximately 90° symmetrical and concave upward.

The (n, α) angular distributions measured by us are summarized in Fig. 5. These were obtained by least-squares fit to $A_0 + A_2P_2(\cos \theta) + A_4P_4(\cos \theta)$ weighted according to statistics. As shown in Fig. 5, all the angular distributions are concave upward and show the similar shape to each other. Thus it may be concluded that the angular distributions of the alpha particles from the interaction of 14.8-Mev neutrons with light medium weight nuclei show the above-mentioned shape.

Rosen and Stewart¹⁷⁾ have measured the energy and angular distributions of neutrons from 14-Mev neutron interactions with heavy elements, while Ahn and Roberts¹⁸⁾ have measured with Zr. Allan⁶⁾ has measured the angular distribution of protons from the interaction of 14-Mev neutrons with Cu⁶³. Their results indicated that the angular distributions of the high energy particles are strongly peaked in the forward direction and those of the low energy particles are isotropic. A marked contrast between those results and the results of the (n, α) reaction should be remembered.

Our results are expected to contain the alpha particle group from the $(n, n\alpha)$ reaction. Since the inelastically scattered neutrons from the $(n, n\alpha)$ reaction are of low energy, the angular distribution of these neutrons seems to be isotropic as the above data and consequently the angular distribution of the corresponding alpha particles seems to be also isotropic. Therefore it is considered that most of the observed deviation from isotropy are due to the contribution from the (n, α) reaction.

The approximate 90° symmetry of the angular distribution of the alpha particles indicates the fact that most of the reactions probably occur through the formation of the compound nucleus although the fairly large deviation from isotropy cannot be explained by the statistical theory of nuclear reactions¹⁹⁾. The observed deviation from isotropy may be explained by introducing a kind of selection rule for the emission of the alpha particles such as the isotopic spin selection rule²⁰⁾ or by further development of an intermediate coupling model such as proposed by

Lane, Thomas and Wigner²¹⁾.

The (p, α) reactions of several elements at 18 Mev were observed by Brady⁷⁾. He showed that the particles "evaporating" with low energy show almost isotropic angular distributions and the angular distribution of emitted fast particles is always in the forward direction. The disagreement of Brady's and ours might be due to different incident nucleons and energies.

(2) Energy spectrum and level density

As in the cases of Al, Co and Mn, the energy distributions show, in the cases of V and S too, that the alpha particles with energies below the Coulomb barrier are more emitted than expected.

The relative level densities measured by us are summarized in Fig. 6, and the nuclear temperatures in Table I. In the cases of Co (n, α) and Mn (n, α) , values averaged over

Fig. 6. Summary of the relative level densities. The dashed curves show the regions which are expected to contain the second alpha particles from $(n, n\alpha)$ events.

energy interval between 2 and 7.5 Mev of the excitation energy are listed. Gugelot⁴¹ obtained the nuclear temperature 2.7 Mev for Al(p, p) and 2.6 Mev for Fe(p, p), respectively. It is remarkable that the temperatures obtained by us are always lower than Gugelot's values.

Table I. Summary of the nuclear temperatures in Mev.

Nucleus	Na ²⁴	Si ²⁹	Sc ⁴⁸	V ⁵²	Mn ⁵⁶
Temperature	1.45	1.5	0.9	0.85	0.7

The shape of the energy level distribution determined from the 40-Mev (α, p) experiment³⁾ was compatible with the Fermi gas model density formula $\omega(\epsilon_r) = \text{const} \exp \sqrt{a\epsilon_r}$. On the other hand, the parameter a was found to have the same value for Cu, Ag, and Au. According to the Fermi gas model a should increase linearly with the atomic number.

The results of our experiment, when analyzed in terms of the statistical theory, are not compatible with the Fermi gas model for the nucleus. The experimentally measured level density increases much less rapidly at low excitation energies than the Fermi gas level density. On the other hand, in contrast to the (α, p) result, the rate of increase of level density with the excitation energy measured in our experiment increases with mass number as can be seen in Fig. 6. This is a general prediction of most nuclear model.

Ribe²²⁾ has observed the energy spectrum of disintegration particles produced by 14-Mev neutrons in argon-gas counter fillings which has two peaks. It is considered that a low energy peak is due to (n, p) reaction and a high energy peak is due to (n, α) reaction. The position of the high energy peak is about 5 Mev which is in fairly good agreement with our data in the cases of V and S.

Brady²³⁾ has observed the energy distribution of the alpha particles resulting from the Ni(p, α)Co reaction. The curve on a semi-log plot of the relative level density calculated from this energy distribution fits a straight line which would correspond to Maxwellian distribution with a temperature of about 0.6 Mev. This temperature is in fairly good

agreement with our value of Mn calculated from the Co(n, α)Mn reaction.

Allan⁶⁾ has measured the energy distribution of protons from the interaction of 14-Mev neutrons with several medium weight nuclei and suggested that the large low energy proton excess might come from the (n, np) reaction because of the reason that the emission of a second neutron is energetically impossible over most of the range of target nucleus excitation and proton emission (n, np) is in competition only with γ -emission. In our cases, however, as shown in Table II

Table II. Binding energies in Mev. These binding energies were derived from the table of Martin.²⁴⁾

Target nucleus	neutron	proton	α particles
Al ²⁷	13.73	5.96	8.05
S ³²	14.88	9.13	7.02
V ⁵¹	10.73	7.68	7.35
Mn ⁵⁶	10.96	7.18	6.64
Co ⁵⁹	11.14	6.65	6.06

alpha particle emission ($n, n\alpha$) is in competition with proton emission (n, np) because of the small difference between the alpha particle and proton binding energy, and the large low energy alpha particle excess cannot be explained by the ($n, n\alpha$) reaction only.

The evaporation of charged particles is favoured by depression of the Coulomb barrier due to the expansion of highly excited nuclei, but this effect is negligible at the temperature concerned here. Further, by introducing a choice of large nuclear radii, we may interpret the larger yield of low energy alpha particles well, but nuclear radii larger than $r_0 = 1.5 \times 10^{-13}$ cm is in disagreement with other experiments. In view of above considerations, it may be probable that the actual boundary of the nuclear potential is not a square well with sharp boundary but rather has a diffuse nuclear surface because the diffuseness of nuclear surface makes the penetration of the potential barrier easier. Recently, Kikuchi²⁵⁾ has reported in this connexion that the energy distribution of the alpha particles of the Al²⁷(n, α)Na²⁴ reaction, which gives somewhat lower temperature than those of others, can be explained with the temperature of 2 Mev by introducing a diffuse potential.

Considerable modification of the theory of Coulomb barrier penetrabilities or of the level density function of the residual nuclei, would be required to explain our (n, p) results.

(3) Cross sections

The total cross sections obtained by other authors and by us are shown in Table III.

Table III. Comparison of cross sections (mb)

Target	Present experiment		Activation methods ($n, \alpha\gamma$)			Theoretical ($n, \alpha\gamma$)
	$(n, \alpha\gamma) + (n, \alpha n) + (n, n\alpha)$	$(n, \alpha\gamma)$	Paul and Clarke	Hughes*	Yasumi	
Al	92±15	82.0±17	78.9±16	110±20	120±14.4	273
S	109±16	38.2±7.6				
V	126±19	43.2±8.6	28.6±12	30±10		4.6
Mn	96±14	39.4±8.0	52.5±7.9	30±12		4.5
Co	84±13	25.0±5.0	39.1±7.8	52± 8		3.7

* These data are summarized by Hughes and Harvey. Theoretical cross sections were derived from the calculation by Paul and Clarke¹⁾.

Column I gives the cross section of $(n, \alpha\gamma) + (n, \alpha n) + (n, n\alpha)$ reactions, while column II gives the cross sections of $(n, \alpha\gamma)$ reactions only which are compared directly with those obtained by other authors¹⁾²⁶⁾ with the activation method. When the emission of the first alpha particles leaves the residual nucleus in states with an excitation energy below neutron binding energy, only γ -ray emission can occur. Therefore when the energy distribution of the alpha particles is cut off at $(14.8 + Q - B_n) \times (A - 3)/(A + 1)$ Mev, it is possible to attribute the high energy part of the energy distribution to the $(n, \alpha\gamma)$ process, where Q is the Q value of (n, α) reaction, B_n the neutron binding energy and A the mass number of target

nucleus. Q and B_n were derived from the papers of Martin²⁴⁾, Segre²⁷⁾ and Endt *et al*²⁸⁾. Our $(n, \alpha\gamma)$ cross sections are in fairly good agreement with those obtained by other authors¹⁾²⁶⁾. Except in the cases of Al and S, the experimental cross sections are higher by a factor of about 10 than those expected from the evaporation theory. The approximately 90° symmetrical angular distributions and the low energy alpha particle excess might suggest that the large experimental (n, α) cross sections are not due to the non-compound processes but rather to the large penetrabilities which are explained by introducing a diffuse potential.

Appendix

(1) *The relation between $\sigma(\theta) \sin \theta d\theta$ and $\sigma(\varphi) \sin \varphi d\varphi$*

Assume that the target is placed on the emulsion as indicated in Fig. 1. Let θ be the angle between the lines of flight of the incoming neutron and of the alpha particle, and φ the angle between the inward drawn normal to the plate and the alpha particle direction. When an incident angle of 45° is chosen for the neutrons, $\sigma(\varphi) \sin \varphi d\varphi$ must be calculated from $\sigma(\theta) \sin \theta d\theta$, since the energy loss and absorption loss are functions of φ , where $\sigma(\theta)$ is a differential cross section per unit solid angle in the laboratory system, and $\sigma(\varphi) \sin \varphi d\varphi$ is the cross section of alpha particles emitted in the direction between φ and $\varphi + d\varphi$.

The relation between $\sigma(\theta) \sin \theta d\theta$ and $\sigma(\varphi) \sin \varphi d\varphi$ is shown in Table IV obtained by graphical calculation. Using Table IV we can calculate $\sigma(\varphi) \sin \varphi d\varphi$ from $\sigma(\theta) \sin \theta d\theta$.

(2) *The correction of energy loss for energy distribution*

The alpha particles resulting from the (n, α) reaction are produced uniformly in the target,

$$N(E)dE = \int_0^{E_0 \max} \int_0^{\pi/2} \frac{n(E_0)F(E, E_0, \varphi) 2\pi \sigma(\varphi) \sin \varphi d\varphi}{\{E_0 - f[R(E_0) - T \sec \varphi]\} \sigma_{\text{total}}} dE_0 dE$$

If, for convenience of calculation, we divide the energy and angle into 1 Mev and 10° intervals, respectively, we have

$$N(E)dE = \sum_{E_0=1,2,\dots,E_0} \int_{E_0}^{E_0+1} n(E_0) dE_0 \left[\sum_{\varphi=5^\circ, 15^\circ, \dots, 85^\circ} \frac{F(E, E_0, \varphi) 2\pi \int_{\varphi-5^\circ}^{\varphi+5^\circ} \sigma(\varphi) \sin \varphi d\varphi}{\{E_0 - f[R(E_0) - T \sec \varphi]\} \sigma_{\text{total}}} \right] dE. \quad (3)$$

Using this equation, we can calculate the corrected energy distribution $n(E_0)dE_0$ from the observed energy distribution $N(E)dE$.

(3) *Correction of absorption loss for angular distribution*

For a particle leaving the target with energy E and at angle φ , the following relation holds

since the absorption of the neutron in the target is negligibly small. If $R(E_0)$ represents the range in the material of the target of an alpha particle of energy E_0 , a particle emitted in the direction φ at the upper surface loses the energy $E_0 - f[R(E_0) - T \sec \varphi]$ before emerging from the target, where $f(R)$ is the inverse function of $R(E_0)$ and T is the target thickness. If we assume that the energy loss per unit length between E_0 and $f[R(E_0) - T \sec \varphi]$ is constant, the emerging particles distribute uniformly between E_0 and $f[R(E_0) - T \sec \varphi]$. When the number of particles emitted in the direction between φ and $\varphi + d\varphi$ with an energy between E_0 and $E_0 + dE_0$ in the target is $N(E_0, \varphi) dE_0 d\varphi$, the number of particles emerging from the target with an energy between E and $E + dE$ is given by

$$\frac{N(E_0, \varphi) dE_0 d\varphi}{E_0 - f[R(E_0) - T \sec \varphi]} F(E, E_0, \varphi), \quad (1)$$

where the function $F(E, E_0, \varphi)$ is defined by

$$F(E, E_0, \varphi) = 1$$

$$\text{for } E_0 > E > f[R(E_0) - T \sec \varphi]$$

$$= 0$$

$$\text{for } E > E_0, E < f[R(E_0) - T \sec \varphi].$$

If the number of particle emitted with an energy between E_0 and $E_0 + dE_0$ in the target is $n(E_0)dE_0$, $N(E_0, \varphi) dE_0 d\varphi$ can be written as

$$N(E_0, \varphi) dE_0 d\varphi = n(E_0) \frac{2\pi \sigma(\varphi) \sin \varphi d\varphi dE_0}{\sigma_{\text{total}}}, \quad (2)$$

using the assumption that the angular distribution for various energy regions are all the same.

Then we get, from (1) and (2), the energy distribution $N(E)dE$ for the particles emerging from the target in the form:

$$(T - T') \sec \varphi = R(E_0) - R(E),$$

where T' is the depth and E_0 the energy of a particle at the point of generation. Assuming that we omit the particle of $E < 1$ Mev from scanning, the absorption rate A' is expressed by

$$A' = \frac{T'}{T} = \frac{T \sec \varphi - \{R(E_0) - R(1)\}}{T \sec \varphi} F'(E, E_0, \varphi),$$

where the function $F'(E, E_0, \varphi)$ is defined by

$$F'(E, E_0, \varphi) = \begin{cases} 1 & \text{for } T \sec \varphi > R(E_0) - R(1), \\ 0 & \text{for } T \sec \varphi < R(E_0) - R(1). \end{cases}$$

Therefore, when the particles generated with the energy distribution $n(E)dE$ and angular distribution $\sigma(\varphi)$ emerge from the target, the absorption rate A is expressed by

$$A = \int_0^{\pi/2} \int_0^{E_0 \max} \frac{n(E_0)dE_0}{n_{\text{total}}} \left(1 - \frac{R(E_0) - R(1)}{T \sec \varphi} \right) \frac{2\pi \sigma(\varphi) \sin \varphi d\varphi}{\sigma_{\text{total}}} F'(E, E_0, \varphi).$$

If, for convenience of calculation, we divide the energy and angle into 1 Mev and 10° intervals, respectively, we get

$$A = \sum_{\varphi=5^\circ, 15^\circ, \dots, 85^\circ} \sum_{E_0=1, 2, \dots} \int_0^{E_0+1} \frac{n(E_0)dE_0}{n_{\text{total}}} \left(1 - \frac{R(E_0) - R(1)}{T \sec \varphi} \right) \frac{2\pi \int_{\varphi-5^\circ}^{\varphi+5^\circ} \sigma(\varphi) \sin \varphi d\varphi}{\sigma_{\text{total}}} F'(E, E_0, \varphi).$$

Some Studies on the Ternary System (Ba-Pb-Ca)TiO₃*

By Takuro IKEDA

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

(Received December 19, 1957)

The phase relation and the dielectric and mechanical properties of ceramic samples on the ternary system (Ba-Pb-Ca)TiO₃ are studied. The ferroelectricity of the solid solution (Ba-Pb)TiO₃ decreases with increasing Ca concentration and disappears at about 50 mole percent of CaTiO₃; and then the structure changes to cubic, pseudocubic and orthorhombic. A certain insoluble region exists in the vicinity along (Ba-Ca)TiO₃ side. The dielectric and piezoelectric constants of BaTiO₃ decrease with increasing concentration of PbTiO₃ and CaTiO₃. The dielectric and mechanical Q's vary in parallel with composition.

§ 1. Introduction

It is well-known that dielectric and mechanical properties of BaTiO₃ are varied by the addition of PbTiO₃ or CaTiO₃. Especially, ceramics of solid solutions of these materials are used for electromechanical transducers and show better properties than pure BaTiO₃ ceramics.

Structural studies on the binary system (Ba-Pb)TiO₃ have been performed by G. Shirane¹⁾ and other authors. With concentration of PbTiO₃, Curie point becomes higher, and the tetragonality increases.

The system (Ba-Ca)TiO₃ was investigated by R. C. DeVries and R. Roy²⁾, and M. McQuarrie and F. W. Behnke³⁾. The Curie point decreases gradually with increasing concentration of Ca, and there is a wide insoluble range of concentration.

E. Sawaguchi *et al*⁴⁾ reported phase relations of (Pb-Ca)TiO₃ system and indicated that the tetragonality of PbTiO₃ decreases with increasing mole percent of CaTiO₃ and disappears at about (Pb_{0.6}-Ca_{0.4})TiO₃. The phase of solid solution containing more than 40 mole percent of CaTiO₃ is prescribed as pseudocubic.

Properties of CaTiO₃ were investigated by L. W. Coughanour, R. S. Roth and others⁵⁾, and M. McQuarrie⁶⁾ and H. F. Kay *et al*⁷⁾. Kay's previous paper (which is quoted in McQuarrie's report⁶⁾) reported that CaTiO₃ has a pseudomonoclinic structure at room temperature and transitions occur at 600° and 1000°C. Roth *et al* performed complete X-ray

study and indicates that CaTiO₃ has an orthorhombic structure at room temperature; lattice parameters are $a=5.381$ Å, $b=7.645$ Å, $c=5.443$ Å and pseudomonoclinic angle is $\beta'=90^\circ 40'$. Recently, Kay⁷⁾ determined the atomic position in CaTiO₃ and it was shown to be antiferroelectric. McQuarrie studied the phase relation of system (Ca-Sr)TiO₃. He concluded that the orthorhombic structure of CaTiO₃ changes into tetragonal at 1100°C and cubic at 1200°C. Gränicher⁸⁾ studied also the system (Ca-Sr)TiO₃, and showed the existence of some other phases. But, as for the phase transition of CaTiO₃, there are some ambiguities. In the present paper, so far as CaTiO₃ is concerned, the phase transition temperatures reported by McQuarrie and the structural investigation by Roth *et al* are quoted.

As materials for electromechanical transducers, mechanical and piezoelectric properties of this system have been investigated by some authors. W. P. Mason⁹⁾ showed that the addition of PbTiO₃ to BaTiO₃ increases coercive field and decreases the temperature dependence of various properties. D. A. Berlincourt and F. Kulcsar¹⁰⁾ examined the effect of addition of PbTiO₃ or CaTiO₃. Mason¹¹⁾¹²⁾ reported subsequently the better quality of the solid solution (Ba-Pb-Ca)TiO₃. Their experiments, however, have been restricted to the vicinity of BaTiO₃.

The present studies were begun chiefly for two purposes: of examining the phase relation from the ferroelectric range to the antiferroelectric CaTiO₃, and of obtaining the systematic information on the electromechanical properties of the system.

Recently, M. McQuarrie¹³⁾ reported the

* The summary of the present report was read at the Meeting of the Physical Society of Japan, on 11th, April, 1957.

structural study on the same system. He measured dielectric properties, showed the complete phase diagram, and emphasized the evaporating loss of PbO.

The present author has independently studied this system and obtains similar diagram. Furthermore, the mechanical and piezoelectric properties of ceramics of the system are measured and systematic results are obtained.

§ 2. Experimental Procedure

(a) Preparation of Samples

The c.p. grade of BaCO_3 , CaCO_3 , PbO and TiO_2 are mixed with various mole concentration and calcined at $1200^\circ\sim 1050^\circ\text{C}$. They were crushed and pressed in the disc shape with diameter of 30 mm and thickness of 2~4 mm, and then sintered at $1420^\circ\sim 1250^\circ\text{C}$. Porosities of the samples are mostly 10~20%.

In the sintering process of those with larger Pb concentrations, the evaporation loss of PbO are not ignorable. Then, some lumps of PbO are laid in the crucible and the sintering is done in the atmosphere of PbO at lower temperature (less than 1300°). None the less, some part near surface of piled up discs of the same composition appear to be a little deficit of Pb, and so inner parts are used for samples. The compositions of samples after sintering are not examined.

In Fig. 1, the compositions (before sintering) of the tested samples are indicated by points.

Fig. 1. Tested samples of the system (Ba-Pb-Ca)TiO₃.

(b) Temperature Dependence of Dielectric Constant.

On the small square plates are glazed silver electrodes. They are immersed in the silicone oil bath and temperature is varied. The

dielectric measurement is done at 550 Kc/s by the resonance-substitution-method with a precise variable air-condenser. The temperature corresponding to a peak of dielectric constant is taken as Curie point.

(c) Dielectric and Electromechanical Measurement of Prepolarized Sample.

The ceramic discs with silver electrodes (diameter of ca. 26 mm) are prepolarized by field cooling process with d.c. fields of 5~15 KV/cm, and aged at $60^\circ\sim 80^\circ\text{C}$ for one or two days. The resonant frequencies of most of them in radial mode vibration are about 120 Kc/s.

Their dielectric quantities are measured at 50 Kc/s by the Radio Frequency Impedance Bridge of Yokogawa Electric Works at room temperature. A measured impedance is the capacity C^F and resistance R_e in series (Fig. 2 (a)). From them, free dielectric constant ϵ_3^F and dielectric Q value Q_e are computed by the following formulae:

$$C^F = \frac{\epsilon_3^F (\pi a^2)}{4\pi d} \quad \text{and} \quad \omega C^F R_e = \frac{1}{Q_e}, \quad (2.1)$$

where a =radius and d =thickness.

Fig. 2. Equivalent circuit and admittance diagram.

The piezoelectric and elastic properties are measured by the resonance curve method and admittance loop method in the radial mode vibration. By denoting the frequencies corresponding to maximum and minimum admittance as f_m and f_n , the electromechanical radial coupling coefficient k_r is calculated by

$$k_r^2 = K \frac{f_n - f_m}{f_m}, \quad K \equiv \frac{R_1^2 - (1 - \sigma^2)}{1 + \sigma} \quad (2.2)$$

where the factor $R_1=2.03$ and $K=2.51$ for a value of Poisson's ratio $\sigma=0.27^*$ (cf. Mason's book⁹⁾). k_r^2 is

$$k_r^2 = \frac{2}{1-\sigma} \cdot \frac{4\pi d_{31}^2}{s_{11}^{(E)} \epsilon_3^{(E)}}, \quad (2.3)$$

where d_{31} =transverse piezoelectric constant, $s_{11}^{(E)}$ =elastic compliance coefficient for constant electric field. The resonant frequency of the radial vibration is

$$f_0 = \frac{R_1}{2\pi a} \sqrt{\frac{1}{\rho s_{11}^{(E)}} \frac{1}{1-\sigma^2}}, \quad (2.4)$$

where ρ =density. In ordinary case, $f_m \approx f_0$. From the measured values of f_m , f_n and C^E , the piezoelectric constant d_{31} is obtained.

The mechanical Q factor Q_m of the vibrator is measured from the admittance circle: that is, by denoting the quadrantal frequencies as f_1 and f_2 (in Fig. 2(c)), the value of Q_m is given by

$$Q_m = f_0 / (f_2 - f_1). \quad (2.5)$$

In the case of the vibrator with small electro-mechanical coupling or low Q factor, the resonance curve method is unsuitable for obtaining the value of k_r^2 . Then, from the admittance diagram,

$$C/C_0 = 1/Q_m \cdot Y_{m0} / (\omega_0 C_0), \quad (2.6)$$

where C_0 =clamped capacity, C =capacity in the piezoelectric branch, Y_{m0} =diameter of admittance circle=reciprocal of internal friction resistance R_i and $\omega_0=2\pi f_0$ (Fig. 2(b) and (c)). Using this value of C/C_0 instead of $(f_n - f_m)/f_m$ in eq. (2.2), more certain value of k_r^2 can be obtained.

(d) Elastic Measurement of Non-piezoelectric Ceramic Sample.

As described later, the samples in the region near CaTiO₃ show no anomalies in the curve of dielectric properties vs. temperature. Then, the elastic measurements of them are adopted here for ascertaining phase changes. They

have not piezoelectricity, and so the temperature variation of elastic modulus and dissipation are measured by the composite-bar method. That is, the resonant frequencies and the minimum to maximum admittance ratio of the composite bar, which consists of the X-cut and Y-long quartz rod and the specimen being cemented endwise, are observed with varying temperature. The anomalies of these quantities vs. temperature curve are considered to correspond to the phase transformations. (cf. an earlier report on the elastic properties of lead zirconate and other solid solutions¹⁴⁾).

(e) X-ray Measurement

Debye photographs are taken by the Weissenberg camera with a goniometer, using Cu-K α radiation. Its diameter is 57.3 mm. The lattice parameters and superstructure lines are examined.

§ 3. Experimental Results

(a) Ferroelectric Phase

In Fig. 3, the temperature variations of the

Fig. 3. Temperature variation of dielectric constant.

(a) $(\text{Ba}_{0.7-x}\text{Pb}_{0.3}\text{Ca}_x)\text{TiO}_3$

(b) $(\text{Ba}_{0.8-x}\text{Pb}_{0.2}\text{Ca}_x)\text{TiO}_3$

dielectric constants of $(\text{Ba}_{0.7-x}\text{Pb}_{0.3}\text{Ca}_x)\text{TiO}_3$ and $(\text{Ba}_{0.8-x}\text{Pb}_{0.2}\text{Ca}_x)\text{TiO}_3$ are shown. The temperature of maximum dielectric constant is considered as Curie point T_c . The distribution of Curie points is indicated in Fig. 4. Under these temperatures, the samples are to be of the same phase as that of BaTiO₃, namely ferroelectric and of tetragonal structure. X-ray pattern of $(\text{Pb}_{0.6}\text{Ca}_{0.4})\text{TiO}_3$, as

* The factors R_1 and K are different corresponding to various values of σ . Namely, $R_1=2.03$, 2.07 and $K=2.51$, 2.55 for $\sigma=0.27$, 0.33, respectively. But these differences are not important in the present paper.

an example, is analyzed and proved to be tetragonal as in BaTiO_3 .

(b) *Insoluble Region*

Ordinarily, Curie point of the solid solution shifts smoothly with composition. When the composition enters the insoluble region, Curie point jumps or becomes unchanged. The insoluble limit in Fig. 4 is thus determined. The limited boundary near CaTiO_3 is drawn according to the X-ray measurement; for example, the pattern of $(\text{Ba}_{0.125}\text{-Pb}_{0.125}\text{-Ca}_{0.75})\text{TiO}_3$ is analyzed as that of mixed crystal.

Fig. 4. Curie point in the ferroelectric phase

(c) *Phase of the Sample in the Vicinity of CaTiO_3 .*

In the case of the sample with concentration of CaTiO_3 more than 50 mole percent (the right side of the solid line in Fig. 4), the dielectric constant goes on decreasing and $\tan \delta$ increasing. With rising temperature no anomalies are found. The neighbouring region to tetra-

gonal phase is of cubic structure, but CaTiO_3 is known to be orthorhombic. According to the previous paper of McQuarrie⁶⁾, orthorhombic CaTiO_3 transforms to tetragonal and then to cubic. A tetragonal region, therefore, may exist between the cubic and orthorhombic phases in the diagram. Debye photographs of several samples in this region are analyzed. Those in the nearest vicinity of CaTiO_3 can be indexed by assuming same structures as that of CaTiO_3 reported by Roth *et al* and are orthorhombic. That of $(\text{Pb}_{0.4}\text{-Ca}_{0.6})\text{TiO}_3$ may be considered to be cubic. It cannot be confirmed if the structures of intermediate compositions are tetragonal or not. Nevertheless, the Debye patterns show a little deviation from cubic. So they are indicated as pseudo-cubic rather than tetragonal.

The phase boundaries cannot be definitely determined by X-ray measurements, and, therefore, the elastic properties are examined *versus* temperature by the composite bar method. When the phase transition occurs, any anomalies may appear at the transition temperature. For example, the resonant frequency and the minimum to maximum current ratio (a measure for internal friction) vs. temperature of the composite bar (of $(\text{Pb}_{0.25}\text{-Ca}_{0.75})\text{TiO}_3$) are shown in Fig. 5 (a). The measurements are done to about 400°C. In Fig. 5 (b), the temperatures thus obtained are plotted by circles. The transition temperatures, 1100° and 1200°C, of CaTiO_3 are those in the previous report of McQuarrie⁶⁾. The dots in Fig. 5 (b) are the temperatures corresponding to peaks of dielectric constant curve, or the

Fig. 5. (a) Elastic measurement by the composite bar method. (b) Determination of phase boundaries.

Curie points, under which the phase is ferroelectric and tetragonal. That of PbTiO₃ is 490°C by Shirane¹¹. Combining these points, the phase boundaries are located. These results thus determined are not inconsistent with X-ray measurements.

(d) Phase Diagram

From above results, the phase diagram of the whole system is obtained in Fig. 6. This result resembles, but is a little different from McQuarrie's recent report.

Fig. 6. Phase diagram of the system (Ba-Pb-Ca)TiO₃.

(e) Dielectric, Piezoelectric and Mechanical Properties.

In Fig. 7, the maps of dielectric constant (ϵ in (a)), electromechanical coupling coefficient (k_r in (b)) and transverse piezoelectric constant (d_{31} in (c)) of the ceramic sample at room temperature are shown. The indicated values of the dielectric constants are those of ϵ_3^F for the prepolarized ceramics and ϵ_0 for the unpolarized one. The electromechanical coupling of ceramics decreases with concentrations of PbTiO₃ and CaTiO₃.

The mechanical and dielectric Q values (Q_m and Q_e) are shown in Fig. 7 (d) (e). Certain regularities are found in them.

§ 4. Discussions

(a) Phase Diagram

It is well-known that the solid solutions of BaTiO₃ with PbTiO₃ have higher Curie points and with CaTiO₃ lower ones, and it has been discussed from standpoints of ionic radius and polarizability. In the system (Ba-Pb-Ca)TiO₃, it may be comprehensible to some extent that Curie points becomes lower from the binary (Ba-Pb)/TiO₃ side towards CaTiO₃. The ferroelectric to paraelectric phase boundary lies near the composition of about 50 mole percent CaTiO₃. But, the present boundary lies a little nearer to CaTiO₃ than those of Sawaguchi⁴) and McQuarrie¹³). This is presumably due to lower purity of CaCO₃ used here. As for other, phase boundaries in the vicinity of CaTiO₃ there may be any suspicion. The pseudocubic phase in the present diagram corresponds to tetragonal of McQuarrie¹³), but tetragonality cannot be confirmed by the Debye patterns. Furthermore, the location of these boundaries are a little different from his report.

The insoluble region is narrower than McQuarrie's. His earlier paper⁶) on the system (Ba-Ca-Sr)TiO₃ reported smaller insoluble range along Ba-Ca binary than his recent report and the result is rather close to the present one. The samples in his recent data are sintered at 1250°C on account of avoiding evaporation loss of PbO, and it is lower than that in this study. The discrepancy between the present and his insoluble limit may be caused by the difference of sintering temperature or of the purity of chemicals used.

(b) Dielectric and Electromechanical Properties

Fig. 7. Dielectric, piezoelectric and mechanical properties.

With concentrations of PbTiO_3 and CaTiO_3 , the Curie points rise or only a little decrease, and on the other hand, the second transition temperatures fall rapidly. Then, the properties at room temperature tend to keep away from any influence of the transition. Although the properties of single crystals of the solid solution have never been studied, the diminution of dielectric constant and piezoelectric constant may be supposed to be caused by these effects; particularly, by the lowering of the second transition temperature. Furthermore, the addition of PbTiO_3 increases the coercive field, and makes the prepolarizing operation more difficult, and so the piezoelectric constant of the ceramics tends to decrease. The increasing of dielectric constants near the ferro- to paraelectric boundary is due to approach of the Curie point.

Mason has measured the mechanical and dielectric Q factors of this system, particularly, in relation to the aging phenomena. In the present result, the systematic variation of the Q values with composition is observed. According to the author's previous study¹⁵⁾, the internal friction of BaTiO_3 ceramics is mainly the dissipation in the single domain crystal. It may be the case also in the present study. In the samples with higher Q_m , however, the dissipation due to ceramic form will become no longer ignorable. It is not yet revealed if the dissipation in the single crystal has a mechanical origin or a dielectric one. As the piezoelectric properties of the single crystals of the solid solutions are not known, further detailed discussions are impossible. Nevertheless, the solid solution with larger dielectric Q has higher mechanical Q in this system.

When the piezoelectric ceramics are used as ultrasonic transducers, the higher mechanical Q and Curie point are necessary for avoiding the influence of heat generation by the internal loss¹⁶⁾ and the larger piezoelectric constant is required for low impedance at resonance. These requirements, however, are often incompatible. Which must be taken up depends on the intention.

§ 5. Conclusion

The following results are derived from the present studies:

(1) The phase diagram of the ternary sys-

tem $(\text{Ba-Pb-Ca})\text{TiO}_3$ is indicated. The ferroelectric and tetragonal phase changes to the orthorhombic structure of CaTiO_3 through cubic and pseudocubic phases.

(2) Some systematic results on the dielectric, piezoelectric and mechanical properties of this system are obtained.

In conclusion, the author wishes to express his sincere thanks to Dr. O. Nomoto, Mr. M. Marutake and Mr. A. Takeda for their useful discussions. He is also grateful to Dr. H. Hagihara and Mr. H. Yamashita for X-ray measurement by the Weissenberg camera and to Mr. Y. Kanda for his help to some part of this experiment.

The present studies were supported by the Scientific Expenditure of the Ministry of Education.

Electrical Properties of Ag_2Te

By Shin-ya MIYATANI

Department of Physics, Faculty of Science, Niigata University

(Received September 2, 1957)

The electronic conductivity, σ_e , Hall constant, R , and thermoelectric power, Θ , in α Ag_2Te are measured as the Ag/Te ratio is varied by the use of the galvanic cell $\text{Ag}|\text{AgI}|\text{Ag}_2\text{Te}|\text{Pt}$, where the e.m.f. of the cell, E , represents the position of the Fermi level relative to Ag-saturated Ag_2Te . According as Ag is removed across the cell, starting from the Ag-saturated composition, σ_e decreases at first, and then increases. Θ changes its sign at the minimum of σ_e , although R is always n-type, due to the large mobility ratio (~ 100). The energy gap is, therefore, as narrow as several kT . When Ag is removed further, σ_e decreases again, keeping E constant. This is a mixed state of Ag_2Te and a new phase mentioned below. After a minimum of σ_e is attained, σ_e and E increase again, suggesting a new phase, $\text{Ag}_{\sim 1.93}\text{Te}$. The energy gap of this phase is fairly larger than that in Ag_2Te phase and the mobilities of electron and hole are far smaller than those in Ag_2Te . When Ag is removed still further, σ_e and E become to be independent of the composition, indicating the precipitation of Te or Te rich compound. Those experimental data are compared with the Lorentz-Sommerfeld theory, proving a good accordance between them. On the other hand, ionic conductivity is estimated from the ionic polarization effect.

§ 1. Introduction

Ag_2Te is one of the Ag_2S group in which electrons and Ag ions are mobile. The author has been engaged in the researches of "ion-mobile semiconductors" and the present paper is concerned to one of such series of experiments. Now, recently, Appel^{1), 2)} has carried out the detailed investigation of the electrical and optical properties of this substance. Regarding the electrical properties, our data are similar to his one in many respects, although our interpretation is considerably different from his one. In particular, the galvanic cell $\text{Ag}|\text{AgI}|\text{Ag}_2\text{Te}|\text{Pt}$ has been used in our present research and it has made the interpretation very easy. The reason is as follows: With the use of the cell, Ag content in Ag_2Te can be varied easily and moreover the e.m.f. of the cell represents the position of the Fermi level relative to that in the Ag-saturated Ag_2Te . In this respect, the ion-mobile semiconductors are very convenient to research only if a proper ionic conductor for the cell exists, like AgI in our present case.

§ 2. Theoretical

To begin with, let us summarize the theoretical formulae which will be used in the later sections.

(a) The galvanic cell $\text{Ag}|\text{AgI}|\text{Ag}_2\text{Te}|\text{Pt}^{3), 4)}$

AgI is a purely ionic conductor and hence the amount of Ag supplied to or removed from the Ag_2Te across AgI is equal to the amount of electricity sent across the cell divided by e , Q/e . Moreover, Ag_2Te is an average crystal⁵⁾ and hence the chemical potential of Ag ion in Ag_2Te is independent of the composition (Ag/Te ratio), resulting in the conclusion that the e.m.f. of the cell, E represents the position of the Fermi level in the Ag_2Te relative to that in the Ag-saturated Ag_2Te .

(b) Formulae for σ_e , R , and Θ

The concentration of carrier, n (or p), the electronic conductivity, σ_e , Hall coefficient, R , and the thermoelectric power, Θ , are given by^{6), 7), 8)}

$$n = 4\pi(2m^*kT)^{3/2}h^{-3}F_{1/2} \equiv \frac{2}{\sqrt{\pi}}N_nF_{1/2}, \quad (1)$$

$$\sigma_e = 16\pi m^*e^2kTl_0(3h^3)^{-1}(r+1)F_r, \quad (2)$$

$$R = \frac{1}{ne} \frac{3}{2} \frac{2r + (1/2)}{(r+1)^2} \frac{F_{1/2}F_{2r-(1/2)}}{F_r^2}, \quad (3)$$

$$\Theta = \frac{k}{e} \left(\frac{2+r}{1+r} \frac{F_{r+1}}{F_r} - \eta \right), \quad (4)$$

$$F_r = \int_0^\infty \frac{x}{1 + \exp(x-\eta)} dx, \quad (5)$$

where η is the reduced Fermi energy (Fermi energy/ kT), the mean free path, l , is assumed to be expressed as $l=l_0(\varepsilon/kT)^r$ (ε is the kinetic energy of a carrier), m^* is the effective mass of the carrier, and $e, k, \hbar$, and T are usual notations. By the way, r will be assumed as $1/2$ in the present paper.

When there are both electrons and holes, σ_e , R , and Θ are expressed as

$$\sigma_e = \sigma_n + \sigma_p, \quad (6)$$

$$R = \left(\frac{\sigma_n}{\sigma_e}\right)^2 R_n + \left(\frac{\sigma_p}{\sigma_e}\right)^2 R_p, \quad (7)$$

$$\Theta = \left(\frac{\sigma_n}{\sigma_e}\right) \Theta_n + \left(\frac{\sigma_p}{\sigma_e}\right) \Theta_p, \quad (8)$$

where the suffices n and p represent the electron and hole components of the quantities concerned respectively.

(c) Ionic conduction

The ionic conductivity, σ_i , can be obtained by the "polarization method" which we have already reported.^{4,9,10)} We shall review it in brief for the later reference.

When a direct current of a constant intensity is sent to a specimen through the platinum electrodes (see Figs. 1 and 7), mobile Ag ions move toward the cathode, and accumulate there. If the applied voltage is not so large as the condition of deposit is fulfilled, that is, if the chemical potential of Ag atom at the cathode is smaller than that in an Ag-saturated specimen, ionic current decreases with time and at last vanishes, leaving electronic current only. Such a state will be called a stationary state (*Polarization process*). When the current is switched off after such a stationary state is attained, a residual potential is left and decays according as the polarization decays (*Decay process*).

For such processes, the electronic and ionic components of the current density, I_e and I_i can be given respectively by

$$I_e = \sigma_e \frac{d}{dx} \left(\frac{\zeta_e}{e} - \Phi \right), \quad (9)$$

$$I_i = -\sigma_i \frac{d\Phi}{dx}, \quad (10)$$

where ζ_e is the Fermi energy of electron and Φ is the electrostatic potential. Eq. (10) has not the diffusion term of ions since Ag_2Te is an average crystal like Ag_2S . For the stationary state, putting $I_i=0$, we have

$$I = I_e = \sigma_e \frac{d}{dx} \left(\frac{\zeta_e}{e} \right). \quad (11)$$

When σ_e is a known function of ζ_e , Eq. (11) can be integrated as

$$\int_{\zeta_0}^{\zeta} \sigma_e d\zeta_e = Iex, \quad (12)$$

which gives the stationary potential distribution $V_s(x) = (\zeta(x) - \zeta_0)/e$, where ζ_0 is σ_e at one end of the specimen. In particular, if ζ_e can be expressed as $A \times F_r(\eta)$, then Eq. (12) is expressed as

$$\int_{\eta_0}^{\eta} F_r(\eta) d\eta = \frac{Iex}{AkT}. \quad (13)$$

Next, at the instant of switching off, we have the relations as

$$\frac{V_r}{V_s} = \frac{\sigma_i}{\sigma_i + \sigma_e}, \quad \frac{V_c}{V_s} = \frac{\sigma_e}{\sigma_i + \sigma_e}, \quad (14)$$

where V_s , V_r and V_c are the potential difference between two probes in the stationary state, that at the instant of switching off, and the potential difference between two AgI cells arranged near the two electrodes at the instant of switching off, respectively (see Fig. 4 in the reference (4)). Thus, σ_i can be obtained from V_r/V_s if it is not too small (*Residual method*). Further, the relaxation time of the polarization and decay processes is deduced from the following consideration: The equation of continuity for mobile ions is given by

$$e \frac{\partial N}{\partial t} = - \frac{\partial I_i}{\partial x}, \quad (15)$$

where N is the concentration of the excess mobile ions. When the applied voltage is sufficiently small (In our present work, ~ 10 mV has been used usually), Eq. (15) can be reduced with the use of Eqs. (9), and (10) to

$$\frac{\partial N}{\partial t} = \frac{\sigma_i \sigma_e}{e(\sigma_i + \sigma_e)} \frac{\partial^2 (\zeta_e/e)}{\partial x^2}. \quad (16)$$

If ζ_e is a known function of N , Eq. (16) can be expressed as

$$\frac{\partial N}{\partial t} = \frac{\sigma_i \sigma_e}{\sigma_i + \sigma_e} \frac{\partial^2 N}{\partial x^2} s, \quad (17)$$

where s is defined as $\partial/(\zeta_e/e)/\partial(eN)$ and so a known function of ζ_e or N . Then Eq. (17) can be integrated with the boundary condition that there is neither supply nor removal of ions at the electrodes. Thus, the relaxation time, τ , is obtained as

$$\frac{1}{\tau} = \left(\frac{\pi}{L}\right)^2 s \frac{\sigma_i \sigma_e}{\sigma_i + \sigma_e} \approx \left(\frac{\pi}{L}\right)^2 S \sigma_i \text{ if } \sigma_i \ll \sigma_e, \quad (18)$$

where L is the length of the specimen. From the measurement of τ , therefore, we can obtain σ_i if s is known (τ -method). When σ_i/σ_e is so small that the residual method is not available, the τ method can be used, where τ is the relaxation time of the potential difference between two AgI cells AgI (probes) as shown in Fig. 7.

§ 3. Experimental

(a) Arrangements

The samples are prepared as follows: Ag (reduced from AgNO_3) and Te(Merck) are put in a hard glass tube in a proper proportion. Then the tube is evacuated, sealed and then heated up to 600°C . Duing to the large ionic mobility in Ag_2Te , the reaction takes place rapidly and so the compound can be prepared easily. The sample obtained in such a way is cut and ground to a proper size. The method of measurements of σ_e , R , and Θ is as usual (Fig. 1). Those electrical

the description of the electrical properties in the α Ag_2Te . Fig. 2 shows the change of

Fig. 2. (a) The change of σ_e and E vs. $d \equiv 2 - \text{Ag}/\text{Te}$ ratio by removing and supplying Ag at 225°C . (b) σ_e vs. d in the range of small d in a different scale. The value of eN (upper abscissa) is related to d by $d = eN/2400$, where N is the concentration of deficit Ag, and the density of Ag_2Te is assumed as 8.5 g/cm^3 .

σ_e and E when Ag is removed from and then supplied to an Ag_2Te specimen across the cell. The figure shows that, starting from the Ag-saturated composition designated by S in the figure, σ_e decreases and E increases rapidly at first according as Ag is removed, and then σ_e increases after passing a minimum (A) and attains a maximum (B). From this point, σ_e decreases remarkably and reaches the second minimum (C), while E is kept constant. At further removal of Ag, both E and σ_e increase again and σ_e reaches the second maximum (D). At still further removal of Ag, E and σ_e do not show any remarkable changes. Let us divide the whole range into four regions; from S to B, B to C, C to D, and D to E. For convenience, they will be called α_1 , mixture α_2 , and precipitation regions respectively. In the following sections, the electrical properties in each region will be described in proper order.

(2) α_1 region. Fig. 3 shows $\log \sigma_e$ and $\log R$ vs. E . The Hall constant is always n -type while the thermoelectric power, Θ , changes its sign near the minimum point of σ_e . From the figure, the following conclusion will be easily deduced; the energy gap is as narrow as several kT and the mobility ratio μ_n/μ_p is

Fig. 1. Schematic diagram of the experimental method for measurements of σ_e , R , and Θ .

quantities are measured as functions of the e.m.f. of the cell, E , or the composition, N , and the temperature, T .

(b) Results

(1) General comments. Ag_2Te has two phases; α phase (stable above about 150°C) and β phase (stable below). In the α phase, the ionic conductivity is fairly large and hence the galvanic cell $\text{Ag}|\text{AgI}|\text{Ag}_2\text{Te}|\text{Pt}$ is very effective. We shall, therefore, begin with

very large. The detailed analysis will be tried in § 4.

(3) *Mixture region.* As mentioned in (1), σ_e begins to decrease when Ag is removed further. In this region, the uniformity of the specimen is not held, as illustrated by Fig. 4, which represents the potential distribution

Fig. 3. $\log \sigma_e$ and $\log R$ vs. E at three temperatures. The broken lines represent the equi-compositions with the values of $eN(\text{C cm}^{-3})$ relative to a certain composition near Ag-saturated.

Fig. 4. Potential distribution along the specimen whose Ag content is varied by the Ag|AgI arranged at the right end. Each curve is regarded as composed of two straight lines of different inclinations, indicating σ_e changes suddenly at a certain point.

along a specimen in the mixture region when a constant current is sent. That is, when Ag is removed at an end of a specimen, σ_e decreases at this end and such a small σ_e region extends according as Ag is removed, until the whole specimen becomes small σ_e . This ununiformity does not disappear by a heat treatment of a fairly long period and so the state in this range of composition is regarded as a mixture of α_1 and a different phase from α_1 , that is, α_2 . The constancy of E also supports this view-point. (see also Fig. 5)

Fig. 5. $\log \sigma_e$ vs. E at various temperatures. The broken lines represent the equi-compositions with the eN values attached on them.

(4) *α_2 region.* After the whole specimen becomes to be of small σ_e , σ_e increases again together with E at further removal of Ag. Fig. 5 shows $\log \sigma_e$ vs. E at various temperatures. In the α_2 phase, R is comparatively small but still n -type, while θ is p -type. Therefore, the mobility ratio will be very large and the energy gap is comparatively small just as in the α_1 phase.

(5) *Precipitation region.* When Ag is removed still further σ_e and E become to be independent of the composition. This independence may be due to the precipitation of Te or Te rich compound, where the precipitation may be formed not to disturb the conduction of electrons. By the way, there is no indication of Ag_7Te_4 as shown in Fig. 2.

(6) *Ionic conductivity in the α phase.* There

are two methods to obtain the ionic conductivity, σ_i ; One is the residual method and the other is the τ method as mentioned in § 2 (c). The former is not available without correction in the α_1 phase since σ_i/σ_e is so small that the residual potential is masked by the potential due to the Peltier effect, while the latter is not available with ease since s in Eq. (18) can not be easily determined. Fig. 6 shows $\log \tau$ and $\log (1/s)$ vs. E

Fig. 6. $\log \sigma_e$, τ_{10} and $1/s$ vs. E . $\tau_{10} = 2.3\tau$. The $1/s$ and τ_{10} curves are parallel to each other, indicating a constant ionic conductivity.

in the α_1 region, where τ is the relaxation time of the potential difference between two cells. They are parallel to each other, indicating that σ_i is independent of E and accordingly the composition. Further, Fig. 7 shows the stationary potential distribution along the specimen. The feature of curves is just as expected.

On the other hand, Fig. 8 shows $\log \sigma_e$ and σ_i vs. the composition in the mixture and α_2 regions, where σ_i is obtained by the residual method. As mentioned above, s is not so definitely determined in these ranges as in the α_1 range, since σ_e does not attain its equilibrium value instantly after Ag is removed or supplied, and so the residual method is preferable although the τ method gives a similar value of σ_i to that from the residual method. For instance, $L = 0.7$ cm, $E = 145$ mV, $\sigma_e = 3 \Omega^{-1} \text{cm}^{-1}$, $\tau = 13$ sec, $s = 4.4 \text{ mV C}^{-1} \text{cm}^3$, resulting in $\sigma_i = 0.9 \Omega^{-1} \text{cm}^{-1}$ at 165°C with

the use of Eq. (18). Thus, as far as the ionic conduction is concerned, there is no remarkable difference between the α_1 and α_2 phase.

(7) α - β transition. Fig. 9 shows E and $\log \sigma_e$ vs. temperature including the transition point, [where σ_i of AgI below about 140°C and σ_i of β Ag_2Te are very small and hence the measurement of E is not too reliable.

Fig. 7. Stationary potential distribution. E_0 is E in the initial state and E_s is E of two cells in the stationary state. The inclination of curves is proportional to $1/\sigma_e$. It is most steep at the anode in the case of (b), while it is at the middle in the case of (a) as expected from the respective values of E .

Fig. 8. $\log \sigma_e$ and σ_i vs. eN , where σ_i is obtained by the residual method.

Now, σ_e decreases at the transition $\beta \rightarrow \alpha_1$. This decrease is not due to the change of mobility but to the decrease of the concentration of electrons owing to the sudden increase of the energy gap at the transition, as seen later. In the case of the α_2 phase, the transition temperature for $\alpha_2 \rightarrow \beta$ is lowered remarkably with increasing deficiency of Ag while that for $\beta \rightarrow \alpha_2$ is not too much changed. Moreover, the change of σ_e at the transition $\alpha_2 \rightarrow \beta$ is very slow. This may be due to the precipitation of Te at the transition. On the other hand, at the $\beta \rightarrow \alpha_2$ transition, it is necessary to heat the specimen to somewhat higher temperature in order for the precipitated Te to re-enter the matrix.

Fig. 9. (a) $\log \sigma_e$ vs. temperature, and (b) E vs. temperature corresponding to (a). The numbers attached on them are the values of eN (C cm^{-3}).

(8) β phase. As shown in Fig. 9, σ_e decreases with increasing deficiency of Ag and there is no indication of another phase at least in the range of composition under consideration. Further, when eN is larger than about 10 C cm^{-3} , E is almost independent of eN , suggesting the mixed state like that in the α phase. Thus the decrease of σ_e may be attributed mainly to the decrease of the mobilities of electron and hole in the mixed state.

§ 4. Analysis of Data and Discussion

(a) α_1 phase

Fig. 10 shows $\log \sigma_e$, $\log R\sigma_e^2$ vs. eE/kT at 300°C and Fig. 11 shows σ_e and eE/kT vs. eN (relative) at 300°C and 220°C . These figures can be analyzed graphically as follows: First

let us separate σ_n from σ_e . Now, the hole component, σ_p , will be negligible in a small E region. $R\sigma_e^2$ is more suitable for such neglect since $R\sigma_e^2 = \sigma_n\mu_n - \sigma_p\mu_p$ and μ_n/μ_p will be large. Therefore, $\log R\sigma_e^2$ vs. eE/kT plot is at first compared with the theoretical graph, $\log F_{1/2}$ vs. η , assuming $r=1/2$ in Eqs. (2) and (3). From such a comparison (overlapping two graphs to each other), the position of $\eta=0$ is obtained. As seen in Fig. 10, the experimental plot of $R\sigma_e^2$ shows a remarkable

Fig. 10. $\log \sigma_e$ and $\log R\sigma_e^2$ vs. eE/kT in the α_1 Ag_3Te . The σ_n and σ_p are obtained graphically as described in text.

Fig. 11. (a) σ_e and eE/kT vs. eN (relative) at 220° and 300°C . The σ_p obtained from Fig. 10 is also plotted against eN . From the inclination of the σ_p curve, the mobility of holes is estimated as shown in the figure. (b) en and ep vs. eN in the composition range in which en and ep are comparable order of magnitude.

deviation from the theoretical curve in a large E range. This deviation is opposite to what would be expected from the contribution of holes, and it is negligible at 165°C and increases with increasing temperature. The cause of such a deviation is not certain (a change of μ_n or of the energy gap with increasing Ag ion vacancies?) and we shall neglect it in the present paper.

Using the zero point of η determined as mentioned above, the $\log \sigma_n$ vs. eE/kT curve can be drawn so that it coincide with the experimental $\log \sigma_e$ vs. eE/kT plot in the range of small E . Further, subtracting σ_n from σ_e we have the hole component of σ_e , σ_p , which can be expressed as

$$\log \frac{\sigma_p}{e\mu_p N_p} = \frac{\zeta_p}{kT} = \frac{eE}{kT} + \text{const.} \tag{19}$$

Thus both σ_n and σ_p are obtained. The mobility and effective mass of conduction electron can be obtained with the use of the position of η , R and σ_n as listed in the table at the end of this section.

Next, although the mobility of hole, μ_p , can not be obtained from R , it can be estimated as follows: As shown in Fig. 11, σ_p obtained by the procedure mentioned above is proportional to eN except in the small E region, indicating that the number of holes changes by just the amount of Ag ions removed or supplied. That is, the number of hole, p , is far larger than that of electron, n , and accordingly the change of n is negligible. This view is supported by the fact that eN can be expressed as $\log(eN) = eE/kT + \text{const.}$ only if a small additive constant for eN is adjusted as also shown in Fig. 10. Thus, the mobility of hole, μ_p , can be obtained from the inclination of the σ_p vs. eN curve. On the other hand, n and p become comparable in the

small E region, and then we have

$$ep - en = eN_a, \tag{20}$$

where N_a is the absolute concentration of the deficit Ag. Fig. 11 (b) shows that this is in fact the case.

Now the distribution of holes in the valence band is classical and hence the position of the top of the valence band can not be determined as in the case of the conduction band. In order to determine it, the thermoelectric power is available. Fig. 12 shows an example

Fig. 12. The graphical deduction of theoretical curve of thermoelectric power, where the energy gap is determined so that the theoretical reversal point of Θ coincides with the experimental one. The potential probes are Nichrome wires whose Θ against Cu is about $-3.3\mu\text{V}/^\circ\text{C}$ ($\theta = 0.04$).

of graphical construction of the theoretical Θ given by Eqs. (4) and (8). The energy gap, E_g , can be determined so that the theoretical reversal point of Θ coincides with the experimental one. Then we have the effective mass of hole. The several quantities obtained so far are listed in the following table.

Temp ($^\circ\text{C}$)	μ_n ($\text{cm}^2\text{v}^{-1}\text{sec}^{-1}$)	m_n^*/m	μ_p ($\text{cm}^2\text{v}^{-1}\text{sec}^{-1}$)	m_p^*/m	E_g (mV)
165	1440	0.054	18	1.0	55
220	1100	0.059	16	1.4	95
300	750	0.069	13	2.0	140

Here, we don't intend to insist that these values are accurate, but we can say with confidence that the energy gap is as small as several kT and the mobility ratio is very large.

(b) α_2 phase
Fig. 13 shows an example of analysis at 165°C . As shown in the figure, when Ag is removed from the specimen in the mixture region, σ_e decreases, R (n -type) increases to

some extent, and θ (p -type) increases until the whole specimen becomes the α_2 phase. At supplying Ag, they changes in the opposite direction although there is a hysteresis effect, particularly at a comparatively low temperature (see also Fig. 5) duing to the large relaxation time of such a phase change.

native models as follows: In the α_2 phase, a complex compound Ag_{2-x}Te may be formed, where x is about 0.071 at 165°C , and 0.067 at 240°C , for example, $\text{Ag}_{27}\text{Te}_{14} \sim \text{Ag}_{31}\text{Te}_{16}$, and the deviation from such a complex composition supplies ionized vacancies, the number of which is equal to the hole. Further, according as the temperature is raised, the crystal changes its form so that the number of Ag ion vacancies increases, resulting in the increase of the number of holes and accordingly the increase of σ_e . This model may not be conclusive but it accounts for the data at least phenomenologically.

Fig. 13. $\log \sigma_e$, $\log R$, $\log R \sigma_e^2$, and $\theta e/k \equiv \theta$ vs. E at 165°C .

Now, in the α_2 phase, σ_n and σ_p can be determined by trial and error so that both is expressed as classical as shown in the figure. Since $R \sigma_e^2$ is considered to be equal to $\sigma_n \mu_n$ as in the α_1 phase, we have the mobility of electron as $300 \text{ cm}^2 \text{ v}^{-1} \text{ sec}^{-1}$. The mobility of hole can be also estimated from σ_p vs. eN curve just as in the α_2 phase as follows: Fig. 14 shows σ_e vs. eN plot. Since p seems to be far larger than n , we may consider that p is equal to the concentration of ionized Ag ion vacancies. If it is assumed that every removed Ag ion forms Ag ion vacancy, then the majority of Ag ion vacancies should be neutral, that is, the Ag ion vacancies should have acceptor levels, the majority of which are occupied by holes. This view can not, however, account for the behavior as shown in Fig. 14. We suggest, therefore, an alter-

Fig. 14. (a) σ_e vs. eN in the α_2 phase. They are straight lines of the almost same inclination. (b) eN_0 vs. temperature, where eN_0 is the eN value corresponding to $\sigma_e=0$.

Thus, the mobility of hole is estimated as $0.3 \sim 0.4 \text{ cm}^2 \text{ v}^{-1} \text{ sec}^{-1}$, which is almost independent of the temperature. With those values of σ_n , σ_p , μ_n , and μ_p , theoretical θ vs. E curve can be drawn so that it fits to the experimental plot as shown in Fig. 13. From such a comparison, the effective mass of electron and holes and the energy gap can be estimated as $m_n^*=0.024m$, $m_p^*=6m$, and $E_G=190 \text{ mV}$. At higher temperature, the accuracy of analysis becomes poor because of the smallness of σ_n/σ_p (e.g. at 240°C , $\mu_n=125$, $m_n^*=0.036m$, $\mu_p=0.33$, $m_p^*=7m$, assuming the

energy gap is equal to that at 165°C i.e. 190 mV).

(c) β phase

As mentioned above, σ_i 's of AgI and $\beta \text{Ag}_2\text{Te}$ are very small and so the Ag content can not be varied at a fixed temperature in the β phase, and moreover, the accuracy of the measurement of E is not too well. Therefore, the reliability of analysis is not so large as in the α phase.

Now, $\beta \text{Ag}_2\text{Te}$ can be divided into the pure state and the mixed state as described in § 3 (8). Fig. 15 shows $\log \sigma_e$, $\log R\sigma_e^2$, and Θ vs. eE/kT in the pure region. The mobility and effective mass of conduction electron are obtainable by the procedure mentioned in (a) as shown in the figure. Fig. 16 shows E vs. eN in the $\beta \text{Ag}_2\text{Te}$, and a similar plot in the α phase (188°C) is also shown for the refer-

ence. The origin of the abscissa is fixed from an analysis in the α phase. Now, σ_p can be obtained by subtracting σ_n from σ_e , although the accuracy is not very well because of the smallness of σ_p . Then μ_p is estimated as $11 \text{ cm}^2 \text{ V}^{-1} \text{ sec}^{-1}$ from σ_p vs. eN plot as shown in Fig. 16. Thus ep and en are obtained, and accordingly the value of E corresponding to the stoichiometric composition is obtained as 86 mV at 125°C. This value is in accordance with that obtained from Fig. 16. supporting our analysis in the β phase. The energy gap obtained from Θ is very narrow as shown in the figure.

Fig. 15. (a) $\log \sigma_e$, and $R\sigma_e^2$ vs. eE/kT at 125°C and 95°C. (b) $\Theta e/k$ vs. eE/kT at 125°C. The energy gap is very narrow (might be negative).

Fig. 16. E vs. eN (absolute) in $\beta \text{Ag}_2\text{Te}$. The stoichiometric position is determined in the α phase (183°C). Besides, σ_p obtained from Fig. 15 is also plotted against eN .

Fig. 17. (a) $\log \sigma_e$ and $\log(R\sigma_e^2)^{1/2}$ vs. temperature, and (b) $\Theta e/k$ vs. temperature corresponding to (a), where (2-3) and (4-5) represent that their σ_e are in the middle between No. 2 and 3, and No. 4 and 5, respectively.

In the mixed region, the precipitation of $\text{Te}(?)$ takes place very slowly and the uniformity of the specimen is not too well, and so we shall only discuss it qualitatively. Fig. 17 shows $\log \sigma_e$, $\log(R\sigma_e^2)^{1/2}$ and Θ vs. temperature when the temperature is raised from the room temperature. From the figure, it is seen that σ_n and σ_p decrease but σ_p/σ_n increases with increasing deficiency of Ag . The decrease of σ_n and σ_p seems to be due mainly to the decrease of the mobility. More detailed discussion will be left to the future.

(d) Remarks

In the present analysis, the energy dependence of the mean free path of conduction electron has been assumed as $l=I_0(\mathcal{E}/kT)^{1/2}$. This assumption may be, however, not necessarily allowed. In fact, other dependence, $l=\text{constant}$, can account for our data with

almost same extent of fitness, resulting in somewhat different values of effective mass and the energy gap, although the essential features so far mentioned are not changed. More detailed experiments and consideration will be necessary in order to determine which dependence is right. In collaboration with Mr. Yokota, the author wishes to discuss this subject in the future.

The author wishes to express his sincere thanks to the members of our Department of Physics, especially to Mr. Yokota, Mr. Suzuki, and Mr. Haga for their kind advices and discussions. The present work was supported by the research grant of the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 4, APRIL, 1958

On the Backward Leakage Current in the Alloyed Germanium p-n Junction

By Makoto KIKUCHI

Electrotechnical Laboratory, Tokyo, Japan

(Received December 12, 1957)

It has been observed that the "creep" phenomenon often found in the backward direction of the alloyed germanium p-n junction occurred in the so-called "leakage current component". It has also been found that in some of the alloyed junction transistor samples, the characteristics of the collector junction was influenced by the creep in the emitter junction. The experimental procedures and results are described.

Although we have no complete theory to explain these experimental observations at present, some essential remarks are given from theoretical consideration. In the last section, an experimental result which might be an evidence for the correlation between the creep phenomenon and the surface field effect is given.

§1. Introduction

It is often observed that the electrical characteristic of $p-n$ junctions, either alloyed or grown, does not obey the Shockley's formula¹⁾. One of the most serious discrepancies is the non-saturable backward current, which is often encountered in the physical experiments and technical procedures.

In general, the backward current of the $p-n$ junction consists of three components, i.e., the saturation current, the leakage current, and the breakdown current. In these components, the saturation and the breakdown

components can be treated theoretically at present, while the leakage current component has been kept rather untouched from the theoretical point of view. Some works on the leakage current²⁾ have been published, which considered its dependence on the humidity and its correlation with the channel conduction, but the theoretical current-voltage characteristic has not yet been derived satisfactorily.

Another characteristic behavior found in the "real" junction is the "creep" phenomenon³⁾. The creep is defined as the variation

of the current under a fixed applied voltage. In the transistor and diode technology, this undesirable phenomenon is to be avoided by rinsing the specimens in the distilled water and baking them in vacuum or dry atmosphere. These treatments are expected to take off any ions from the surface. Hence, it may be thought that the ions on the surface are playing important role in the creep. Nevertheless, simple theory based on the model of the ions on the surface can explain straightforward neither the i - v characteristic of the leakage current nor the creep phenomenon. We have been performing transistor lifetest for about three years, and it has come out very difficult to explain the electrical characteristics, such as collector cutoff current, collector impedance, current amplification factor, etc., of the deteriorated transistors from simple channel theory.

Recently, Plummer⁴⁾ has reported that the creep of the backward current occurred in the saturation current component. He adopted such an experimental procedure that the current-voltage characteristic can be taken for the same surface condition. Moreover, he observed the growth of channel during the drift and its rapid disappearance after the cessation of the applied voltage.

Fig. 1. Examples of the two typical creeps.

We have really observed the creep of the saturation current component but do not believe that is only the case. In the course of analysis of the transistor lifetest results, we found two types of creep as shown in Fig. 1, one is the increase of saturation current under the applied voltage (Fig. 1(a)), and the other is the increase of leakage current (Fig. 1(b)). These experimental results were obtained by an X - Y recorder varying the bias voltage more slowly than the time constant of the recorder but fast enough to prevent the creep during the voltage variation. The creep was observed keeping the junction under the bias voltage for three minutes, as shown in Fig. 1. When we observed these two types of creep, i.e., the creep in the saturation and the leakage current component, we tried to attribute the former to the formation of the channel conduction and the latter to simple surface ohmic leakage. To check these models, photocurrent was observed at the same time as the creep was going on. Fig. 2 shows the experimental results, where (a) and (b) correspond to the saturation and the leakage component creep, respectively. As are shown in the figure, the photocurrent (which was observed by a weak chopped light) varies in parallel with the current for the case of leakage creep. This might be thought to be

Fig. 2. Results of the simultaneous measurement of the photocurrent and the creeping current. (a) the saturation creep, and (b) the leakage creep.

an evidence for the above mentioned models, but it soon turned out to be very difficult to explain all of the characteristics of the deteriorated transistors on the basis of such a simple model⁶⁾.

In this paper, experiments especially on the drift of the leakage current component, and on the correlation between the surface conditions and the leakage current are described. Typical present theories are surveyed in trying to explain these experimental results. In the last section, a possibility that the drift phenomenon has correlation with the surface field effect is suggested with the help of the experimental results of time variation of the current.

§ 2. Creep Phenomena

(2.1) Experimental apparatus

As mentioned above, the creep phenomena can be observed with an $X-Y$ recorder. Strictly speaking, however, the time constant of the recorder can not be neglected. A simple measuring circuit has been devised to avoid the effect of measuring operation on the creep effect. The circuit is shown in Fig. 3. The key switches in the figure which are encircled by dotted lines are being set under a purely mechanical pendulum. Setting the pendulum free, it opens these switches in the order of No. 1, 2 and 3 with desired

Fig. 3. Circuit for measuring the instantaneous characteristics.

time lags of the order of milliseconds. At first, these three switches are closed and the junction is forced to creep under the applied voltage of V_1 . When the switch No. 1 is opened, the creep stops, and the junction is subjected to no bias. At the next instant, the switch No. 2 is opened, therefore is the switch S closed, and hence the current flows through the junction by virtue of the battery voltage V_2 . This current continues to flow until the switch No. 3 is opened at the next moment. In this way, the current voltage characteristics of the junction for the junction conditions just at the moment of the cessation of the voltage V_1 . (At least within some milliseconds after that moment.)

The current was measured using the galvanometer ballistically, and with the aid of calibrated data. The result of calibration of the relation between the current and the deflection of ballistic galvanometer is shown in Fig. 4. The linearity is fairly good as shown. The arrangement shown in Fig. 3 is for the case of measurement of the effect of the emitter creep on the collector characteristic of junction transistor about which mentioned in the next section.

Fig. 4. The result of the calibration of the ballistic galvanometer. (ballistic use of usual galvanometer)

(2.2) Experimental results

A typical example of the negative creep is shown in Fig. 5. The sample #A-1 is a deteriorated alloy junction transistor. Therefore, the initial current at the reverse voltage of 16 volts is above 100 microamperes. As the negative creep goes on, however, it de-

creases to about 30 microamperes in 70 seconds. In general, the decay of the current can not be expressed by a simple exponential function, as in the case of the same kinds of phenomena⁶⁾. If the result of Fig. 5 is replotted in a semi-log scale, it is usually noticed that the apparent decay time constant increases as the time goes on.

Fig. 5. Negative creep observed in a deteriorated alloy junction transistor.

The fact that the negative creep occurs in the leakage current component will be seen in Fig. 6. The variation of the current voltage characteristic by the creep as shown in the figure is quite typical in the creep phenomena observed in this experimental work. As is seen in the figure, the saturation current component is not altered, while the leakage current component is remarkably reduced by the creep. The characteristic curves in the figure do not contain cumulative creep effect by virtue of the circuit in Fig. 3. It is noticed that the ratio of the leakage current before and after the creep is nearly

Fig. 6. Variation of the current voltage characteristic of a junction by the creep effect.

independent of the bias voltage. The leakage currents (total current minus saturation current) are plotted in semi-log scale in Fig. 7. Though, apparently, the currents are nearly exponential for the bias voltage, it is not exactly the case for the wider range of voltage. It is noticed, however, that the two lines are nearly parallel, which means that the ratio of the currents does not depend on the voltage.

Fig. 7. Semi-log plot of the leakage currents before and after the creep.

The effect of the emitter creep on the collector characteristic has been observed by the circuit arrangement as shown in Fig. 3. A typical result is shown in Fig. 8. At the time 0 in the figure, reverse voltage of 35 volts is applied to the emitter of the alloy junction transistor # A-5, which is one of the deteriorated transistors after about 10000 hours' lifetest, and the collector current is observed for 30 seconds. At that moment, the emitter is opened, and then the recovery of the collector characteristic is observed for 60 seconds. As is shown, the collector characteristic is remarkably changed by the emitter creeping. Fig. 6 shows the change in the current voltage characteristic of the collector corresponding to this kind of measurement. It is observed that very similar change in the current voltage characteristic of the collector junction as shown in Fig. 6 is caused both by the emitter creep and the creep of the collector itself. The interaction of the collector and emitter creep on each other has been observed

not in all of the samples investigated. The probability of finding this effect was about 30 percent.

can not be attributed to the thermal effect in the junction. This may easily be verified from the fact that the saturation current is not altered. In fact, temperature rise in the junction was sometimes observed when the creep was forced by relatively high reverse voltages. This effect, however, was small and turned out to be negligible.

Fig. 8. Negative creep observed in the collector junction of an alloy transistor forced by the emitter creep.

In general, it may be concluded that the time constant of the creep is considerably less than that of its recovery. This has been already pointed out by some of the workers⁷⁾ and also by the author⁸⁾. For instance, owing to our previous (unpublished) work, the time constants in the two types of creep mentioned in the introduction, (Fig. 1), were found to be as shown in Table I.

Table I. Time constants of the creep and its recovery.

	time constants of the	
	creeping	recovery
saturation current creep	294 min.	10.4 min.
leakage current creep	9.5 min.	6.5 sec.

In both cases, the time constants of the recovery is smaller than that of creeping. It will not be so worthwhile to compare the absolute values of the time constants found in the different experiments, since they are believed to be sensitively dependent on the surface conditions.

It must also be noticed here, that these experimental results of the creep phenomena

§ 3. Effect of Glow Discharge on Germanium Surfaces

On the course of the work to investigate the effect of ambient atmosphere on the transistor characteristics, it has been found out that the collector characteristic was remarkably changed by the discharge in the Geisler tube connected between the rotary pump and the glass bell jar. The effect occurred only when the vacuum was rather low and therefore the glow discharge could be observed extending to the bell jar from Geisler tube. The change in the collector characteristic was the remarkable increase of the *leakage current*. Experiments on the effect of glow discharge in low vacuum on the junction characteristic and on the surface recombination velocity was performed.

(3.1) The effect on diode characteristics

Fig. 9. The effect of glow diacharge on the backward characteristic of a junction.

The junction diode specimens were mounted in a bell jar and kept at the earth potential, and the jar was evacuated by a rotary pump. The diode characteristic was measured by an X-Y recorder, the results are illustrated in Fig. 9.

The curves (a) and (b) correspond to before and after the discharge, respectively. As is shown, the leakage current component is increased about one or two orders of magnitude, while the saturation current component is increased only about three times or so.

The increase in the saturation current could

easily be understood on the basis of the increased surface recombination velocity by the glow discharge. It seemed, however, to be difficult to explain the change in the leakage current by the change in the recombination velocity. Therefore, another model which took into account the local surface breakdown was imagined.

This model was checked by the following experiment using the local photocurrent technique⁹⁾. As is shown in the right-hand side of Fig. 10, a small light spot is moved along on the periphery of the alloyed In dot of the

Fig. 10. Result of the local photocurrent measurements to check the occurrence of surface breakdown.

junction. The local photoresponse is measured and plotted in Fig. 10. From the previous experimental results⁹⁾, it has been established that if a small breakdown region is formed on the periphery, a sharp peak comes out at that point in the photoresponse curve. The curve (a) is the photoresponse before the discharge, and (b) and (c) are after the discharge. As is seen from the figure, no peak appears after the discharge, while the response is reduced at every point. These results compel us to believe that the local breakdown model is not the case and to go back to the surface recombination velocity model again.

(3.2) The effect on surface recombination velocity

To confirm the effect of glow discharge on the surface recombination velocity, the local photoresponse along on the germanium rod

was examined. For constant geometry, the photoresponse is a unique function of the surface recombination velocity, provided that

Fig. 11. The effect of glow discharge on the surface recombination velocity measured on the rod of germanium single crystal.

the temperature is kept constant. The experimental results are shown in Fig. 11. Germanium rod of $0.2 \times 3 \times 20$ mm in dimension is etched and the photoresponse is measured. The photoresponse shows no change after five minutes exposure to vacuum of 10^{-2} – 10^{-3} mmHg. When the surface is subjected to the discharge in the vacuum, however, the photoresponse is reduced drastically as shown in the figure. The response recovered its initial value after 48 hours' exposure to the room air. In the next run, recovery occurred by high humidity. From these results, it will be concluded that the discharge affects the surface in enhancing the surface recombination velocity. Therefore, a question remains that how the large increase in the leakage current be explained from the increase of surface recombination velocity.

§ 4. Effect of Alcohol on Germanium Surfaces

It has often been experienced in the course of experiments on germanium diodes and germanium surfaces that the characteristics of the diodes and surfaces are considerably affected when they are subjected to alcohol.

Since it is difficult to treat the effect of alcohol quantitatively, only the experimental results are mentioned here and qualitative considerations are postponed to the following section.

(4.1) The effect on diode characteristics

The effect of alcohol on the current voltage characteristic has been observed on an oscilloscope as shown in Fig. 12. In the pictures of Fig. 12, units of the current and voltage are as follows,

current...50 microamp. per div.

voltage.... 5 volts per div..

When the diode is wetted by alcohol, the initial characteristic as shown in (a) is changed to that shown in (b). Because of the long

Fig. 12. Effect of alcohol on the current voltage characteristic of a junction. current; 50 microamp. per div., voltage; 5 volts per div.

persistance of the cathode ray tube, the characteristic corresponding to the intermediate state (or transient) can be seen in the figure. As the alcohol vaporizes in the room air, the characteristic recovers gradually as shown in the figures (c) and (d).

It must be noticed that when the surface of the diode is wet, considerable creep (hysteresis) appears as seen from (b) and (c). This hysteresis disappears when the surface is dried again. Another point which must be noticed is the fact that the alcohol induces *leakage current* remarkably. By rough estimation, the characteristic of (b), which corresponds to the most wetted state, may be understood as the result of shunting the diode by ohmic resistance of the liquid alcohol. The intermediate state characteristics, however, can not be understood by such a simple model, since they are not of ohmic character and have rather complicated shapes as shown in (c) and (d). For instance, when the alcohol begins to evaporate, the corresponding change in the characteristic occurs for higher voltages, while the current for lower voltages are kept almost unchanged, as shown in (c). The drift of the characteristic curve is illustrated schematically in Fig. 13. These instantaneous current voltage characteristic curves can not be fitted by any existing theories.

Fig. 13. Schematic representation of the recovery of the characteristic curve.

(4.2) *The effect on surface recombination velocity*

The effect of alcohol on the surface recombination velocity has ever been observed in many kinds of minority carrier lifetime measurements. For instance, in the Morton-Haynes method, the output signal is increased by

wetting the surface by alcohol. This signal recovers its initial value as the alcohol evaporates. In the Haynes-Shockley method, similar increase in the collector signal by alcohol is observed. When a germanium slab of 0.2 mm in thickness is used in this kind of measurement, as shown in Fig. 14, the signal on the oscilloscope is changed from (a) to (b) when the surface is wetted by alcohol.

Fig. 14. Effect of alcohol on the lifetime measurement. (Haynes-Shockley method)

These experimental observations seem to show that the surface recombination velocity is reduced by alcohol. There is, of course, another possibility that the alcohol enhances the collectivity (or intrinsic alpha) of the point contact, but it has not been tried to ensure or rule out this possibility. At any rate, the reduction of the surface recombination velocity by alcohol was confirmed by the experiment using germanium rod in the same manner as mentioned referring to Fig. 11.

It is an open question that in spite of the opposite effect on the surface recombination velocity, glow discharge and alcohol show the the similar influence on the leakage current component of the junction diode.

§ 5. Discussion

Summarizing above mentioned experimental results, problems may be picked out as follows;

- (1) What is the nature of the creep phenomena?

- (2) Through what kind of mechanism do the creep of emitter and collector of a transistor correlate?
- (3) Have we any junction rectification theories which involve the leakage current component that may creep under the influence of applied voltage?

Since it is quite difficult to answer these questions and explain all of the experimental results mentioned above, it is intended here to make a critical survey on some existing theories in the following at first, and then a discussion on the correlation between the creep and the field effect is given.

(5.1) The leakage current

Eriksen¹⁰⁾ has presented a theory of junction characteristics taking channel conduction into account. According to his theory, leakage current which flows in the channel may be expressed in the form;

$$I = \sqrt{2j_0 C} \left(\int_0^V g(V') dV' \right)^{1/2}, \quad (1)$$

where j_0 is the saturation current across the surface $p-n$ junction, C the length along the periphery of the junction on the surface, g the surface conductivity. He assumed that j_0 is constant and independent of the position along on the channel. It has been observed that the surface conductivity g is roughly inversely proportional to the applied voltage across the surface junction (V' in this case)¹¹⁾. Therefore, it is not so crude to substitute this voltage dependence into Eq. (1), which results in the following equation;

$$I = \sqrt{2j_0 C} a \log \frac{V + V_0}{V_0}, \quad (2)$$

where V_0 is a constant introduced to avoid the divergence of the integration, and a is the proportionality constant.

As is seen from the equation, the leakage current calculated in this way does not represent the characteristic of the actual diodes. The leakage current observed in the actual diodes shows steady growing up, or strictly speaking, has positive second derivative with respect to the voltage, while Eq. (2) gives only negative second derivative. It can also be shown that this discrepancy has occurred not because of the assumed special voltage dependence of g .

Eriksen has already pointed out that the geometry must be taken into account when

this theory is applied to the alloyed junctions, since above equation is the result for the grown junction. It has been found by rough estimation, however, that even if the geometry is considered, the above mentioned discrepancy would not disappear, as long as the *usual* voltage dependence of g is assumed.

Cutler has calculated independently the leakage current in Si fused junction on the similar channel model¹²⁾. In this case, g was assumed to be independent of the voltage difference across the surface junction, while the theoretical junction current was used for the surface junction instead of the simple saturation current j_0 in the Eriksen's formula. The result is expressed as follows;

$$I = \sqrt{2gC^2 j_0 \frac{kT}{q}} \left(e^{qV/kT} - \frac{qV}{kT} - 1 \right)^{1/2}, \quad (3)$$

where the notations are rearranged for the convenience of the comparison with Eq. (1). In this calculation, geometry was considered only for the grown junctions.

As is seen from Eq. (3), the leakage current derived in this way has negative second derivative, as was the case of Eriksen's result.

A remark which has been given independently by these authors, is the invalidity of assuming j_0 to be independent of the position along on the channel. We believe this is one of the most important factors that must be considered hereafter, since it involves the correlation between the leakage current and the surface recombination velocity. One difficulty occurs in this model when the experimental results of the creep phenomenon are considered. Since the result show the independentness of the change in the leakage current on the bias voltage, as mentioned referring to Fig. 7, the factor which is changed by the creep phenomenon must be involved in the quantities that can be put *out of the integral* in Eq. (1). If this is the case, the insertion of j_0 into the integral is utterly meaningless.

It must be noticed here that there is another blindspot in the consideration of these channel models. It is usually believed that g is almost inversely proportional to the voltage difference across the surface junction, so the assumption made by Cutler that g is a constant with respect to the voltage seems to be crude. If, however, the voltage dependence of the surface conductivity g is assumed to

be unknown, it is possible, in principle, to deduce the dependence from the experimental results. By rough estimation, it promptly turns out that the voltage dependence of g so determined is quite unusual and no longer is a monotonic decreasing function of the voltage¹³⁾.

In considering the creep phenomenon on this point of view, one must also estimate the validity of the assumption used so far that the surface potential φ_s is constant with respect to the voltage difference.

In the above discussion, the possibility of the ionic conduction as proposed by Law¹⁴⁾ has not been considered. It has been ruled out since the electrical characteristic was observed under relatively low humidity, and also since no ohmic character was measured in the experiments.

(5.2) Creep phenomena and the surface field effects.

Attention is focused on the creep phenomenon again in this section. If, in general, the current is expressed;

$$I = F(V, \alpha), \quad (4)$$

the effect of the creep appears in the factor α . The time dependence of the creep and its recovery is understood as that of α . The nature of the quantity α is still in question at present, but it may be believed that the phenomenon is not the thermal one and is essentially connected with the *surface properties*. This is evident since the creep appears in the deteriorated transistors and diodes which exhibited no creep before the deterioration.

One of the most striking feature of the creep phenomenon is the *large time constant*. The time constants associated with the creep are of the order of seconds or minutes, which are several orders of magnitude larger than the ordinary electronic reactions in the semiconductors.

It is noticed here, however, that such long time effects are rather familiar to the investigators of the semiconductor surface phenomena. In the surface field effect, relaxation with the time constants of the order of minutes are commonly experienced which results from the slow transportation of electrons across the surface oxide layer. The time constants are dependent upon the thickness

of the oxide layer¹⁵⁾. In both of the above two phenomena, creep and field effect, slow effect is observed under the application of the electric field on the surface. Hence, there may be some correlations between them. In the field effect, it is believed that the fast reaction occurs at first and then follows the slow reaction. The former completes within the time comparable to the minority carrier lifetime while the latter takes seconds or minutes depending on the surface conditions. Therefore, the response of the field effect is generally observed as reported by Many et al¹⁶⁾.

Hence, it is quite natural to expect to find out the similar fast process at the beginning of the creep, if it is really correlated to the field effect. According to the field effect mechanism, this fast process must be of opposite direction with respect to the following slow creep.

Experimental evidence has been obtained by single sweep method as shown in Fig. 15, and 16. The photographs show the variation of the current under a constant voltage as a function of time from the application. As is seen from the figures, the expected fast process could be observed. For instance, fast positive creep occurs in 1 millisecc. after the application of the voltage, after which slow negative creep follows as shown in Fig. 15. In another junction shown in Fig. 16, fast negative creep is followed by a slow positive creep. Denoting the time constants of the fast and slow creep, by τ_1 and τ_2 , respectively, the results are summarized in the Table II. The signs in the table are referred to the direction of the creep.

Table II. Time constants of the fast and slow creep.

	τ_1	τ_2
# 5	-240 microsec.	+ 1.2 sec.
# 15	+550 microsec.	-165 millisecc.
# 4	- 22 microsec.	+430 millisecc.
# 11	-100 microsec.	+130 millisecc.

It was not possible to observe the fast creep in all of the samples tested. Two reasons are imagined, i.e., too small time constants to be detected by the apparatus used, or the lack of the effect itself.

One may notice at once seeing the results of Table II that τ_1 is somewhat larger than the time constants of the fast process in the field effect experiment, since the time constant of the fast process in the field effect is believed to be of the order of the carrier lifetime. However, we have some informations concerning on this result.

Fig. 17 and 18 show the results of the measurement of the field effect mobility as a function of frequency. As are shown in the figures, field effect mobility is sensitively af-

ected by the surface conditions. In some cases, inflection appears in the curve. Montgomery¹⁷⁾ has already pointed out that this inflection point corresponds to the minority carrier lifetime. In our experimental results, however, the time constants obtained from the inflection point were sometimes considerably larger than that expected from the lifetime. The similar results are published by Iwata et al¹⁸⁾ on the surface experiments of Si. The time constant of the fast decay was ranging from several hundred microseconds

(a) 500 μ sec/5 div

(b) 2 m sec/5 div

(c) 20 m sec/5 div

Fig. 15. Result of the single sweep experiment. The unit of the time scales are: (a) 500 microsec./5 div, (b) 2 milli-sec./5 div, (c) 20 milli-sec./5 div. (sample # 15)

(a) 200 μ sec/div

(b) 500 μ sec/div

(c) 500 μ sec/5 div

Fig. 16. Result of the single sweep experiment. The unit of the time scales are; (a) 200 microsec./5 div, (b) 500 microsec./5 div, (c) 500 milli-sec./5 div. (sample # 13)

to some milliseconds¹⁹⁾. Hence, it seems that there remains some questions on the belief that the time constant of the fast process in the field effect should be correlated with the carrier recombination.

It must be noticed that the discovery of the fast process in the creep phenomenon may give a strong evidence for the correlation between the surface field effect and the creep.

Fig. 17. Field effect mobility as a function of the frequency. 1, etched, 2, polished surface, respectively.

Fig. 18. Field effect mobility as a function of the frequency. 1, original, 2, HNO₃ treated, respectively.

§ 6. Conclusion

Experimental results on the backward characteristic and the creep phenomenon of the junction diodes have been given with the related surface and diode phenomena. The difficulties encountered in explaining the results on the basis of the present theories have been surveyed. It is noticed that no existing theories are successful in the explanation without introducing some additional models or concepts.

It has been pointed out that there is a possibility that the creep is caused by the same mechanism which is underlying the surface field effect. Though it is still a *possibility*, the experimental evidence presented by the single sweep observation seems to support the model strongly.

As a final comment, it should be noticed that there are at least two kinds of creep phenomenon, i.e., the creep in the relatively low humidity ambient and in high humidity, respectively. The former may be treated on the basis of electronic process, while it will not be adequate to treat the latter on the same basis. The same will be true for the case of the surface effects of semiconductors. Thus, the discussion of the surface properties whether they are of electronic or ionic without specifying the surface conditions may sometimes further introduce more confusions than clarify the situation.

Effect of External Stress on the Domain Structure of WO_3

By Sigetosi TANISAKI

Faculty of Literature and Science, Yamaguchi University

(Received December 23, 1957)

WO_3 is monoclinic at room temperature and has a domain structure with walls of (110) and (100) twin planes. The (110) wall is displaced sideways by a pressure externally applied along the b axis, resulting in the change of the axis b to the shorter axis a . The (100) domains change to a single domain by stress X_z . The single domain crystal obtained in this way is used to determine the optic elasticity axes of WO_3 . Two peculiar types of domain structure appear by a pressure along the c axis, which can be understood as resulting from the change of the axis c to the axis a by the stress. This sensitivity of domain structure to the stress seems to be due to the monoclinic and pseudosymmetric structure of this crystal.

§ 1. Introduction

Tungsten trioxide, WO_3 , was first reported to be a ferroelectric by Nagasawa¹⁾ and Mathias²⁾ and then there have been many reports in relation to the ferroelectricity or antiferroelectricity. According to Ueda and Kobayashi³⁾ WO_3 is monoclinic and has an antiferroelectric atomic arrangement at room temperature and the unit cell dimensions are $a=7.274\text{\AA}$, $b=7.501\text{\AA}$, $c=3.824\text{\AA}$, $\beta=90^\circ 56'$. It has a domain structure with walls of (110) and (100) twin planes which is sensitive to external stress. Hirakawa⁴⁾ and, Ueda and Ichinokawa⁵⁾, reported on the effect of stress on (110) domains. In the present paper, the effect of external stress on both (110) and (100) domains and two peculiar types of domain structure which appear by stress will be reported.

§ 2. Experiments

The crystals used in this experiments are thin plate crystals with well-developed c surfaces produced by sublimation of purified tungstic acid in the same way as was reported in the previous paper⁶⁾. The purer is tungstic acid, the fewer and the greater are the domains of the crystals obtained, and such crystals are convenient to observe the effect of external stress on the domain structure.

a) (110) domain

When a c surface of plate crystal is observed by the metallurgical microscope, (110) and (100) domain walls can be seen clearly because the crystal is monoclinic and therefore the c surface is not flat but zigzag on account of its domain structure. Five straight lines which

make an angle of 45° to the crystal edges in Photo. 1 (a) are (110) domain walls, and the many fine parallel lines which are parallel or perpendicular to the crystal edges are (100) walls and so the direction of the b axis of the crystal can be known easily from these (100) walls. When a pressure is applied along the a or b axis of such crystal, (110) walls are displaced sideways and the domains whose b axis is perpendicular to the pressure widen and the domains whose b axis is parallel to the pressure narrow. On being applied a sufficiently strong pressure all (110) walls are displaced and disappear in a thin crystal. But in a thicker crystal it is not easy to move (110) walls and sometimes the crystal is destroyed by severe stress before wall displacements are observed. Photo. 1 (b) shows the effect of the pressure shown by arrows on (110) walls. Among the five (110) walls of Photo. 1 (a), two pairs of walls disappear and there is one short wall left near the right lower corner of the crystal.

Photo. 1. Effect of the pressure shown by arrows on (110) walls.

b) (100) domain

In order to observe (100) domains, it is better to observe a b surface of the crystal by

a polarizing microscope. Because one of the three optic elasticity axes of WO_3 is coincident with the crystallographic b axis and the other two in the b plane are different from a and c axes by a small angle in the monoclinic phase. Therefore extinction positions are different in each adjacent domains, and so a beautiful domain pattern is observed between crossed nicols as shown in Photo. 2 (a). The dark and bright parts of the domain pattern can be interchanged by a rotation of the crystal. When shearing stress X_z is applied to this crystal, it can be changed into a single domain crystal as shown in Photo. 2 (b). The orientation of the two optic elasticity axes in the b plane can be determined by observing the extinction positions of such single domain crystal in consideration of the sense of the applied shearing stress. Fig. 1 shows the positions of optic elasticity axes with respect to the crystallographic axes. A gypsum plate was used in order to distinguish the X' axis from the Z' axis.

These changes of (110) and (100) domain structure by the external stress do not recover even if the stress is removed.

Photo. 2. Effect of the stress X_z on (100) walls.

Fig. 1. Optic elasticity axes of WO_3 .

at the crystal edges and extend across the crystal (Photo. 3). When the stress is removed, only small wedges in the initial stage of formation disappear at once, but the other large new domains do not show any change of appearance. These new domains extend through the thickness of the crystal. When such crystal is observed by the polarizing microscope using only a polarizer, the new domains and the original part of the crystal show the dichroism, and the difference of the absorption of two parts of the crystal is maximum

Photo. 3. Domain structure obtained by the pressure along the c -axis.

Photo. 4. First type of the domain structure obtained by the pressure along the c -axis.

Photo. 5. Second type of the domain structure obtained by the pressure along the c -axis.

c) two peculiar types of domain structure

When a b surface is observed, a new type of domain structure produced by a pressure applied along the c axis is found. If the pressure is increased slowly, wedge-shaped domains making about 45° to the c axis are nucleated

in the position in which the c axis of the original crystal is parallel to the direction of polarization and the contrast is reversed at the perpendicular position to this. From this fact it seems that in the new domains the orientation of the a and c axes is interchanged with respect to that of the original part of the crystal. This is ascertained by taking X-ray rotation photographs of a crystal, which mostly consists of new domains, and is obtained by widely applying a pressure to the c surface.

Inside this new domain many fine laminar domains are observed between crossed nicols, which extend nearly perpendicularly or parallel to the c surface of the crystal. Their domain walls seem to be (001) and (100) twin planes respectively judging from the reversal of the a and c axes. Such indices of planes in the new domains are expressed for convenience with a prime like $(100)'$ and indices without prime are used only for the original part of the crystal in the following. These $(001)'$ domains are related to the original (100) domains at the boundary as shown in Photo. 4 and 5. These photographs show the two standard types of domain structure near the boundary. In Photo. 4 the right upper side of the boundary is the original part of the crystal and the left lower side of it is the new domain part, and in Photo. 5 the left upper side is the original part and the right lower side is the new domain part. In the first type the upper dark (100) domains link to the lower bright $(001)'$ domains and the bright (100) domains to the dark $(001)'$ domains and an angle between the (100) and $(001)'$ walls measured on the photograph is about 177° . In contrast to this, in the second type the dark (100) domains link to the dark $(100)'$ domains and the bright (100) domains to the bright $(100)'$ domains and an angle between the (100) and $(100)'$ walls is about 87° .

Those two peculiar types of domain structure can be explained as follows by taking into consideration the reversal of the a and c axes on either side of the boundary. The orientation of the crystallographic axes of each domain in the first type can be determined, as shown in Fig. 2, from the domain pattern observed between crossed nicols and the orientation of the optic elasticity axes relative to the crystallographic axes shown in

Fig. 1. Then the boundaries of the original and new domains seem to be (201) or $(201)'$, and $(2\bar{0}1)$ or $(2\bar{0}1)'$, which are their twin planes, and the angle between (100) and $(001)'$ in each case is calculated to be $177^\circ 10'$ and $177^\circ 4'$ respectively from the crystallographic data by Ueda and Kobayashi³⁾. There is a difference of angle $6'$ between them but the calculated value and the measured one coincide very well. In order to maintain the condition of continuity at the domain boundary so that the crystal does not show any crack or overlapping, there must be in the crystal a strain caused by this difference of angle $6'$. Sometimes very fine $(100)'$ domains which seem to be due to this strain can be observed inside the $(001)'$ domains.

Fig. 2. Crystal axes of each domain in the first type.

In the same way as in the first type, the orientation of the crystallographic axes of each domain in the second type can be determined as shown in Fig. 3. There is no boundary plane of low indices in which the condition of continuity is completely fulfilled. Among several probable combinations of boundary planes, for example (201) $(2\bar{0}1)'$, (101) $(40\bar{1})'$, (403) $(30\bar{1})'$, (302) $(80\bar{3})'$, and (805) $(50\bar{2})'$ etc., a combination of (302) and $(80\bar{3})'$ shows the best fitness and so the orientation of the boundary plane seems to be very close

to (302) and $(80\bar{3})'$, or $(80\bar{3})$ and $(302)'$. When it is assumed to be (302) and $(80\bar{3})'$ themselves, calculated values of angles between (302) and (100) and between $(80\bar{3})'$ and $(100)'$ are $51^\circ 10'$ and $35^\circ 49'$ respectively, and the sum of them is $86^\circ 59'$ which coincides very well with the measured value 87° .

Fig. 3. Crystal axes of each domain in the second type.

Thus the characteristics of the two types of domain structure can be almost explained, but the condition of continuity at the boundary is not fulfilled completely in both cases. In fact, the real domain structure is not always one or the other of the above two standard types, but is a complex structure in which the two types are mixed together and sometimes a few domains disappear at the boundary in such a way that the strain caused in the crystal becomes as small as possible.

§ 3. Discussions and Conclusions

The fundamental unit of the structure of this material is a WO_6 octahedron formed by a tungsten atom and octahedrally coordinating six oxygen atoms, and these octahedra are

coupled together by sharing corners to form a three dimensional crystal lattice. WO_3 is not cubic but monoclinic at room temperature and there are four somewhat distorted WO_6 octahedra per unit cell. Therefore the a and b axis lengths are each approximately twice the c axis length and the relation, $a < b < 2c$, is noticed between the three axis lengths. In the above experiments, the (110) wall is displaced sideways by a pressure along the b axis with the change of the axis b to the shorter axis a , and the (100) domains change to a single domain by stress X_z , and two peculiar types of domain structure appear by the pressure along the c axis with the change of the axis c to the axis a . Judging from the monoclinic and pseudosymmetric structure above described, all these changes of the domain structure are not astonishing and needs only a small displacement of each atom. Thus the sensitivity of domain structure to the external stress seems to be due to the monoclinic and pseudosymmetric crystal structure of this material.

In conclusion the author wishes to express his hearty thanks to Prof. K. Tanaka of Kyoto University for his continual guidance and encouragement, and to Dr. T. Nakamura of Tokyo University for his valuable suggestions. This work was supported partly by the Scientific Research Expenditure of the Ministry of Education.

Ferroelectric and Optical Properties of $\text{Na}(\text{K-NH}_4)\text{-tartrate}$ Mixed Crystals

By Yasuharu MAKITA and Yutaka TAKAGI

Tokyo Institute of Technology, Oh-okayama, Tokyo

(Received January 10, 1958)

The phase diagram of the mixed crystals composed of NaK-tartrate and its isomorph $\text{NaNH}_4\text{-tartrate}$ has been investigated over the whole range of the concentration. The properties of each phase have been studied by dielectric and pyroelectric measurements and by optical observations. In 90.5 per cent $\text{NaNH}_4\text{-tartrate}$ crystal three kinds of polymorphic modification have been found, that is, successively, a ferroelectric phase with spontaneous polarization along the crystallographic b axis, another ferroelectric phase with spontaneous polarization along the crystallographic a axis and a paraelectric phase. The phase of compositions near the pure $\text{NaNH}_4\text{-tartrate}$ has been confirmed to be ferroelectric with spontaneous polarization along the b axis.

§ 1. Introduction

It has recently been found that $\text{NaNH}_4\text{-tartrate}$ is ferroelectric below the transition point of -164°C with a spontaneous polarization in the direction parallel to the b axis¹⁾. The crystal shows many peculiar properties: 1) Its dielectric constant along each crystallographic axis does not follow the Curie-Weiss law above the transition point, and the pyroelectric charge developed on the crystal surface at the transition point remains constant for further cooling. 2) The domain structure is not affected by an ac electric field of 20 Kv/cm, while it can easily be affected by a shearing stress Z_x . These properties form striking contrasts if compared with those of NaK-tartrate (Rochelle salt) or other normal ferroelectrics.

As well known, the non-polar phase of $\text{NaNH}_4\text{-tartrate}$ ($\text{NaNH}_4\text{C}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$) is isomorphous with the non-polar phase of NaK-tartrate ($\text{NaKC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$), and they can form a continuous series of solid solution over the whole range of concentration. These mixed crystals were first investigated by Kurtzschatow *et al.*²⁾ and have recently been re-examined by Melmed *et al.*³⁾ Substitution of very small amount of $\text{NaNH}_4\text{-tartrate}$ reduces the temperature range of ferroelectric activity in NaK-tartrate very rapidly. Substitution of about two per cent eliminates the spontaneous polarization entirely. The ferroelectric activity, however, reappears in the crystals containing more than about eighteen percent of $\text{NaNH}_4\text{-tartrate}$.

These crystals show a single Curie point at low temperatures, exact position of the transition depending upon the concentration. The Curie point-composition curve goes down linearly from about 20 per cent to about 60 per cent. It seemed to be difficult to foretell how it can be connected with the transition point of -164°C of $\text{NaNH}_4\text{-tartrate}$. Moreover, it must be emphasized that the spontaneous polarization of $\text{NaNH}_4\text{-tartrate}$ lies in the direction parallel to the b axis while the spontaneous polarization of NaK-tartrate and those of all the mixed crystals which have been so far investigated lie in the direction parallel to the a axis. So it can not be expected that the Curie point-composition curve given by the previous investigators should be connected smoothly with the transition point of $\text{NaNH}_4\text{-tartrate}$.

However, Melmed *et al.* have found that the crystal containing 98.1 per cent of $\text{NaNH}_4\text{-tartrate}$ shows a small anomaly in the dielectric constant at -155°C , the behavior of which being quite similar to that observed in the pure $\text{NaNH}_4\text{-tartrate}$. It seems, therefore, that this transition point of -155°C of the 98.1 per cent crystal should be connected with the transition point of -164°C of the pure $\text{NaNH}_4\text{-tartrate}$.

Our primary concern in the present paper is to study in more detail the dielectric, pyroelectric and optical properties of the mixed crystals of the compositions near the pure $\text{NaNH}_4\text{-tartrate}$. Our second purpose is to re-

examine and to complete the phase diagram over the whole range of this system.

§ 2. Preparation of the Crystal Plates

The crystals were grown by cooling method in a 2-litre beaker filled with saturated aqueous solution. It usually required two weeks to decrease the temperature from 28°C to 26°C; the regulation was achieved by a thermoregulator.

The composition of the crystal depends upon the composition of the solution, as shown in Fig. 1. The data have been obtained by chemical analysis through the measurement of the weight of potassium contained in the crystal; the accuracy of the analysis is within 0.5 per cent. The results are in fairly good agreement with those obtained by Melmed *et al.*, though slightly different from those obtained by Kurtchatow *et al.* The latter investigators did not give the temperature of crystallization used in their experiment.

Fig. 1. The relation between the compositions of the crystals and the solutions.

The pure NaNH_4 -tartrate and the mixed crystals around it show a pronounced tendency to dehydrate, while the pure NaK -tartrate and the mixed crystals around it sometimes show a tendency to deliquesce. In the course of our studies, therefore, the crystals have always been preserved in five desiccators, each being kept at a suitable humidity according to the composition of the mixed crystals, except the short time when the crystals were set in the measuring apparatus. The specimens used were cut out of mother crystals by means of a wet thread saw and then ground on a linen

cloth with the abrasive of fine powder of chrome oxide suspended in liquid paraffin. In the cutting and grinding processes, special attention was paid to the orientation of the crystal plates with reference to the crystallographic axes.

§ 3. Dielectric Properties

1. Dielectric Constants

As the electrodes, silver-foils have been attached by absolute alcohol on the surfaces of the specimens of the area 0.7 to 6 cm² and the thickness 0.7 to 1.5 mm. The dielectric constants have been measured over the temperature range from about 30°C down to -190°C by a usual bridge method with an ac field of 1 KC/sec and the field intensity of 5 to 10 v/cm.

According to the dielectric properties, it is convenient to divide the mixed crystals into four groups, as was done so by Kurtchatow *et al.* and Melmed *et al.*

The first group covers the range 0 to 2.5 per cent. This group is characterized by the typical NaK -tartrate behavior, all crystals except the 2.5 per cent one having two transition points. In the pure NaK -tartrate, as known well, there are two high peaks in the dielectric constant along the a axis, ϵ_a , at the two transition points of -18°C and 24°C, respectively. In the crystal containing only 2.5 per cent NaNH_4 -tartrate, the upper and the lower transition points merge with each other at -5.5°C. It is observed that the effect of the addition is much more pronounced for the upper transition point than for the lower one. The results are shown in Fig. 2.

The second group covers the range 2.5 to 18 per cent. This group is characterized by

Fig. 2. Dielectric constants along the a axis in the crystals belonging to the groups I, II and III.

a low and broad peak in the dielectric constant, ϵ_a . The peak is lowest for about 15 per cent NaNH₄-tartrate (Fig. 2).

The third group covers the range 18 to 85 per cent. This group exhibits a pronounced single peak in the dielectric constant, ϵ_a , of which the peak value decreases as the concentration of NaNH₄-tartrate increases (Fig. 2).

On the whole, our results of the dielectric constant along the *a* axis of the crystals containing less than 85 per cent of NaNH₄-tartrate are in fairly good agreement with those obtained by Melmed *et al.* In these groups, the dielectric constants along the *b* and *c* axes (ϵ_b and ϵ_c) have also been carefully examined. They show no anomalies at the transition points mentioned above, as shown in Fig. 3a.

Fig. 3. Dielectric constants along the *b* and *c* axes.
Solid circles: ϵ_b , Open circles: ϵ_c .
(a): The groups II and III.
The arrows show the temperature where the peak of the dielectric constant along the *a* axis appears.
(b): The group IV.

The fourth group covers the range 92.5 to 100 per cent. This group is characterized by a small anomaly in all three dielectric constants ϵ_a , ϵ_b and ϵ_c with a discontinuity at the lower temperature side of the transition point (Figs. 3b and 4). A small peak is observed in ϵ_a

in the crystals containing about 92.5 per cent NaNH₄-tartrate, but it tends to disappear as the composition approaches 100 percent, as shown in Fig. 4. The locus of these transition points proves to be a phase boundary.

Fig. 4. Dielectric constants along the *a* axis of the crystals belonging to the group IV.

The 90.5 per cent crystal, lying between the groups III and IV, reveals two phase transitions at -163°C and -176°C . It has been confirmed that the upper transition is the same as those observed in crystals of the group III, because it is accompanied with a fairly large peak of only one dielectric constant ϵ_a , while the lower transition is the same as those observed in the crystals of the group IV, because it is accompanied with a small anomaly of all three dielectric constants ϵ_a , ϵ_b and ϵ_c (Fig. 5).

Fig. 5. Dielectric constants along the three crystallographic axes of the 90.5 per cent crystal.

2. Dielectric Hysteresis Loops

Under a high ac field of 50 cycles/sec applied parallel to the a axis, the dielectric hysteresis loop has been observed on a cathode ray oscilloscope. The crystals belonging to the group I reveal ferroelectric hysteresis loops at temperatures between their two transition points (Fig. 6).

On the other hand the 12 per cent crystal, which belongs to the group II, does not display a ferroelectric hysteresis loop for an applied field of 25 Kv/cm. Contrary to our expectation, we observed hysteresis curves much resembling those of ferroelectrics in the crystals just outside the phase boundaries of the groups I and III.

The crystals belonging to the group III reveal ferroelectric hysteresis loops below the transition points. The coercive field increases not only with decreasing temperature but also with increasing concentration of NaNH_4 -tartrate.

The crystals belonging to the group IV reveal only straight lines instead of the hysteresis loops all over the temperature range from 30°C to -190°C under an applied field as strong as 25 Kv/cm.

It has been found that the 90.5 per cent crystal reveals ferroelectric hysteresis loops only at temperatures between the upper and the lower transition points, although an ac field strength of 20 Kv/cm was not enough to bring about the saturation, as shown in Fig. 7.

The hysteresis curve has also been sought under a high ac field parallel to the b or the c axis. But it turned out that all the crystals, including those belonging to the group IV, display only straight lines instead of the hysteresis loops all over the temperature range from 30°C to -190°C under an applied field of 25 Kv/cm.

In the course of the study of hysteresis phenomena, some double hysteresis loops have been observed. The 20 percent crystal is very notable with its peculiar properties. With this crystal, it is possible to observe a double hysteresis loop at temperatures ranging from about -76°C (the transition point) down to about -150°C and under a relatively weak field (Fig. 8a). This anomalous hysteresis phenomenon is very similar to those recently

observed by Yurin⁴⁾* in NaK-tartrate crystal which had been intensely irradiated by γ -ray for several hours. However, there exists a striking difference: in our case the double hysteresis loop changes into an ordinary ferroelectric hysteresis loop as the applied field is increased, while in the Yurin's experiment the double hysteresis loops are observed to persist even under the field high enough to cause the saturation. Moreover, the life time of the double hysteresis loop is usually very short after a high field had been applied to our specimen and it becomes much shorter if the temperature of the crystal is changed several times up and down across the transition point under a high ac or dc field. After such a treatment the double loop often disappears, giving rise to the normal loop, and both the maximum electric polarization and the slope of the hysteresis loop become much larger than those observed before the treatment (Fig. 8 (b), (c)). It is very interesting to notice that the coercive field observed after treatment is often smaller than the threshold field (Fig. 8d). The recovery to the initial state with its double hysteresis loop requires several weeks or more, and it appears that the longer we keep the specimen at a temperature below the transition point, the more stable becomes the double hysteresis loop.

The double or the double-like hysteresis loops are also observed in other crystals at compositions adjacent to the phase boundaries between the group II and its neighboring groups on both sides under the same experimental conditions as above. Some examples are shown in Fig. 9.

§ 4. Pyroelectric Properties

In order to make clear the peculiar properties described in the preceding sections, the pyroelectric tests have been carried out by means of Simizu-type electrometer⁵⁾. The sensitivity of about 5×10^{-11} Coul/division can be attained by this device. A cooling rate of $1^\circ\text{C}/\text{min}$ was adopted.

As will be expected, all the crystals cut perpendicularly to the a axis (X -cut specimen) belonging to the group I, except the 2.5 per

cent one, show a pronounced pyroelectricity at temperatures between the upper and the lower transition points.

The X-cut specimen of 12 percent crystal, which belongs to the group II, did not show any trace of pyroelectricity at its passage through the dielectric peak point.

The X-cut specimens belonging to the group III show a pronounced pyroelectricity below the transition point. The results for some representative crystals are shown in Fig. 10.

The crystals cut perpendicularly to the b or the c axis (Y- or Z-cut specimens), belonging to the groups I, II and III did not show any trace of pyroelectricity at their passage through the transition points or the dielectric peak points.

The pyroelectric tests of the X-, the Y- and the Z-cut specimens belonging to the group IV have been carried out. The Y-cut specimens show a sudden occurrence of pyroelectricity just at the transition point and the charge amount proves to be temperature independent, as shown in Fig. 11. The X- or the Z-cut specimen did not show any trace of pyroelectricity at its passage through the transition point.

As expected, the 90.5 per cent X-cut specimen, lying between the groups III and IV, displays a pyroelectricity characteristic of the normal ferroelectrics at temperatures only between the upper and the lower transition points. Moreover, the Y-cut specimen of this

crystal reveals the same type of pyroelectricity as those observed in the crystals belonging to the group IV only below the lower transition point, as clearly demonstrated in Fig. 11.

The Z-cut specimen of this crystal did not show a trace of pyroelectricity. The results mean undoubtedly that this crystal begins to polarize spontaneously in the direction parallel to the *a* axis at the upper transition point, and spontaneous polarization increases until the temperature reaches the lower transition point, at which its direction rotates suddenly by 90° towards the direction parallel to the

Fig. 10. Behaviors of pyroelectric charge in the X-cut specimens of the crystals belonging to the groups I, II and III.

b axis and thereafter its magnitude seems to remain constant.

Fig. 11. Behaviors of pyroelectric charge in the 90.5 per cent crystal and those of the group IV.

It is to be noted that: 1) The X-cut specimens of the 20 per cent crystal yield a considerable amount of pyroelectric charge of the order comparable to those measured in the pure NaK-tartrate, though the values of pyroelectricity vary according to various pre-treatments. The effect of a field cooling treatment is clearly shown in Fig. 12. 2) It seems very likely that the pyroelectric charge detected in the X-cut specimens of the 3 per cent crystal arises from a certain kind of inhomogeneous monoclinicity: although the monoclinicity should disappear just at the compo-

Fig. 12. Effect of the field cooling on the pyroelectricity in the 20 per cent crystal (X-cut specimen).

sition of 2.5 per cent, if the crystal happened to be perfect. 3) Even at temperatures in the paraelectric region but not far from the transition point, all mixed crystals reveal a small amount of pyroelectricity, though it is almost negligible in unstressed crystals if compared with normal pyroelectricity caused by the spontaneous polarization. The pyroelectricity may be ascribed to crystal imperfections: to the internal strain and/or perhaps to the space charge stored somewhere in the interior of the crystals. 4) The Y-cut specimens of the crystals of the group IV as well as in the pure NaNH₄-tartrate are affected by means of field cooling, though the effect is very small if compared with that due to stress cooling (Z_x).

§ 5. Electric Polarization Induced by Shearing Stresses in the Crystals of Group IV

In the preceding paper, we reported that the shear stress Z_x can easily affect the electric polarization in the pure NaNH₄-tartrate crystal. We made, therefore, several 45° cut slabs of the crystals of which one edge bisects the a and c axis and the thickness of the plates lies along the b axis (45° Y-cut specimens), and applied a normal stress on one pair of narrow surfaces of each slab. The specimens below the transition point reveal a pronounced hysteresis curve in the shear stress *vs.* the electric polarization relation (Z_x - P_y curve), while above the transition point they show only a linear relation.

Fig. 13. Hysteresis curve induced by shearing stress in the 98 per cent crystal, at -183°C .

On the other hand, the 45° X -cut specimens and the 45° Z -cut specimens displays only linear relations in the shear stress *vs.* the electric polarization curves, the Y_z - P_z curves and the X_y - P_z curves respectively. The results in the 98 per cent crystal are shown, as an example, in Fig. 13.

The spontaneous polarization estimated from those cycles turns out to be 0.21μ Coul/cm², being independent of the concentration within the accuracy of the experiment.

It has also been confirmed that the 45° X -cut specimens belonging to the groups I and III, display pronounced hysteresis curves in the relation, the shear stress *vs.* the electric polarization (Y_z - P_z curves), at temperatures in their ferroelectric range; while the 45° Y -cut and the 45° Z -cut specimens show only linear relation in the Z_x - P_y curves and the X_y - P_z curves.

§ 6. Optical Properties

1. Domain Structure

At temperatures between the upper and the lower transition points, the crystals belonging to the group I become monoclinic owing to the spontaneous shear strain y_z^0 , since the crystals polarize spontaneously along orthorhombic a axis. There is a possibility for us to observe domain structures through a polarizing microscope, because the angle between the monoclinic a axis and one of the indicatrix axes of the monoclinic phase is far larger than the spontaneous shear strain y_z^0 ⁽⁶⁾. The direction of observation must be parallel to the a axis. The same situation is also expected with regards the crystals belonging to the group III.

The crystals belonging to the group IV becomes monoclinic owing to the spontaneous shear strain z_x^0 , since the spontaneous polarization lies as proved in the preceding sections along the orthorhombic b axis. These crystals must, therefore, be observed in the direction parallel to the b axis.

The crystals belonging to the group II have no spontaneous polarization both above and below the temperature at which there is a broad peak in the dielectric constant *vs.* temperature curve. If it is true, the crystals must remain orthorhombic below the peak temperature, the domain should not be observed anywhere.

Fortunately all these expectations turned out to be true. The X -cut specimens belonging to the group I reveal the domain structure consisting of many fine stripes which are parallel to the c axis, only if the specimens are kept at temperatures between the upper and the lower transition points. The X -cut specimens belonging to the group II do not show a domain pattern even at temperatures below the broad peak point. The X -cut specimens belonging to the group III also reveal the domain structure which is quite similar to those observed in the group I, if the specimens are cooled below the transition point.

On the other hand, the Y -cut specimens belonging to the group IV display a domain structure consisting of many stripes which are parallel to the c axis at temperatures below the transition point, while the X -cut and the Z -cut specimens have never shown a domain pattern.

The behavior of the X -cut specimens of the 90.5 per cent crystal, which lies between the groups III and IV, is very interesting. It displays a domain structure consisting of a lot of stripes which are parallel to the c axis, if the specimens are kept at temperatures between the upper and the lower transition points, whereas the pattern suddenly disappears at the moment the crystal is cooled through the lower transition point. On the other hand, the Y -cut specimens at temperatures between the upper and the lower transition points do not show a domain pattern, but they display a domain structure, when they are cooled below the lower transition point. This confirms that a sudden change of the spontaneous shear strain from y_z^0 to z_x^0 occurs at the lower transition point. The effect of the shear stress Z_x upon the domain boundaries in the Y -cut specimens of this crystal is not very different from those observed in the Y -cut specimens of the crystals belonging to the group IV, as shown in Fig. 14.

2. Optically Biaxial Properties

Both the pure NaNH_4 -tartrate and the pure NaK -tartrate are optically biaxial. Lavinir⁽⁷⁾, using sodium light, has determined the principal refractive indices. The values at 20°C are as follows:

Fig. 14. Response of the domain structure to the shearing stress Z_x in the 90.5 per cent Y-cut₁specimen, at -186°C .

$\alpha=1.4900, \beta=1.4920, \gamma=1.4954,$
for NaK-tartrate,
 $\alpha=1.4953, \beta=1.4985, \gamma=1.4996,$
for NaNH₄-tartrate.

On using these values, we obtain for the optical angle (2Ω):

$\Omega=37^{\circ}20'$ for NaK-tartrate,
 $\Omega=59^{\circ}40'$ for NaNH₄-tartrate.

Hence NaK-tartrate is optically positive. As known well, the optical plane is (010), and the acute bisectrix is the a axis. We get therefore the following identification:

$n_a=\gamma, n_b=\beta, n_c=\alpha,$ for NaK-tartrate, where n_a, n_b and n_c denote the refractive indices for the light of which the electric vector lies along the crystallographic a, b and c axes, respectively. On the other hand, NaNH₄-tartrate is optically negative. We have confirmed that the optical plane is (100) and the acute bisectrix is the c axis. We get therefore

$n_a=\beta, n_b=\gamma, n_c=\alpha,$ for NaNH₄-tartrate.

We have examined the crystals at room temperature in convergent polarized light.

In NaK-tartrate the optical axes lie in fact in (010) plane. The optical axes approach gradually the crystallographic c axis on increasing the concentration of NaNH₄-tartrate. It seems that the two optical axes coincide with the c axis at the concentration of about 65 per cent, though we could not obtain a uniaxial figure, since the crystal of requisite composition was missing. On further increasing the concentration of NaNH₄-tartrate the optical axes get away from the crystallographic c axis. If the refractive indices change linearly with the composition, the optically uniaxial crystal must be located at somewhere

Fig. 15. Refractive indices *vs.* composition curves.

about 74 percent as shown in Fig. 15. The reason of the discrepancy between our observation and the expectation derived from Fig. 15 is not clear yet.

§ 7. Conclusion and Discussion

The phase diagram summarizing the result of the present investigation is shown in Fig. 16, where the phase boundaries obtained by Kurtchatow *et al.* and Melmed *et al.* are also included for the convenience of comparison.

Fig. 16. The phase diagram of Na(K-NH₄)-tartrate mixed crystals. The chain line shows the temperature where the broad dielectric peak appears.

The phase boundary of the region I is in good agreement with those determined by previous investigators. On the other hand, the phase boundary on the left hand side of the region III appears to be slightly different from that determined by Melmed *et al.* The discrepancy is, however, mainly due to the fact that they used directly the chemically analyzed values themselves, in place of the values which should be obtained if they used their own curve which is shown in Fig. 1. In fact, if we were allowed to correct their value by means of their curve, it turns out that their phase boundary shifts to agree quite well with ours as shown by dotted lines in the figure.

In the phase diagram, the phase I is ferroelectric and the crystals in this temperature range are monoclinic, while the phase II is paraelectric and the crystals in this tempera-

ture range are orthorhombic. The phase III is ferroelectric and the crystals are monoclinic with the same type of spontaneous shear strain y_z^0 as those in the phase I. On the other hand, the phase IV is another ferroelectric phase with spontaneous polarization parallel to the b axis and crystals in the temperature range are monoclinic owing to the spontaneous shear strain z_x^0 .

The properties of the crystals belonging to the group IV are very peculiar as compared with other groups. The Curie-Weiss law does not hold above the transition point. The transition seems to be of the first order. The spontaneous polarization is independent of temperatures below the transition point.

It is of some interest to notice that direction of spontaneous polarization in NaK-tartrate as well as NaNH₄-tartrate is parallel to the direction of the maximum refractive index, although the correspondence is actually not so perfect as to give the uniaxial crystal just at the boundary between the groups III and IV. The correspondence should become better at low temperatures, if the optically uniaxial composition would go towards the right as the temperature is decreased. But the indices *vs.* temperature formulae given by Lavinir predicts that the contrary is the case. We have observed that it really goes towards NaK-tartrate side from the room temperature values with decreasing temperature.

The authors wish to express their hearty thanks to Professor H. Takahashi of Tokyo University, Dr. M. Marutake of Kobayashi Institute, Dr. G. Shirane of Westinghouse Research Laboratories, Dr. E. Sawaguchi of Electrotechnical Laboratory, Dr. T. Mitsui of Pennsylvania State University, and Dr. H. Maniwa of Tokyo Institute of Technology, for their very illuminating discussions. The chemical analysis of all the specimens has been carried out by Dr. T. Katsura under the direction of Professor I. Iwasaki of Tokyo Institute of Technology. The authors greatly appreciate the kindness of both of them. The authors are also indebted to Mr. S. Takayanagi for his cooperation in this study in its early stage. The expenditure of this study has been defrayed from the Science Research Grant of the Ministry of Education.

The Change of Carrier Concentration in the Simple Semiconductors with Static Magnetic Field

By Yasutada UEMURA and Masaharu INOUE

Department of Physics, University of Tokyo

(Received January 11, 1958)

The change of carrier-concentration with static magnetic field is discussed by using the simple model of the semiconductors. The attention is mainly focused on whether the concentration of free carriers increases or decreases with the field. The situations are classified into three cases [A], [B] and [C] according to the degree of concentration of the centers.

[A] The concentration of the trapping centers is dilute and a center can trap only one carrier. In this case the carrier concentration n is a monotonously decreasing function of the field H , namely $dn/dH^2 \geq 0$,

[B] The impurity levels lose the locality and form a band so called "impurity band," however, the width of which is still smaller than kT . In this case we obtain

$$\begin{aligned} (dn/dH^2)_{\text{weak } H} &> 0 & \text{when } (m/m^*) < \sqrt{3\delta} \\ (dn/dH^2)_{\text{weak } H} &< 0 & \text{when } (m/m^*) > \sqrt{3\delta} \end{aligned}$$

where m^* is the effective mass of carriers and δ means the degree of compensation, namely $\delta = (N_d - N_a)/Nd$.

[C] The width of impurity band is larger than kT and the Fermi-level ζ_0 at $H=0$ lies in this band. In this case we obtain

$$(dn/dH)_{\text{weak } H} > 0 \quad \text{when } (m/m^*) < \sqrt{3(1-s)}$$

where

$$s = kT \left[\frac{\partial}{\partial E} \log D(E) \right]_{E=\zeta_0}.$$

$D(E)$ means the state density of the impurity band.

It seems that there is no possibility to explain the so-called "magneto-conductive" phenomena observed in p -InSb from this stand-point.

§ 1. Introduction

The aim of this paper is to investigate the change of carrier-concentration in the simple semiconductors with the static magnetic field. Our attention is mainly focused on whether the concentration increases or decreases with

the field. This problem has been considered by several authors⁽¹⁾⁽²⁾⁽³⁾ to explain the increase of the carrier-concentration due to the magnetic field, so called magneto-conductive phenomena, observed in the p -type InSb. The characteristics of their standpoints and

their results are summarized in the Table I, comparing with those of this paper shown in the last column of the table.

In the former researches there remained some questions about the choice of the distribution function for the trapped state of carriers. As shown in the Table I, they used the distribution function $f_{\pm}=\frac{1}{2}[\exp(E_{\pm}-\zeta/kT)+1]^{-1}$, which would lead us to the conclusion that the distribution function of Trapped carriers without the magnetic field might be $f=f_{+}+f_{-}=[\exp(E-\zeta/kT)+1]^{-1}$. This conclusion is not correct and it is supposed that it should be $f=[\frac{1}{2}\exp(E-\zeta/kT)+1]^{-1}$ when a trapping center can trap only one electron and it should be $f=2[\exp(E-\zeta/kT)+1]^{-1}$ when a trapping center can trap two electrons. In order to discuss the change of carrier concentration, it is important that the correct types of distribution function are used for the different concentrations of the trapping centers. In this paper we classify the situations into three typical cases and for each of them we took the correct types of the distribution function of the trapped carriers. The effect of the compensation of carriers which was neglected in the former papers is also considered in this paper.

For the simplicity we assume that the dis-

tribution of the free carriers is classical, and then discuss the effects of the orbital diamagnetism and spin paramagnetism on the change of the carrier-concentration with the static magnetic field.

§ 2. A Simple Model

Here we take a simple model of a semi-conduction which has one conduction band, a single donor level, and some acceptors. The levels of acceptors are assumed that they are sufficiently far apart from the level of donors in the energy scale. We further assume that the energy surface of the free carriers is spherical and the effective mass of them is m^* . (Fig. 1A).

Fig. 1. (a, b)

If the magnetic field H is applied in the z direction the motion of the free carriers in x - y plane is orbitally quantized. Their states

are described by the discrete quantum number l and the momentum p_z in the z direction. The energy of a free carrier $E_{\pm}$ consists of three terms, i.e. the kinetic energy in the z direction, the quantized energy of the circular motion in the x - y plane which is represented by the energy of a simple harmonic oscillator, and the Zeeman-energy due to the spin of the carrier.

$$E_{\pm} = \frac{p_z^2}{2m^*} + 2\mu^* H(l + \frac{1}{2}) \mp \mu H$$

$$\mu = \frac{e\hbar}{2m^*} \qquad \mu^* = \frac{e\hbar}{2m^*c}$$

$$l = 0, 1, 2, \dots$$

In the Fig. 1(B), the field dependence of $E_{\pm}$ is shown when $p_z = 0$.

For the trapped state, only the effect of the spin paramagnetism is taken into account, and the effect of the orbital diamagnetism is negelected in this paper. It is noticed that the orbital diamagnetism of trapped carriers should be included when the m^* is small and the field H is large.

By assuming the classical distribution of the free carriers, their concentration $n_{\pm}$ is expressed as follows:

$$n_{\pm} = \frac{4\pi}{h^3} \frac{\hbar e H}{c} \sum_{l=0}^{\infty} \int_{-\infty}^{+\infty} dp_z \exp\left(\frac{\zeta + E_{\pm}}{kT}\right)$$

where $(\pm)$ refers to + or - spin respectively, and ζ means the Fermi-energy.

For the convenience, let us introduce the following nondimensional parameters such as ε , η , θ and θ^* which are defined by:

$$\begin{aligned} \varepsilon &\equiv \frac{E_d}{kT} & \eta &= \frac{\zeta}{kT} & \theta &\equiv \frac{\mu H}{kT} \\ \theta^* &= \frac{\mu^* H}{kT} \end{aligned}$$

As to the concentrations we introduce the following quantities:

$$\begin{aligned} N_0^* &= 2 \left(\frac{2\pi m^* kT}{h^2} \right)^{3/2} & A &\equiv \frac{N_0^* e^{\varepsilon}}{2N_a} \\ \delta &\equiv \frac{N_a - N_a}{N_a} \end{aligned}$$

where N_d and N_a are the concentrations of the donors and acceptors. The non-dimensional parameter δ represents the degree of the compensation and is assumed to be $1 \geq \delta > 0$. In the usual cases, A is sufficiently smaller than 1 especially at the low temperature.

By using these notations, the concentration of free carriers n can be written as follows:

$$\begin{aligned} n &= n_+ + n_- \\ n_{\pm} &= \frac{1}{2} N_0^* e^{\eta} \frac{\theta}{\sinh \theta^*} e^{\pm \theta} \end{aligned} \tag{1}$$

Fermi-energy η in the above equation should be determined by the neutrality condition which is

$$n_+ + n_- + N_+ + N_- = N_d - N_a \tag{2}$$

$N_{\pm}$ is the concentrations of trapped electrons. The suffix $(\pm)$ corresponds to their $(\pm)$ spin. In the following three sections, we get three different expressions of $n(H)$ from the equation (2) by using the best fitted forms of $N_{\pm}$ in each cases.

§ 3. Case A. The Concentration of the Donor is Dilute and a Donor-center can Trap Only One Carrier

In this case $N_{\pm}$ is not given by the Fermi-distribution in a perfect sense of the one body approximation but is given by the following modified form: ⁽⁴⁾⁽⁵⁾

$$N_{\pm} = \frac{N_d}{1 + e^{\pm \theta} - \eta + e^{\mp \theta}} \tag{3}$$

By using the equations (1), (2), (3), n can be obtained as follows:

$$\begin{aligned} \frac{n}{N_a} &= \frac{1}{2} [-(a+1-\delta) + \sqrt{(a+1-\delta)^2 + 4\delta a}] \\ a &\equiv A\theta^*/\sinh \theta^* \end{aligned} \tag{4}$$

The equation (4) can be written approximately in the simple expressions when $a \ll 1$.

$$\frac{n}{N_a} \doteq \begin{cases} \sqrt{a} & (\delta = 1) \\ \frac{\delta}{1-\delta} a & (a \ll (1-\delta)^2) \end{cases}$$

Some remarks should be made in the equation (4), that is to say, n does not include θ . This means that the effect of the spin paramagnetisms does not appear explicitly. As it is easily proved that dn/dH^2 is always negative in the case A, so n is a monotonously decreasing function of H .

§ 4. Case B. The Donor Levels Lose the Locality and from a Band so Called "Impurity Band", However, the Width of which is Still Smaller than kT .

In this case the Fermi-distribution function can be applied to the trapped electrons and $N_{\pm}$ is given by:

$$N_{\pm} = \frac{N_a}{1 + e^{\pm\theta - \eta}} \quad (5)$$

By introducing the quantities z , β_1 and β_2 which are defined by

$$Z \equiv n/N_a A$$

$$\beta_1 \equiv \frac{\theta^*}{\sinh \theta^*} (1 + e^{\mp 2\theta}) \quad (6)$$

and substituting (1) and (5) into (2), the following equation is obtained:

$$A + \frac{1}{Z + \beta_1} + \frac{1}{Z + \beta_2} = \frac{\delta}{Z} \quad (7)$$

If we get the solution z of this equation, we can see how the concentration of carriers n depends on the magnetic field H through β_1 and β_2 . But the exact root z is complicated and is not convenient to understand the dependence of n on the parameters A , β_1 , β_2 and δ . In stead of (5), Appel used $N_{\pm} = \frac{1}{2} N_a / (1 + e^{\pm\theta - \eta})$ and solved the equation (7) in the case $\delta = 1$.

In order to obtain the physical insight of the situation we consider to solve the equation (7) approximately. As to the parameter A , we mentioned in § 2 that A is sufficiently smaller than 1 ($A \ll 1$), so that as the first approximation we neglect the first term of the left side of equation (7). The root $\bar{z}$ of this approximate equation can be easily obtained as follows:

Fig. 2.

$$z = \frac{1}{2(2-\delta)} [(\beta_1 + \beta_2)(\delta - 1) + \sqrt{(\beta_1 + \beta_2)^2(\delta - 1)^2 + 4(2-\delta)\delta\beta_1\beta_2}] \quad (8)$$

The change of $\bar{z}$ with θ is shown in the Fig. 2.

The behavior of $\bar{z}$ in the range of the weak magnetic field can be seen by expanding the formula (8) as the power series of θ .

$$\bar{z} = \frac{2\delta}{2-\delta} [1 + \frac{1}{2}\theta^2(\delta - \frac{1}{3}\delta^2) + \dots] \quad (9)$$

$$r \equiv m/m^*$$

The expression (9) means that

$$\left(\frac{dn}{dH} \right)_{\text{weak } H} > 0 \quad \text{if } \frac{m}{m^*} < \sqrt{3\delta}$$

$$\left(\frac{dn}{dH} \right)_{\text{weak } H} < 0 \quad \text{if } \frac{m}{m^*} > \sqrt{3\delta}$$

We can see that the effect of the orbital diamagnetism exceeds the effect of the spin paramagnetism when the effective mass m^* of free carriers is small, ($m^* < m/\sqrt{3\delta}$) and the concentration n decreases with the magnetic field. In other words we can expect the increase of n with the magnetic field only when the effective mass of free carriers is not too small ($m^* > m/\sqrt{3\delta}$) and the effect of the spin paramagnetism is predominant.

§ 5. Case C. The Concentration of the Donors is sufficiently Dense and the Width of Their "Impurity Band" is Larger than kT . The Fermi-level ζ_0 at $H=0$ lies in this Band.

This case was not discussed in the former papers, but is supposed to be realized in the most semiconductors at the low temperature.

The total density N of electrons in the impurity band at $H=0$ is as follows:

$$N = 2 \int_{-\infty}^{+\infty} \frac{D(E)dE}{1 + e^{\eta_0 - \eta}}$$

where η_0 means the Fermi-level at $H=0$ and $D(E)$ is the state density of impurity band.

The Fermi-level $\eta(H)$ can be determined approximately by the equation:

$$F(\eta + \theta; T) + F(\eta - \theta; T) = 2F(\eta_0; T) \quad (10)$$

The function $F(x; T)$ is defined by the following integral:

$$F(x; T) = \int_{-\infty}^{+\infty} \frac{\rho(\epsilon kT)}{1 + e^{\epsilon - x}} d\epsilon \quad (11)$$

where

$$\rho = \rho(E) = \frac{\Delta E}{N_d} D(E)$$

in which ΔE means the width of impurity band. The quantity ρ is non-dimensional and corresponds to the state density of the impurity band.

To see the behavior of η in the small range of θ , the expansion is made in (10) and if we put

$$\eta = \eta_0 + \gamma$$

Then γ is given by:

$$\gamma = -\frac{F''}{2F'} \theta^2$$

where F' and F'' mean dF/dx and d^2F/d^2x respectively.

By introducing the parameter s which is defined by:

$$s = \left(\frac{F''}{F'} \right)_{\eta=\eta_0} = \left[\frac{d}{d\eta} \log F' \right]_{\eta=\eta_0} \quad (12)$$

the γ is written as follows:

$$\gamma = -\frac{1}{2}s\theta^2 \quad (13)$$

By using the equation (13) and (1) we get:

$$\begin{aligned} n &= n_{H=0} \frac{\theta^*}{\sinh \theta^*} \cosh \theta e^\gamma \\ &\doteq n_{H=0} \left[1 + \frac{1}{2}\theta^2 \left(1 - s - \frac{\gamma^2}{3} \right) + \dots \right] \end{aligned} \quad (14)$$

In (14) we can see that $(dn/dH^2)_{\text{weak } H}$ is positive if $(m/m^*) < \sqrt{3(1-s)}$.

When kT is sufficiently small and the carriers in the impurity can be considered as the Fermi-gas, the equation (13) becomes

$$s \doteq kT \left[\frac{\partial}{\partial E} \rho(E) / \rho(E) \right]_{E=\zeta_0} \quad (15)$$

Fig. 3.

In order to be $(dn/dH^2)_{\text{weak } H} > 0$ in the case of the small effective mass m^* of the free carriers, s should be negative such as the case shown in the Fig. 3.

§ 6. Discussions

Above results suggest us that it is hard to be $(dn/dH^2)_{\text{weak } H} > 0$ for the large m/m^* because of the effect of the orbital diamagnetism. In the cases A and B we cannot reduce the origin of so-called "magneto-conductive" phenomena in the p-InSb to the change of carrier concentration due to magnetic field. However, if the situation is such as the case C the conclusion is not definite. It will be needed to know n and $N = N_+ + N_-$ by the phenomenological treatment of the impurity band and to consider whether the phenomena can be explained by the results of equation (14) or not where we take into account the large difference of mobilities of carriers between in the impurity band and in the conduction band. But the last possibility to explain the "magneto-conductive" phenomena seems to be rare when we see that n itself is very small at the sufficiently low temperature. Then we may write the answer "perhaps no" in the last column of the Table I.

§ 7. Acknowledgement

The authors express their cordial thanks to the valuable discussions given by Prof. R. Kubo and the members of his research group. This research was partially supported by the research grant of the Ministry of Education.

The Change of Carrier Concentration in the Graphite with Static Magnetic Field

By Yasutada UEMURA and Masaharu INOUE

Department of Physics, University of Tokyo

(Received January 11, 1958)

The change of carrier concentration with static magnetic field in a single crystal of graphite is considered and the Hall coefficient R is discussed from this point of view.

The Wallace's model of the two dimensional zone and its orbital quantization proposed by McClure are the starting point of the analysis. By comparing with the Kinchin's experiment we propose that the acceptor levels exist at 11×10^{-3} eV. above the bottom of the conduction band and their concentration is 1.7×10^{18} /c.c.. As to the Wallace's resonance integral γ_0 we estimate its value as 1.43 eV. semiempirically. The ratio of the mobilities of two carriers $b = \mu_p/\mu_n = 0.87$ gives the best fit of R at the low temperature under the strong magnetic field. By using these reasonable values of the parameters the Hall coefficient R is plotted as the function of temperature and magnetic field. The agreement with experimental data may be good except the low field region. The origins of discrepancy are discussed.

§ 1. Introduction

In the previous paper¹⁾ it has been considered how the concentration of carriers changes with the static magnetic field in a simple extrinsic semiconductor. In this paper we treat the carrier concentration in the graphite as an example of intrinsic case and would like to propose that the interesting change of the Hall coefficient with magnetic field observed by Kinchin²⁾ in a single crystal of graphite may be interpreted from this point of view.

The model of the graphite crystal assumed in this paper is the simple one in which we take the two dimensional zone treated by Wallace³⁾ as the band structure of the host crystal which has a single acceptor level in the conduction band. We further assume that the mobility μ_n of conduction electrons is slightly larger than that of holes μ_p and their ratio μ_p/μ_n is denoted by b .

In the § 2 we review briefly the interesting nature of the Hall effect in the single crystal of graphite observed by Kinchin and point out some possible ways to interpret it. In this paper we pick up the one of them in which the change of carrier concentration due to the magnetic field is mainly considered. In the § 3, the orbital quantization of the Wallace's two dimensional zone is discussed and the interband effect pointed by McClure⁴⁾

is especially mentioned. In the § 4, the distribution of carriers is determined in the usual way and the concentration of electrons and holes is calculated as the functions of the temperature and the magnetic field. In the § 5, the parameters appeared in our model such as γ_0 , one of the resonance integrals defined by Wallace, b , E_a , the energy separation between the acceptor level and the bottom of conduction band, and the acceptor density N_a , are determined semiempirically by comparing the result of calculation in the § 4 with the observed data by Kinchin. Further we examine the behavior of the Hall coefficient R in the whole range of the temperature and the field by using the estimated values of the parameters. The agreement with experiment seems to be good except in the low field region. In the last section (§ 6) the origins of the discrepancy are discussed and the relation between the galvano-magnetic phenomena and the other such as the de-Haas van Alphen effect and the diamagnetic susceptibility is pointed out briefly.

§ 2. The Hall Effect of Graphite

In 1953 Kinchin²⁾ observed the Hall effect of the single crystal of the natural graphite in which he applied the magnetic field H along the c -axis of the crystal. As shown in the Fig. 1, his result exhibits the very inter-

Fig. 1. The Hall coefficient of Graphite. The solid lines are calculated values and experimental data are taken from Kinchin.

esting nature especially in the field dependence of the Hall coefficient R and the satisfactory explanation of his data has not been given by any one else.

The Fig. 1 shows that in the limit of low magnetic field ($H \rightarrow 0$) the sign of R is negative in the low temperature range. As the temperature rises, it changes to positive, but in the sufficiently high temperature it becomes negative again. In order to interpret this behavior Kinchin proposed that the crystal contains the acceptors and the level of which lies in the conduction band. He assumed that the mobility μ_n of the electrons is larger than that of holes μ_p so that the Hall coefficient R is negative in the low temperature range. As the temperature rises the acceptors begin to trap the electrons and the concentration of free electrons becomes smaller than that of holes to change the sign of R . However if the temperature reaches sufficiently high the effect of trapped electron should be neglected compared with the large concentration of free carriers and then the sign of R is determined

again by the difference of the mobilities between electrons and holes. Kinchin suggested in his paper that E_a is 6×10^{-3} eV., N_a is 10^{18} /c.c. and the value of $b = \mu_p/\mu_n$ falls between 0.8 and 1.

What is the origin of the field dependence of R ? Several origins may be considered to give the possible explanations of this interesting nature. We mention the three of them.

(i) In the recent experiment of the cyclotron resonance^{6), 6)} of the graphite it is shown that there are four kinds of current carriers such as the majority electrons and holes and the minority electrons and holes. It may be possible to interpret the field dependence of R by the usual treatment of the theory of conduction if we take into account the four components of the current carriers. The existence of carriers which have the very light mass seems to be preferable.

(ii) The radius of the circular motion of free carriers under the strong magnetic field is comparable to the mean free path of them in the low temperature range, so that we may expect some anomalous effects in the scattering processes, such as that the relaxation time depends on the magnetic field. The origin of the interesting field dependence of R may be attributed to the anomalous effects mentioned above.

(iii) The diamagnetic susceptibility of the graphite is comparatively large so that it is possible that the change of carrier concentration due to the magnetic field may play an important role in the field dependence of R .

At the present situation there are no detailed discussions about these possibilities. In this paper the last case is picked up so that we assume that the Hall coefficient R is given in the following expression

$$R = \frac{3\pi}{8|e|} \frac{1}{p} \frac{b^2 - (n/p)}{[b + (n/p)]^2} \quad (1)$$

which is obtained by the usual theory of conduction in the semiconductor containing free

electrons and free holes as the current carriers, where n and p mean respectively the concentration of them. The field dependence of R is given by (1) in which n and p depend on the magnetic field as the result of the orbital quantization. Exactly speaking the factor $3\pi/8$ in (1) should be 1 if the carriers are degenerate, however, the factor is not important in the following discussions so that we always use (1) approximately.

§ 3. The Two Dimensional Wallace's Model and its Orbital Quantization due to the Magnetic Field

The investigation of the band structure of the graphite has been made by many authors^{3), 7), 8), 9), 10)} in both theoretical and experimental aspects. In this paper we take rather simple one in which we assume the two dimensional model (single hexagonal layer) after Wallace³⁾. According to his results, the Hamiltonian $\mathcal{H}$ is given by:

$$\mathcal{H} = \begin{pmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{pmatrix} \quad (2)$$

where

$$H_{11} = H_{22}$$

$$= E_0 - 2\gamma_0' (\cos \kappa_y a + 2 \cos \frac{\sqrt{3}}{2} \kappa_x a \cos \frac{\kappa_y a}{2})$$

$$H_{12} = H_{21}^*$$

$$= -\gamma_0 (e^{-i(1/\sqrt{3})\kappa_x a} + 2 \cos \frac{1}{2} \kappa_y a e^{i(1/2\sqrt{3})\kappa_x a}).$$

The parameters γ_0 and γ_0' are the resonance integrals and $a = 2.46 \text{ \AA}$ is a distance between the nearest identical atoms in the hexagonal layer. By using above $\mathcal{H}$ it is shown that there are two bands, the one is called the conduction band and the other is called the valence band, which touch each other at the corners of the first Brillouin zone. The attention may be focussed on the structure near the corner points and the approximate expression of (2) near this point is given as follows

$$\mathcal{H} = \begin{pmatrix} -\frac{3}{4}\gamma_0' a^2 [\kappa_x^2 + \kappa_y^2] & \hbar v i e^{(\pi/3)\kappa_x a} [\kappa_x + i\kappa_y] \\ -\hbar v i e^{-(\pi/3)\kappa_x a} [\kappa_x - i\kappa_y] & -\frac{3}{4}\gamma_0' a^2 [\kappa_x^2 + \kappa_y^2] \end{pmatrix} \quad (3)$$

where $\hbar v \equiv (\sqrt{3}/2)r_0 a$ and the energy is measured from the origin of $E_0 + 3\gamma_0'$ and κ_x, κ_y are measured from the corner of the first Brillouin zone.

Let be the magnetic field H applied in the z direction. In this case κ_x and κ_y in (3) are not commutable each other and by considering the method of Kohn and Luttinger⁷⁾ they are regarded as the operators which satisfy the following commutation relation

$$[\kappa_x, \kappa_y] = \frac{1}{i} \frac{eH}{\hbar c}. \quad (4)$$

By introducing the operators κ_+ and κ_- defined by

$$\kappa_+ \equiv \frac{1}{\sqrt{2}} [\kappa_x + i\kappa_y], \quad \kappa_- \equiv \frac{1}{\sqrt{2}} [\kappa_x - i\kappa_y]$$

the following wellknown relations are obtained

$$\begin{aligned} [\kappa_-, \kappa_+] &= \frac{eH}{\hbar c} \equiv s \\ \kappa_- u_n &= (ns)^{1/2} u_{n-1} \\ \kappa_+ u_n &= [(n+1)s]^{1/2} u_{n+1} \\ \kappa_+ \kappa_- u_n &= ns u_n \\ \kappa_- \kappa_+ u_n &= (n+1) s u_n \end{aligned} \quad (5)$$

where u_n means the eigenfunction of a simple harmonic oscillator and n indicates its quantum number.

The $\mathcal{H}$ in (3) is written by κ_+ and κ_- as follows:

$$\mathcal{H} = \begin{pmatrix} -\frac{3}{4}\gamma_0' a^2 [\kappa_+ \kappa_- + \kappa_- \kappa_+] & \sqrt{2} \hbar v i e^{(\pi/3)\kappa_x a} \kappa_+ \\ -\sqrt{2} \hbar v i e^{-(\pi/3)\kappa_x a} \kappa_- & -\frac{3}{4}\gamma_0' a^2 [\kappa_+ \kappa_- + \kappa_- \kappa_+] \end{pmatrix}.$$

The Schrodinger equation is

$$\mathcal{H} \Psi = \varepsilon \Psi \quad (6)$$

in which we use the above expression of $\mathcal{H}$.

The solution of (6) is easily obtained if we put Ψ as follows

$$\begin{aligned} \Psi &= \begin{pmatrix} c_1 u_n \\ c_2 u_{n-1} \end{pmatrix} \quad \text{for } n \geq 1 \\ \Psi &= \begin{pmatrix} c_1' u_0 \\ 0 \end{pmatrix} \quad \text{for } n = 0 \end{aligned}$$

where c_1, c_2 and c_1' should be determined by the following equations

$$\begin{pmatrix} -\frac{3}{4}\gamma_0' a^2 [2n+1]s & \sqrt{2} \hbar v i e^{(\pi/3)\kappa_x a} [ns]^{1/2} \\ -\sqrt{2} \hbar v i e^{-(\pi/3)\kappa_x a} (ns)^{1/2} & -\frac{3}{4}\gamma_0' a^2 [2n-1]s \end{pmatrix} \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} = \varepsilon \begin{pmatrix} c_1 \\ c_2 \end{pmatrix} \quad \text{for } n \geq 1 \quad (7)$$

$$\begin{pmatrix} -\frac{3}{4}\gamma_0' a^2 s & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} c_1' \\ 0 \end{pmatrix} = \varepsilon \begin{pmatrix} c_1' \\ 0 \end{pmatrix} \quad \text{for } n = 0. \quad (8)$$

The eigen value ε of the equations (7) and (8) is solved as follows.

$$\left. \begin{aligned} \varepsilon_n &= -\frac{2}{3}\gamma_0' a^2 s \cdot 2n \pm \sqrt{(\frac{2}{3}\gamma_0' a^2)^2 s^2 + 2\hbar^2 v^2 n s} & \text{for } n \geq 1 \\ \varepsilon_0 &= -\frac{2}{3}\gamma_0' a^2 s & \text{for } n = 0. \end{aligned} \right\} \tag{9}$$

In the following discussions of the Hall effect the role of γ_0' is not important, so that we take into account the resonance integral only between the nearest neighbors and neglect γ_0' as the approximation.

Then the energy levels (9) are reduced to the following simple expression.

$$\left. \begin{aligned} \varepsilon_l &= \pm \nu \sqrt{s l} \quad (l=0, 1, 2, \dots) \\ \nu &\equiv \sqrt{2} \hbar v = \sqrt{3/2} \gamma_0 a. \end{aligned} \right\} \tag{9'}$$

The state density w of each levels is given by (10)

$$w = q s = 8(2\pi)^{-3} (2\pi/c_L) (2\pi s) \tag{10}$$

where $c_L = 6.74\text{\AA}$ is the distance between the identical layers. The energy spectra of (9') and the state density (10) were at first obtained by McClure⁴⁾ and were used to discuss the diamagnetic susceptibility of the graphite. McClure attributed the origin of the comparatively large value of the susceptibility to the anomalous energy spectra of (9') in which the 0-point energy disappears owing to a kind of the interband effect. By comparing with the observed data McClure estimated the value of γ_0 as 2.6 eV semiempirically. We would like to show in the following discussions that in the field dependence of the Hall coefficient R this effect may also play an important role.

The orbital quantization due to the magnetic field is discussed for the case of a more complicated model in the same way, however its details will be discussed in the forthcoming paper. (See the additional note.)

§ 4. The Concentration of Carriers

By using the results of (9') and (10) the concentration of the free electrons n and the free holes p are given as follows

$$\left. \begin{aligned} n &= \frac{q(kT)^2}{\nu^2} \sum_{l=0}^{\infty} \frac{\alpha}{1 + e^{\sqrt{\alpha l} - \eta}} \\ &= \frac{q(kT)^2}{\nu^2} F(\alpha; -\eta) \\ p &= \frac{q(kT)^2}{\nu^2} \sum_{l=0}^{\infty} \frac{\alpha}{1 + e^{\sqrt{\alpha l} + \eta}} \\ &= \frac{q(kT)^2}{\nu^2} F(\alpha; +\eta) \end{aligned} \right\} \tag{11}$$

where α is the nondimensional parameter de-

fined by

$$\left. \begin{aligned} \alpha &= \frac{\nu^2 s}{(kT)^2} = \left(\frac{2\mu H}{kT} \right) \frac{3}{2} \left(\frac{\gamma_0}{kT} \right) \left(\frac{\gamma_0}{\hbar^2/m a^2} \right) \\ \mu &\equiv \frac{e\hbar}{2mc} \end{aligned} \right\} \tag{12}$$

and η is the Fermi energy divided by kT . The concentration n of electrons which are trapped in the acceptor level is given by

$$n_a = \frac{2N_a}{1 + e^{s_a - \eta}}; \quad \varepsilon_a = \frac{E_a}{kT}. \tag{13}$$

Because of the large effect of the orbital diamagnetism we neglect the effect of the spin paramagnetism for the simplicity. The Fermi level is determined by the following neutrality condition.

$$F(\alpha; \eta) = F(\alpha; -\eta) + \frac{2\nu^2 N_a}{q(kT)^2} \frac{1}{1 + e^{s_a - \eta}}. \tag{14}$$

If the approximation is allowed that the distributions of both carriers can be treated as classical (non-degenerate), $F(\alpha, \pm\eta)$ is written as follows:

$$F(\alpha, \pm\eta) = e^{\mp\eta} \sum_{l=0}^{\infty} \alpha e^{-\sqrt{\alpha l}} \equiv e^{\mp\eta} G(\alpha). \tag{15}$$

The function $G(\alpha)$ is calculated by the following approximate formula

$$\left. \begin{aligned} G(\alpha) &\doteq \alpha + 2[1 + \sqrt{\alpha} + \frac{1}{4}\alpha]e^{-\alpha} \\ G(0) &= 2. \end{aligned} \right\} \tag{16}$$

The function (16) is shown in the Fig. 2

Fig. 2.

and the validity of the approximation is examined in the Appendix. It is supposed to be good to use the classical distribution function for n_a however there remains some ques-

tion to assume that the distribution of free carriers is also classical. As to the n and p it is rather better in the case of n than in the case of p to use the classical distribution. Taking into account this point we use (17) in the analysis of the data at the low temperature under the strong magnetic field where $\alpha \gg 1$.

$$\left. \begin{aligned} F(\alpha, \pm\eta) &\doteq \frac{\alpha}{1+e^{\pm\eta}} \\ G(\alpha) &\doteq \alpha \end{aligned} \right\} \quad \alpha \gg 1. \quad (17)$$

§ 5. The Empirical Determination of the Parameters

In this section, the evaluation of E_a , N_a , $b = \mu_p/\mu_n$ and r_0 is made and it is discussed in the § 6 whether these values are plausible or not. Further the temperature and the magnetic field dependence of the Hall coefficient R is investigated in detail. The values of these parameters are determined mainly by the observed condition where R vanishes. ($R=0$) The condition $R=0$ implies that in the formula (1) the numerator must vanish and by using the relations (11) and (13) the following condition is obtained.

$$b^2 = \frac{n}{p} \doteq \left[1 + \frac{K(T)}{G(\alpha)} \right]^{-1} \quad (18)$$

$$K(T) \equiv \frac{2\nu^2 N_a}{q(kT)^2} e^{-\varepsilon_a} \quad (19)$$

where non-degenerate approximation for the trapped state is used. The equation (18) can be written as follows

$$\frac{2\nu^2 N_a}{q(kT)^2} e^{-\varepsilon_a} = G(\alpha) \frac{1-b^2}{b^2}. \quad (20)$$

[A] *The value of E_a :* If the temperatures T_1 and T_2 at which R vanishes are known in the limiting case of the weak magnetic field ($H \rightarrow 0$), the following relation is deduced from (20)

$$\left(\frac{T_2}{T_1} \right)^2 e^{-(\varepsilon_{a1} - \varepsilon_{a2})} = 1$$

so that E_a is estimated by

$$E_a = 2k \left(\frac{T_1 T_2}{T_1 - T_2} \right) \ln \left(\frac{T_1}{T_2} \right) \equiv k T_a. \quad (21)$$

By comparing with the Kinchin's data shown in the Fig. 1, it is found that $T_1 = 29^\circ\text{K}$ and $T_2 = 192^\circ\text{K}$ and by substituting these values in (21) we get $E_a = 11 \times 10^{-3} \text{ eV}$. $T_a = 129^\circ\text{K}$.

[B] *The determination of r_0 :* If the magnetic field H' at which R vanishes is known at

the fixed temperature T' , we get the following relation from (20)

$$\begin{aligned} G(\alpha') &= 2 \left(\frac{T_1}{T'} \right)^2 e^{-(\varepsilon_{a1} - \varepsilon_{a'})} \\ &= 2 \left(\frac{T_1}{T'} \right)^2 e^{-(T_a/T_1 - T_a/T')}. \end{aligned} \quad (22)$$

The value α' is then estimated by using the graph $G(\alpha)$ of Fig. 2. By the definition (12) of α , r_0 is known as follows.

$$r_0 = \left(\frac{\hbar^2}{ma^2} \right) \sqrt{\frac{\alpha'(kT')}{\hbar^2/ma^2}} \cdot \sqrt{\frac{(kT')}{3(\mu H')}}. \quad (23)$$

The Kinchin's data show $T_1 = 29^\circ\text{K}$, $T' = 77^\circ\text{K}$, $H' = 5 \text{ K gauss}$ and by using these values and $T_a = 129^\circ\text{K}$ obtained in [A], $G(\alpha)$ is found as 4.54 and the corresponding value of α' is 3.82. The resonance integral r_0 is then estimated as $r_0 = 1.43 \text{ eV}$ by (23). We also tried to estimate the value of r_0 by using the data at $T' = 63.5^\circ\text{K}$ and got the same value of it.

[C] *The relation between N_a and b :* In the case where $H \rightarrow 0$ so that $\alpha \rightarrow 0$, the value $G(\alpha)$ tends to 2 and in this consideration we deduce (24) from (20).

$$\frac{2(1-b^2)}{b^2} = \frac{3\pi}{4} c_L a^2 N_a \left(\frac{r_0}{kT_1} \right)^2 e^{-T_a/T_1}. \quad (24)$$

This equation is rearranged as follows:

$$N_a = \frac{8}{3\pi} \frac{(1-b^2)}{b^2} \frac{1}{c_L a^2} \left(\frac{kT_1}{r_0} \right)^2 e^{T_a/T_1}. \quad (25)$$

If we know the value of b we can estimate N_a from (25) by substituting the obtained values of r_0 , T_1 , and T_a . As being shown in the following discussions [D], we get $b = 0.87$ as an appropriate value so that N_a is estimated $1.7 \times 10^{18}/\text{c.c.}$

[D] *The Hall coefficient at the low temperature under the strong magnetic field:* In this case α is sufficiently larger than 1 ($\alpha \gg 1$) and the Fermi level η is supposed to be nearly zero. By using the equation (1), (11), (17), and (23) we have R in this condition as follows.

$$\begin{aligned} R &= \frac{3\pi}{8e} \frac{1}{p} \frac{b-1}{b+1} \\ &= \left(\frac{b-1}{b+1} \right) \left(\frac{c_L a^2}{e} \right) \left(\frac{9\pi^2}{32} \right) \frac{1}{\alpha'} \left(\frac{r_0}{kT'} \right)^2 \left(\frac{H'}{H} \right). \end{aligned} \quad (26)$$

It is noticed that in the limit of low temperature and strong magnetic field ($\alpha \gg 1$, $\eta = 0$), the Hall coefficient R is inversely proportional

to the field strength H and does not depend on the temperature. This characteristic feature is also found in the Kinchin's experimental data. If the observed value $R = -0.5$ cm³/coulomb at $H = 7$ K. gauss is fitted to the expression (26), the value of b is estimated as $b = 0.87$. As being shown in Fig. 1 the behaviour of R calculated by (26) seems to agree well with the observed data in the range of the low temperature and the strong magnetic field.

[E] *The Hall coefficient R calculated by using the parameters determined above:* By using the above obtained values of the parameters E_a , N_a , γ_0 and b , the dependence of the R on the temperature and the magnetic field is plotted in the Fig. 1. We can not well reproduce the observed tendency in the weak field range by our calculation. The discrepancy is especially remarkable at the low temperature where observed R exhibits the minimum at certain magnetic field. However in the other range the calculated curves of R reproduce well the nature of observed data qualitatively or even semi-quantitatively.

§ 6. Discussions

At first we discuss that the values of the parameters determined in § 5 are plausible or not.

As to N_a , E_a , and b , Kinchin suggested $N_a = 2 \times 10^{18}$ /c.c., $E_a = 6 \times 10^{-3}$ eV, and $1 > b \geq 0.8$. Our results are $N_a = 1.7 \times 10^{18}$ /c.c., $E_a = 11 \times 10^{-3}$ eV, and $b = 0.87$. There is a difference in the value of E_a which seems to be the result of using the two dimensional model in our consideration.

It is an important point for understanding the magnetic field dependence of R whether the value of γ_0 is plausible or not. The theoretical calculations of the γ_0 suggested that it should be nearly between 0.9 and 3 eV. As it is already mentioned in the § 3, McClure proposed $\gamma_0 = 2.6$ eV by using the observed data of the diamagnetic susceptibility. Our result $\gamma_0 = 1.43$ eV determined by using the Kinchin's data of the Hall effect seems to be plausible. The value determined in this paper may be somewhat smaller one because of our somewhat larger value of E_a . It is supposed that we can not ignore the effect discussed in this paper if the value of γ_0 is larger than this value.

The calculated curve of R seems to have a good agreement with the observed data except in the range of the low temperature and the low magnetic field. The characteristic behavior of R in the low temperature under the strong magnetic field referred in [D] of § 5 suggests that our considerations show the part of the essential features of the phenomena. The physical meaning of the expression (26) is that the almost part of the carriers occupies the level $l=0$ in the spectra (9') because of the conditions of $\alpha \gg 1$, $\eta = 0$. The inverse proportionality of R to H has its origin in the proportionality of the state density w to H . Here we see that the absence of the 0-point energy in (9') plays an important role in our considerations as in the discussions on the diamagnetism presented by McClure⁴⁾.

The discrepancy between the theory and the experiment is found rather in the low field region especially at the low temperature and the origins of which seem to be in the simple assumption of the two dimensional band structure. In our model the n and p tend to zero as the temperature tends to the absolute zero. However if the actual band exhibits the slight overlap of the energy surface then n and p do not tend to zero as the temperature tends to zero. The observations on the de Haas van Alphen effect¹²⁾, the oscillatory behaviour of the galvano-magnetic effects¹³⁾, and the cyclotron resonance^{5), 6)} suggest that there exists the slight overlap in the energy surface so that in order to interpret the behavior of R at the low temperature it is necessary to take into account these fine structures of the energy band. The discussions of the effect of the magnetic field on the complicated band remain as the problem in the forthcoming paper.

§ 7. Acknowledgement

The authors express their cordial thanks to Prof. R. Kubo and the members of his research group for the valuable discussions. This work was partially supported by the research grant of the Ministry of Education.

Additional Note

Recently, after this paper had been prepared we read the paper entitled "Band Structure of Graphite and de Haas-van Alphen

Effect" by J. W. McClure¹⁴). According to his paper the six kinds of parameters γ_0 , γ_1 , γ_2 , γ_3 , γ_4 and Δ are proposed to characterize the fine structure of the energy band. The γ_3 plays a role to give the bands of minority carriers and the γ_2 is the origin of the band overlap. By using his Hamiltonian and neglecting the effect of γ_3 and γ_4 , we try to find the quantized energy levels due to the magnetic field in the same way as § 2.

The quantized energy levels ε_n are obtained as solutions of the following equations

$$\begin{aligned} & (E_1 - \varepsilon_0)(E_2 - \varepsilon_n)(E_3 - \varepsilon_n)^2 \\ & - (\hbar v)^2(2n+1)S(E_1 - \varepsilon_n)(E_3 - \varepsilon_n) \\ & - (\hbar v)^2(2n+1)S(E_2 - \varepsilon_n)(E_3 - \varepsilon_n) \\ & + 4(\hbar v)^4 n(n+1)S^2 = 0 \quad (\text{for } n \geq 1) \\ & (E_1 - \varepsilon_0)(E_2 - \varepsilon_0)(E_3 - \varepsilon_0) - (E_1 - \varepsilon_0)(\hbar v)^2 S \\ & - (E_2 - \varepsilon_0)(\hbar v)^2 S = 0 \quad (\text{for } n = 0) \\ & \varepsilon_{-1} = E_3 = \frac{1}{2} \gamma_2 P^2 \quad (\text{for } n = -1) \end{aligned}$$

where E_1 , E_2 , E_3 and Γ represent

$$\begin{aligned} E_1 &= \gamma_1 \Gamma + \Delta \\ E_2 &= -\gamma_1 \Gamma + \Delta \\ E_3 &= \frac{1}{2} \gamma_2 \Gamma^2 \\ \Gamma &= 2 \cos \frac{k_z c_2}{2} \end{aligned}$$

In the case of the semiclassical limit ($n \gg 1$), we get

$$\begin{aligned} \varepsilon_n &= \frac{1}{2} (E_1 + E_3) \pm \sqrt{\frac{1}{4} (E_1 - E_3)^2 + 2(\hbar v)^2 n S} \\ \varepsilon_n &= \frac{1}{4} (E_2 + E_3) \pm \sqrt{\frac{1}{4} (E_2 - E_3)^2 + 2(\hbar v)^2 n S} \end{aligned}$$

The lowest level which corresponds to $l=0$ in (9') is found to be

$$\varepsilon_{-1} = \frac{1}{2} \gamma_2 l'^2 ;$$

If the effect of band overlap is neglected ($\gamma_2 \rightarrow 0$) the level $\varepsilon=0$ appears also in the three dimensional case. In the condition of the low temperature $T \rightarrow 0$ there remains the finite concentration of carriers owing to the parameter γ_2 which indicates the effect of band overlap.

Is it necessary to assume the existence of the acceptors in order to explain the temperature dependence of R at $H \rightarrow 0$, even if the

effect of γ_3 is considered? It is a difficult problem and no satisfactory answer seems to be proposed at present time.

Appendix

The derivation of $G(\alpha)$ in (16)

$$G(\alpha) \doteq \alpha + 2[1 + \sqrt{\alpha} + \frac{1}{2}\alpha]e^{-\sqrt{\alpha}}.$$

In the Euler's formula

$$\begin{aligned} \sum_{j=-m}^n f(j) &= \int_m^n f(x) dx + \frac{1}{2}[f(m) + f(n)] \\ &+ \sum_{k=1}^{\infty} (-)^k \frac{B_k}{(2k)!} [f^{(2k-1)}(m) - f^{(2k-1)}(n)] \end{aligned}$$

we put $f(j) = \alpha e^{-\sqrt{\alpha}j}$, then we get

$$\begin{aligned} G(\alpha) &\doteq \alpha + \int_1^{\infty} \alpha e^{-\sqrt{\alpha}x} dx + \frac{1}{2}[f(1) + f(\infty)] \\ &= \alpha + 2[1 + \sqrt{\alpha} + \frac{1}{2}\alpha]e^{-\sqrt{\alpha}}. \end{aligned}$$

The error of this approximation is given by

$$\begin{aligned} |R_1| &< \frac{B_1}{2} [f'(1) - f'(\infty)] < \frac{B_1 \alpha \sqrt{\alpha}}{2} e^{-\sqrt{\alpha}} \\ \therefore |R_1| &< \frac{1}{24} \alpha \sqrt{\alpha} e^{-\sqrt{\alpha}} < \frac{27}{24e^3} = 0.0564. \end{aligned}$$

On the other hand $G(\alpha) \geq 2$ so that the approximate formula (16) is supposed to be good.

Effect of the Basic Strength of Attached Groups on Light Absorption Spectra III: Dissociations in the Excited States of Naphthalene Derivatives

By Reikichi ITOH

Kobayashi Institute of Physical Research, Kokubunzi, Tokyo

(Received January 8, 1958)

The dissociations in the excited states of the derivatives of naphthalene, i.e., α - and β -naphthylamine, and α - and β -naphthol are discussed by the molecular orbital treatment using semi-empirical L.C.A.O. method. The difference of the proton dissociation constant between the excited and the ground state, $pK_1 - pK_2$, is expressed by a certain parameter connecting the coulomb integral with the basic strength of attached groups. The value of the parameter is derived by the light absorption spectra of the similar molecules. The calculated values of the differences, $pK_1 - pK_2$, are 5.0 and 5.5 in the case of β -naphthylamine and α -naphthol in good agreement with the experimental values of 6.0 and 6.0 respectively. The similar calculations for the case of β -naphthol give considerably smaller value of which discussion is given briefly as well as the experiment.

§ 1. Introduction

The dissociation in the excited state of a molecule has been discussed by several authors¹⁾ from the experimental point of view in the cases of naphthalene- and oxypyrene-derivatives. It was pointed out that pH dependence of the light absorption spectra of those molecules shows different behavior from that of the fluorescent spectra, and that the changing point of the absorption spectra is higher about 6 units in pH scale than that of the fluorescent spectra. Förster¹⁾ has made the experiments on the derivatives of naphthalene and oxypyrene, and Weeler¹⁾ has calculated the dissociation constants in the excited states of naphthol and its sulfonate derivative on the ground of chemical kinetics. The present author¹⁾ gave a method of estimating the dissociation constant in the excited state from the experimental data on the light absorption. However, no theoretical explanation of these experiments on the ground of molecular orbital treatment has appeared till now. Weeler's treatment which leads to a quantitative result in the case of naphthol and its sulfonate derivative is not based upon the electronic theory of the molecules. The present work gives the explanation of the nature of dissociation in the excited states of naphthol and naphthylamine from the electronic point of view by using the semi-empirical L. C. A. O. method.

§ 2. pH-dependences of Absorption and Fluorescent Spectra

At first, we summarize experimental results of Förster and Weeler.

a) β -naphthol

The proton dissociation constant pK_a of the molecule in the ground state at 20°C is 9.6. Both of the absorption and fluorescent spectra of the dissociated form (ion) shift towards longer wavelength than those of undissociated molecule. The change of the absorption spectrum takes place at pH=8, i. e. the shift from 3250 Å to 3470 Å, and that of the fluorescence at pH=2 corresponds to the shift from ultraviolet (3500 Å) to blue (4200 Å). Since the fluorescence arises from the electronic excited state of the molecule, the aspect of the dissociation in the excited state should change at pH=2, while that of the ground state changes at pH=8.

b) α -naphthol

In this case the behavior of both of absorption and fluorescent spectra through the change of pH is similar to those of β -naphthol, except that the ultraviolet fluorescent spectra is lacking in water solution and the complete quenching process occurs in strong acidic solution with pH < 2. The reaction for the proton dissociation in the excited and ground state will be given by

c) *β -naphthylamine*

The absorption spectrum changes at pH=4 from 2750 Å to 2800 Å or 3400 Å, while that of the fluorescence at pH=-2 (Hammett's scale) from ultraviolet (3400 Å) to blueviolet (4100 Å) and at pH=12 from blueviolet to green (5000 Å), the former corresponding to the change from cationic to neutral form and the latter from neutral to anionic form of the molecule respectively. These reactions are expressed by the equations;

respectively, where A denotes the naphthalene. It is expected that these reactions occur in the excited state (fluorescence change) as well

as in the ground state (absorption change). The change of the absorption spectra in the second equation is observed in the very strong alkaline solution of pH~20, which will be realized in the special solution as liquid ammonia solution and is not observed in the ordinary alkaline solutions.

d) *α -naphthylamine*

The behavior of the absorption spectra is similar to that of β -naphthylamine, while that of fluorescent spectrum is completely quenched and the intensity of the fluorescence is too weak to be observed.

The changes of absorption and fluorescent spectra of those four derivatives against pH scale are summarized in Fig. 1 schematically.

Fig. 1. pH dependences of the fluorescent and the absorption spectra of various naphthalene derivatives are shown, where A is the naphthalene and the molecule in the excited state is denoted by a star.

§ 3. Ground and Excited Electronic States

Substances considered in this paper are composed of a parent molecule A (naphthalene and a substituent BH (hydroxyl or amino group). The latter has two non-bonding electrons containing π -component or lone pair electrons. It is naturally expected that the non-bonding electrons in the substituent could migrate to the parent molecule in consequence of the interaction between A and BH. Since the mode of interaction between A and BH is different for the different electronic state of A, the rate of the migration in the ground state is assumed to be different from that of the excited state of the molecule A. Here, we denote the rate of the migration of the former state by λ_g and that in the latter by λ_e , respectively. Both of them can be calculated by assuming the interaction between the occupied π -electron level of the non-bonding electrons of BH, χ , and the lowest level of the vacant orbital of A in the ground state, ω_2 , or between χ and that of the vacant orbital

in the first excited state, ω_1 , as the perturbation. The absorption spectrum of A is given by the difference of ω_2 and ω_1 . As the relation $\chi < \omega_1 < \omega_2 < 0$ is expected, the interaction between χ and ω_1 is stronger than that between χ and ω_2 . It is likely that the mixing rate, λ_1 , of π -orbital of BH, ϕ_s (χ level), with that of A, ϕ_1 (ω_1 level), is larger than λ_2 , the mixing rate of ϕ_s with ϕ_2 (ω_2 level). The above considerations lead to the following relations,

$$\lambda_g = 2\lambda_2, \quad \lambda_e = \lambda_1 + \lambda_2, \quad (1)$$

which show that λ_e is larger than λ_g . Now, densities of the π -electrons in BH under the influence of the ground and the excited state of A which are denoted by q_g and q_e respectively, are given by

$$q_g = q_0 - 2\lambda_2^2, \quad q_e = q_0 - (\lambda_1^2 + \lambda_2^2). \quad (2)$$

It is concluded also from equation (2) that q_g is larger than q_e and this leads us to the following considerations;

a) By the so called inductive effect of the

σ -electrons in BH bond on the π -electrons of B atom, the degree of localization of σ -electron in BH bond is conversely affected by the change of π -density of B atom*;

b) Then it is natural to assume that the larger π -density on the B atom leads to the smaller density of σ -electrons of the atom, the effect of which drives the σ -electrons to the more localization in the BH bond and consequently brings about the stronger BH bond;

c) Since the bond strength of BH directly relates to the proton affinity for protonic dissociation, $\text{BH}=\text{B}^-+\text{H}^+$, a stronger BH bond is more basic, or less acidic, than a weaker BH bond. By the same reason it is also concluded that the excited state is more acidic than the ground state. This conclusion is consistent with the observation.

The similar correlation is found for the cases of various aromatic compounds with OH or NH_2 group through the solvent effect on their absorption spectra²⁾. For example, we consider the effect of hydrogen bond formation on the near ultraviolet absorption spectra of benzene derivatives such as aniline and phenol. In these molecules it is well known that their absorption spectra shift to longer wave length (so called red shift) when the solvent is changed from non-polar to polar one, e. g., from carbontetrachloride to dioxane. When these molecules form the hydrogen bonds, the bond length of BH (OH or NH_2) group becomes larger by 0.02~0.03 Å due to the attraction on the proton by the proton acceptor of the polar solvent³⁾. By this effect, the σ -electrons in BH bond tend to localize more strongly on the B atom than without it, and this causes the migration of non-bonding electron on B atom to the parent molecule much more strongly and results in the red shift of the absorption spectra.

In the case of the absorption spectra, the

* The so called red shift²⁾ in the absorption spectra through the hydrogen bond formation is caused by the inductive effect of σ -electrons in the bond of the attached group on the π -electrons of the same group as discussed in later place. The effect conventionally goes from σ - to π -electrons, but the one in the present phenomena goes from π - to σ -electrons in the attached group due to the induction effect between σ - and π -electron and the word, conversely, means the latter situation.

delocalization of σ -electrons in BH bond affect the electron migration, while in the case of the proton dissociation treated in this paper, the electron migration to the parent molecule in the excited state arising from light absorption brings about the delocalization of σ -electron in the bond conversely. Thus the origin of the effect is the correlation between σ - and π -electrons through the induction effect in both cases. In this paper, the magnitude in the difference of the proton dissociation constant in the ground and the excited states of the derivatives are estimated from the difference of the degree of the electron migration in the ground and the excited state of the parent molecule.

§ 4. Relation between the Basic Strength of Attached Group and Its Coulomb Integral

In the previous papers, I and II⁴⁾, the author has pointed out that there exists a linear relation between the basic strength, pK_b , of the attached group and the value of the coulomb integral, α , for the cases of triphenylmethane dyes and aniline derivatives. Thereby it was given by

$$\alpha_i - \alpha_j = k(pK_{b_j} - pK_{b_i}), \quad (3)$$

where the constant k was taken to be about 0.4 eV so that equation (3) was consistent with the spectroscopic data of these molecules. In this paper it is also assumed that there exists a similar relation

$$\alpha_2 - \alpha_1 = k(pK_{a_1} - pK_{a_2}), \quad (4)$$

where the suffixes 1 and 2 refer to the ground and the excited state of the molecule respectively and pK_a the proton dissociation constant (i. e. acidic strength) of the whole molecule, instead of the attached group itself. The change of pK_a of the former, however, will be proportional to that of the latter, because the dissociation of the molecule takes place at the attached group. The main difference between equations (3) and (4) is that (3) is concerned with the relation before the perturbation to the molecule A by BH is introduced, while (4) is the relation after the introduction of the perturbation. In other words, the quantities in (3) are for the attached group only, while those in (4) are for the molecule as a whole, though the both equations are expressed by the same parameters, the

coulomb integral and the basic strength pK .

The attached groups hitherto considered are amino groups only. When another sort of groups such as OH is attached to the parent molecule, the value of the parameter k should be changed because of the different electronic configuration between N (sp^3 , V_3) in NH_2 and O (s^2p^4 , V_2) in OH. Therefore it is necessary to use different parameters k_n and k_0 for these two cases separately. Now it is convenient to determine the values of the parameters from the experimental data of the red shift in the absorption spectra. Since the bond length of OH bond is nearly equal to that of NH bond (1.07 Å and 1.08 Å respectively), it is expected that nearly equal degree of the delocalization of σ -electron for the two bond is caused through the effect of the hydrogen bond formation with the solvent which makes the bond length longer by about 0.02~0.03 Å which localizes more σ -electrons on B atom. This localization effect of σ -electrons reveals the red shifts, the amount of which are 300 cm^{-1} (phenol) and 610 cm^{-1} (aniline)⁶. It is possible to consider that the localization of σ -electron induces π -electron migration in the same manner for naphthol to naphthylamine as for phenol to aniline. Owing to the different configuration of electrons in O and N, the rate of the migration of π -electrons accompanied by the same amount of localization is different in both cases.

The above considerations are summarized as

$$\Delta\tilde{\nu}_{OH}/\Delta\tilde{\nu}_{NH} = \Delta\epsilon_{OH}/\Delta\epsilon_{NH} \quad (5)$$

$$= \Delta\alpha_{OH}/\Delta\alpha_{NH} \quad (6)$$

$$= k_0 \Delta pK / k_n \Delta pK \quad (7)$$

$$= k_0/k_n \quad (8)$$

where $\Delta\tilde{\nu}$ is the red shift due to the hydrogen bond formation, and $\Delta\epsilon$ is the corresponding energy of stabilization which is in the first approximation given by⁶)

$$\Delta\epsilon_i = \sum c_i^2 \Delta\alpha_i$$

$\Delta\alpha$ is the change of the value of the coulomb integral due to the hydrogen bond formation and c_i is the A.O. coefficient of attached group in M.O. of the iso-electronic homocyclic molecule under consideration. The suffixes, OH and NH, refer to phenol and aniline respectively, and ΔpK is assumed to be nearly equal in both cases because the degree of localization of σ -electron is almost same in

both cases. As in the previous papers k_n is determined to be about 0.4 eV, while k_0 is to be 0.2 eV according to equation (8). As in the paper I, the coulomb integral of B atom (N or O) is expressed semi-empirically by⁷⁾

$$\alpha_r = I_r - 1/2 \cdot q_r (E_r - I_r), \quad (9)$$

where q_r is the π -electron density, I_r is the ionization potential and E_r is the electron affinity of the atom respectively. However, it will be better to use the first and the second ionization potential of B atom instead of the electron affinity and the first ionization potential respectively, because of the neglect of the contribution from proton in M.O.'s of the parent molecule. When q_r takes different value for the excited state from that for the ground state, the difference of the coulomb integrals, α_1 and α_2 , is expressed by

$$\begin{aligned} \alpha_2 - \alpha_1 &= 1/2 (q_e - q_0) (I_1 - I_2) \\ &= 1/2 (\lambda_1^2 - \lambda_2^2) (I_1 - I_2) \end{aligned} \quad (10)$$

according to equation (2), and combining this equation to (4), it is obtained that

$$k(pK_{a_1} - pK_{a_2}) = 1/2 (\lambda_1^2 - \lambda_2^2) (I_1 - I_2), \quad (12)$$

where k is to be 0.4 eV or 0.2 eV according to that attached group is NH_2 or OH. It is now necessary to evaluate the rates of migration, λ_1 and λ_2 , in order to calculate the dissociation constant in the excited state.

§ 5. Results and Discussions

As the same process of the calculation of λ_1 and λ_2 as in the previous paper II is adopted for evaluating the rate of migration, λ_1 and λ_2 , the details of the calculation are not reproduced except to give the necessary data for calculation. The wave function, $\phi(\nu)$, and the potential, $H(\nu)$, for the migrating electron are given as

$$\phi(\nu) = \sum a_i \phi_i + b \phi_s, \quad H(\nu) = H_p + H_s$$

where the summation is taken over the vacant orbitals of the parent molecule, and H_p and H_s denote the potential for the migrating electron in the parent molecule and the substituent respectively. As the result of the perturbation calculation minimizing the energy for the total molecule, the expression

$$\lambda_i = a_i/b = (\rho_i - T_i \chi) / (\chi - \omega_i) \quad (13)$$

is obtained. ρ_i and T_i are the resonance and the overlap integral between ϕ_i and ϕ_s and are given by

$$\rho_i = c_k/2 (\gamma + s(\chi + \omega_i)), \quad T_i = c_k S,$$

where $S = (\phi_k | \phi_s)$, $\gamma = (\phi_k | H | \phi_s)$ and c_k is the A. O. coefficient of M. O. for the atom in the parent molecule to which the substituent attaches. In the case of naphthalene, ϕ_i 's are given by⁸⁾

$$\begin{aligned} \phi_1 &= 0.4085(\phi_1 - \phi_i + \phi_5 - \phi_8) \\ &\quad + 0.2883(\phi_2 - \phi_3 + \phi_6 - \phi_7), \\ \phi_2 &= 0.4142(\phi_1 - \phi_i + \phi_5 - \phi_8) \\ &\quad - 0.2801(\phi_2 - \phi_3 + \phi_6 - \phi_7). \end{aligned}$$

Now the relation $\gamma/\gamma_0 = s/s_0^{9)} = 1.2$ (for NH_2) or 1.4 (for OH) is assumed, where γ_0 and s_0 are the resonance and overlap integral of A. O.'s for the M. O.'s in benzene respectively, and the values $\gamma_0 = -5.0$ eV and $S_0 = 0.25$ are taken throughout the calculation. The values for energy levels, ω_i and χ , have been given as

$$\omega_1 = -8.10 \text{ eV}^{10)}, \quad \omega_2 = -2.67 \text{ eV}, \quad \chi = -9.8 \text{ eV}$$

(for NH_2) or -10.8 eV (for OH) respectively¹¹⁾, where the difference, $\omega_2 - \omega_1$, corresponds to the absorption at $2200 \text{ \AA}^{12)}$ in naphthalene molecule. The values for the ionization potentials I_2 and I_1 are taken from Mulliken's work¹³⁾.

$$\begin{aligned} I_1: & \text{N}(sp^4, V_3), \quad \text{N}^+(sp^3, V_4), \quad -12.24 \text{ eV} \\ I_2: & \text{N}^+(sp^3, V_4), \quad \text{N}^{++}(sp^2, V_6) \quad ? \end{aligned}$$

and

$$\begin{aligned} I_1: & \text{O}(s^2p^4, V_2), \quad \text{O}^+(s^2p^3, V_3) \quad -13.73 \text{ eV} \\ I: & \text{O}(s^2p^4, V_2), \quad \text{O}^{++}(s^2p^2, V_4) \quad -36.68 \text{ eV}, \end{aligned}$$

where $I = I_1 + I_2$. However, in the case of NH_2 , $I_2 - I_1 = -14.98$ eV was derived from the data for the free atomic state instead of for the valence state, since the available data is lacking, and in the case of OH , $I_2 - I_1 = -9.22$ V was estimated from the Mulliken's data in the valence state. The result of the calculation is listed in Table I.

Table I. Results of the Calculation

attached group	λ_1	λ_2	$\Delta\lambda^2$	$\Delta\alpha$	$\Delta pK_{\text{calc.}}$	$\Delta pK_{\text{obs.}}$
$\alpha\text{-NH}_3^+$	0.75	0.11	0.55	4.1 eV	10.0	—
$\beta\text{-NH}_3^+$	0.53	0.08	0.27	2.0	5.0	6.0
$\alpha\text{-OH}$	0.50	0.10	0.24	1.1	5.5	6.0
$\beta\text{-OH}$	0.35	0.12	0.12	0.6	3.0	6.0

As seen from Table I, the differences of pK are in good agreement with observation for the β -naphthylamine and α -naphthol, while it is too smaller than the one for the β -naph-

thol, though the calculated value is not certain due to the estimation of the ionization data $I_2 - I_1$. Since the fluorescence of α -naphthylamine is completely quenched, the calculated value of pK can not be compared with the observed one, and only the relative change from β -derivatives is brought here.

In this connection we note that such considerations will be useful also for discussing the difference of the chemical character between α - and β -derivatives as follows. As easily shown by the simple L. C. A. O. theory, the densities of π -electrons for α - and β -derivatives in the stable ground state are¹⁴⁾

$$q_\alpha = 1.45, \quad q_\beta = 1.53$$

respectively. According to the consideration on the inductive effect given in § 3, the strength of the BH bond should be stronger in β -than α -derivatives, since the localization of σ -electrons in BH bond is presumably less in the latter by the induction effect between σ - and π -electrons. This is to be the case of naphthol and naphthylamine, where the observation shows that α -naphthol ($pK_a = 9.2$)¹⁵⁾ is more acidic than β -naphthol ($pK_a = 9.6$)¹⁵⁾ and α -naphthylamine ($pK_b = 10.1$)¹⁶⁾ is less basic (more acidic) than β -naphthylamine ($pK_b = 9.9$)¹⁶⁾. These facts are the other strong support for us to the assumption in the correlation between σ - and π -electron in the attached group. When these molecules are brought in the excited state by the absorption of light, π -electron density of attached group is reduced much more in the α -derivatives than in the β -derivatives, the difference of which is about 0.1~0.3, and this means that in the excited state as well as in the ground state, α -derivatives should be more acidic than β -derivatives and α -derivatives are more liable to set its proton free towards the solvent than to stabilize itself after the emission of fluorescence. Thus α -derivatives would be likely to be rendered to the quenching process by the formation of hydrogen bond in strong acidic solution, or for the anionic forms in alkaline solution the effect of hydration may play the same role. These are possibly the reasons why the ultraviolet fluorescence of α -naphthol and α -naphthylamine are lacking in the solutions.

Our conclusion that the excited molecule is more acidic than in the ground state as the result of the difference in the migration of

non-bonding electrons of the attached group between the ground and the excited state, have been derived on the ground of a reasonable electronic structure of the molecules.

The author thanks Prof. I. Oshida for his helpful discussions. This work was supported by the Scientific Research Fund granted by the Ministry of Education.

On the Absorption Spectra of Complex Ions

IV. The Effect of the Spin-orbit Interaction and the Field of Lower Symmetry on *d* electrons in Cubic Field

By Yukito TANABE

*Department of Applied Physics, Faculty of Engineering,
University of Tokyo*

and Hiroshi KAMIMURA

*Department of Physics, Faculty of Science,
University of Tokyo*

(Received January 11, 1958)

It is shown that the matrix elements of the crystalline field of lower symmetry than cubic and of the spin-orbit interaction for *d*-electrons in octahedral complex ions can be easily evaluated by the method of tensor operators, and the tables necessary to evaluate these elements by this method are given. It is also pointed out that the effective Hamiltonian which plays the same role as the spin Hamiltonian for the non-degenerate states can be constructed for the degenerate orbital states and will be useful for the analysis of line spectra of these complexes.

§ 1. Introduction

Since 1951, many investigations have been carried out on the absorption spectra of the transition-metal complex ions and we have now fairly complete knowledge of the electronic excited states which correspond to the

spin-allowed absorption bands of these ions. Further progress will be made by studying the spin-forbidden bands, the line spectra (especially the Zeeman effect of these), the optical anisotropy observed in the complexes of lower symmetry, etc. Some of these pro-

blems were already treated in part by several authors. It seems to us, however, many problems remain unsolved. In order to clarify these points, it is first necessary and will be important to consider the effects of the crystalline field of lower symmetry than cubic and of the spin-orbit interaction which were neglected in the previous paper.¹⁾

We will therefore present here the matrix elements of these operators in the form suitable to any application. To this end, the method of tensor operators is most useful and we will develop the algebra of tensor operators in § 2 and show that the matrix elements in question can be evaluated by simple multiplication of several factors which will be given here. Before applying the matrix elements evaluated in this way to practical problems, we will discuss a general treatment by the effective Hamiltonian in § 3 that will be useful in the analysis of line spectra of complex ions, in which we are interested and for which this calculation was first carried out. Practical application of the results will be given in a later paper.

§ 2. Method of Tensor Operators

As in (I), we want to evaluate the matrix elements of the spin-orbit interaction and of the field of low symmetry in SI' scheme. Namely, the basic functions are $\Psi(f_{2g}^n(S_1\Gamma_1)e_{g^n}(S_2\Gamma_2)SI'M_Sr)$. (We write f_{2g} , e_g in place of d_z , d_{γ} in order to indicate that they need not necessarily be constructed from the d functions.) Since the evaluation is most conveniently carried out by using the method of tensor operators, we study first the properties of tensor operators.

i) Tensor operators

We define as irreducible tensor operators of type Γ each operator $X(\Gamma)$, whose (Γ) (=dimension of the irreducible representation Γ) components $X_{\gamma}(\Gamma)$ transform in the same way as the basis of the irreducible representation $\varphi(\Gamma\gamma)$ under the operations of the octahedral group. For example, the so-called "Kubic Harmonics" are the components of such tensor operators. The non-cubic perturbation V can thus be written as the sum of irreducible tensors $V_{\gamma}(\Gamma)$ as follows:

$$V = V(A_{2g}) + \mathcal{E}_{\gamma}c_{\gamma}V_{\gamma}(E_g) + \mathcal{E}_{\gamma}c_{1\gamma}V_{\gamma}(F_{1u}) \\ + \mathcal{E}_{\gamma}c_{2\gamma}V_{\gamma}(F_{2g}) + V(A_{1u}) + V(A_{2u})$$

$$+ \mathcal{E}_{\gamma}c_{\gamma}'V_{\gamma}(E_u) + \mathcal{E}_{\gamma}c_{1\gamma}'V_{\gamma}(F_{1u}) \\ + \mathcal{E}_{\gamma}c_{2\gamma}'V_{\gamma}(F_{2u}), \quad (2.1)$$

where $V_{\gamma}(\Gamma)$ may be expanded in terms of Kubic Harmonics, namely

$$V(A_{2g}) = f_6(A_{2g}|r)\mathcal{E}x^4(y^2 - z^2) + \dots, \\ \begin{cases} V_u(E_g) = f_2(E_g|r)(3z^2 - y^2) + \dots, \\ V_v(E_g) = f_2(E_g|r)\sqrt{3}(x^2 - y^2) + \dots, \\ V_{\gamma}(F_{1g}) = f_4(F_{1g}|r)xy\sqrt{3}(x^2 - y^2) + \dots, \text{ (cycl.)} \\ V_{\zeta}(F_{2g}) = f_2(F_{2g}|r)xy + \dots, \text{ (cycl.)} \end{cases} \quad (2.2)^*$$

and

$$V(A_{1u}) = f_9(A_{1u}|r)xyz\mathcal{E}x^4(y^2 - z^2) + \dots, \\ V(A_{2u}) = f_3(A_{2u}|r)xyz + \dots, \\ \begin{cases} V_u(E_u) = f_6(E_u|r)xy\sqrt{3}(x^2 - y^2) + \dots, \\ V_v(E_u) = f_6(E_u|r)xyz(-3z^2 + r^2) + \dots, \\ V_{\gamma}(F_{1u}) = f_1(F_{1u}|r)z + \dots, \text{ (cycl.)} \\ V_{\zeta}(F_{2u}) = f_3(F_{2u}|r)z\sqrt{3}(x^2 - y^2) + \dots, \text{ (cycl.)} \end{cases}$$

where (cycl.) shows that the other components α , β (or ξ , η) of $V(F_1)$ (or $V(F_2)$)* can be derived from the component γ (or ζ) by cyclic change of x , y , z .

One may observe that $V_u(E)$ and $V_{\gamma}(F_1)$ have (axial+) tetragonal symmetry, and $V(A_2)$, $V_v(E)$ and $V_{\zeta}(F_2)$ rhombic, while, $V(A_2)$, $(1/\sqrt{3})\mathcal{E}_{\gamma}V_{\gamma}(F_1)$ and $(1/\sqrt{3})\mathcal{E}_{\gamma}V_{\gamma}(F_2)$ are of trigonal symmetry with respect to the three-fold symmetry axis of the octahedron.

One also observes that these non-cubic perturbations (the fields of low symmetry or coupling with the nuclear motion) are not only hermitian but also real, namely the matrix elements of these operators are real if we

* Note that (2.2) also could be used as the definition of the basic functions $\varphi(\Gamma\gamma)$ of the irreducible representation Γ . One may observe that this choice of bases is different from that made in (I). In (3.7) of (I), we chose the bases of F_{1u} and F_{2g} in the following way: $\alpha \propto -x$, $\beta \propto y$, $\gamma \propto -z$; $\xi \propto -yz$, $\eta \propto zx$, $\zeta \propto -xy$. That is not a convenient choice of phases, so we make here the usual choice of phases $\alpha \propto x$, $\beta \propto y$, $\gamma \propto z$; $\xi \propto yz$, $\eta \propto zx$, $\zeta \propto xy$ as in (2.2). However, the matrix elements, tables and formulae given in (I) need not be changed at all even if this choice of phases were adopted, excluding, of course, (3.7), so that the matrix elements evaluated in this paper can be used together with the energy matrices of the coulomb interaction given in (I) without any modification.

** We will suppress the suffices g , u when there is no fear of confusion or when the statement applies both to g and u .

refer to the real basic functions. We denote such operators as $V_\gamma(I')$. In practice, however, pure imaginary operators also appear, for example, the angular momentum operator $\mathbf{L}$, which is of the type F_{10} . These will be denoted as $T_\gamma(I')$. They always appear in the form combined with the spin operator $\mathbf{s}$ as in the spin-orbit interaction or with an external magnetic field $\mathbf{H}$ as in the Zeeman term, in the Hamiltonian.

The problem to evaluate the matrix elements of the non-cubic perturbations is thus reduced to the evaluation of the matrix elements of $V_{\bar{\gamma}}(\bar{I}) : (\alpha I \gamma | V_{\bar{\gamma}}(\bar{I}) | \alpha' I' \gamma')$. This matrix element can, however, be factorized into two factors, one of which depends on γ, γ' and $\bar{\gamma}$, while the other does not, as is easily shown.

$$(\alpha I \gamma | V_{\bar{\gamma}}(\bar{I}) | \alpha' I' \gamma') = (\alpha I \gamma | \mathbf{V}(\bar{I}) | \alpha' I' \gamma') (I')^{-1/2} (I' \gamma' | \bar{I} \bar{\gamma}), \quad (2.3)$$

where $(I' \gamma' | \bar{I} \bar{\gamma})$ is the Wigner (or Clebsch-Gordan) coefficient given in (I). This may be compared with the formula for the general tensor operators $T_q^{(k)}$

$$(\alpha j m | T_q^{(k)} | \alpha' j' m') = (\alpha j | \mathbf{T}^{(k)} | \alpha' j') (2j+1)^{-1/2} (j m | j' m' k q) \quad (2.4)$$

given by Racah²⁾. Thus we only need to evaluate the double barred matrices $(\alpha I | \mathbf{V}(\bar{I}) | \alpha' I')$. Since our Wigner coefficients have the following property,

$$(I')^{-1/2} (I' \gamma' | \bar{I} \bar{\gamma}) = \varepsilon(I' \bar{I} I') (I')^{-1/2} (I' \gamma' | I' \bar{\gamma}), \quad (2.5)$$

where

$$\begin{aligned} \varepsilon(I' A_1 I') &= \varepsilon(I' F_2 I') = 1, \\ \varepsilon(I' A_2 I') &= \varepsilon(I' F_1 I') = -1 \end{aligned} \quad (2.6)$$

and $\varepsilon(I' E I') = 1$

except for $\varepsilon(F_1 E F_2) = \varepsilon(F_2 E F_1) = -1$,

it follows for real operators

$$(\alpha I | \mathbf{V}(\bar{I}) | \alpha' I') = \varepsilon(I' \bar{I} I') (\alpha' I' | \mathbf{V}(\bar{I}) | \alpha I), \quad (2.7)$$

so that particularly

$$(\alpha I | \mathbf{V}(\bar{I}) | \alpha I') = 0 \text{ for } \bar{I} = A_2, F_1. \quad (2.8)$$

(2.3) is valid also for operators $\mathbf{T}$. For these operators the double barred matrices are pure imaginary and

$$\begin{aligned} (\alpha I | \mathbf{T}(\bar{I}) | \alpha' I') \\ = -\varepsilon(I' \bar{I} I') (\alpha' I' | \mathbf{T}(\bar{I}) | \alpha I), \end{aligned} \quad (2.9)$$

so that particularly

$$(\alpha I | \mathbf{T}(\bar{I}) | \alpha I') = 0 \text{ for } \bar{I} = A_1, E, F_2. \quad (2.10)$$

The matrix elements of the spin-orbit interaction operator is of the form

$$V_{s0} = \sum_{\sigma \bar{\gamma}} a_{\sigma \bar{\gamma}} \sum_{t=1}^N s_{t\sigma} t_{t\bar{\gamma}} = \sum_{\sigma \bar{\gamma}} a_{\sigma \bar{\gamma}} V_{\sigma \bar{\gamma}}(1F_1), \quad (2.11)$$

where $\mathbf{t}$ (usually written as $\zeta \mathbf{L}$) is the operator of the type F_{10} , and the suffices σ and $\bar{\gamma}$ run over x, y, z and α, β, γ respectively. For the isotropic spin-orbit interaction

$$\begin{aligned} a_{x\alpha} &= a_{y\beta} = a_{z\gamma} = 1 \\ a_{\sigma \bar{\gamma}} &= 0 \quad \text{for other pair of } \sigma \text{ and } \bar{\gamma}. \end{aligned}$$

Since our scheme is $SI'M_s\gamma$, it is more convenient to evaluate the matrix elements of following operators $V_{q\bar{\gamma}}(1F_1)$ instead of $V_{\sigma \bar{\gamma}}(1F_1)$:

$$\begin{aligned} V_{+1\bar{\gamma}}(1F_1) &= -\frac{1}{\sqrt{2}} (V_{x\bar{\gamma}} + iV_{y\bar{\gamma}}) = \sum_i s_{i+1} t_{i\bar{\gamma}}, \\ V_{0\bar{\gamma}}(1F_1) &= V_{z\bar{\gamma}} = \sum_i s_{i0} t_{i\bar{\gamma}}, \\ V_{-1\bar{\gamma}}(1F_1) &= \frac{1}{\sqrt{2}} (V_{x\bar{\gamma}} - iV_{y\bar{\gamma}}) = \sum_i s_{i-1} t_{i\bar{\gamma}}. \end{aligned} \quad (2.12)$$

Then we can show for such double tensors

$$\begin{aligned} (\alpha SI'M_s\gamma | V_{q\bar{\gamma}}(1F_1) | \alpha' S'I'\gamma') \\ = (\alpha SI' | \mathbf{V}(1F_1) | \alpha' S'I') ((2S+1)(I'))^{-1/2} \\ \times (SM_s | S'M_s' 1q) (I' \gamma' | I' \gamma' F_1 \bar{\gamma}), \end{aligned} \quad (2.13)$$

where the Wigner coefficients $(SM_s | S'M_s' 1q)$ are, for instance, given in TAS³⁾. The double barred matrices are imaginary and

$$\begin{aligned} (\alpha SI' | \mathbf{V}(1F_1) | \alpha' S'I') \\ = (-1)^{S-S'} (\alpha' S'I' | \mathbf{V}(1F_1) | \alpha SI'). \end{aligned} \quad (2.14)$$

It is to be noted that the double barred matrices of an irreducible tensor operator defined above are independent of the choice of basic functions, if the components of the tensor operator are properly defined corresponding to the new choice of bases. When new bases $\varphi(\Gamma M)$ are derived from the old bases $\varphi(\Gamma \gamma)$ in the following way

$$\varphi(\Gamma M) = \sum \varphi(\Gamma \gamma) (I' \gamma | \Gamma M), \quad (2.15)$$

the invariancy of double barred matrix is assured if we define $\bar{M}$ component of the tensor operator $\mathbf{X}(\bar{I})$ by the relation

$$X_{\bar{M}}(\bar{I}) = \sum_{\bar{\gamma}} X_{\bar{\gamma}}(\bar{I}) (\bar{I} \bar{\gamma} | \bar{I} \bar{M}) \quad (2.16)$$

and the Wigner coefficient in the new scheme by

$$(I' M | I' M' \bar{I} \bar{M})$$

$$= \sum_{\gamma\gamma'\bar{\gamma}} (I'M|I\gamma)(I\gamma|I'\gamma', \bar{I}\bar{\gamma})(I'\gamma'|I'M') \\ \times (\bar{I}\bar{\gamma}|\bar{I}\bar{M}), \quad (2.17)$$

since

$$(I'M|X_{\bar{M}}(\bar{I})|I'M') \\ = \sum_{\gamma\gamma'\bar{\gamma}} (I'M|I\gamma)(I\gamma|X_{\bar{\gamma}}(\bar{I})|I'\gamma') \\ \times (\bar{I}\bar{\gamma}|\bar{I}\bar{M})(I'\gamma'|I'M') \\ = (I'\|X(\bar{I})\|I')(I')^{-1/2} \sum_{\gamma\gamma'\bar{\gamma}} (I'M|I\gamma) \\ \times (I\gamma|I'\gamma'\bar{I}\bar{M})(I'\gamma'|I'M')(\bar{I}\bar{\gamma}|\bar{I}\bar{M}) \\ = (I'\|X(\bar{I})\|I')(I')^{-1/2}(I'M|I'M'\bar{I}\bar{M}). \quad (2.18)$$

ii) The evaluation of the matrix elements for a given configuration

We now proceed to the evaluation of the double barred matrix elements of spin-independent operators $X(\bar{I})$ ($X=V$ or T)

$$X_{\bar{\gamma}}(\bar{I}) = \sum_i X_{i\bar{\gamma}}(\bar{I}) = \sum_{i=1}^n X_{i\bar{\gamma}}(\bar{I}) + \sum_{i=n+1}^{n+n'} X_{i\bar{\gamma}}(\bar{I}) \\ = X_{\bar{\gamma}}(\bar{I})_n + X_{\bar{\gamma}}(\bar{I})_{n'}. \quad (2.19)$$

The elements which are diagonal with respect to the number of electrons in the f_2 and e shells can be written as the sum of two terms, thus

$$(f_2^n(S_1I_1)e^{n'}(S_2I_2)SI\|X(\bar{I})\|f_2^n(S_3I_3)e^{n'}(S_4I_4)SI') \\ = (f_2^n(S_1I_1)e^{n'}(S_2I_2)SI'\|X(\bar{I})_n\|f_2^n(S_3I_3)e^{n'}(S_4I_4)SI')\delta(S_2S_4)\delta(I_2I_4) \\ + (f_2^n(S_1I_1)e^{n'}(S_2I_2)SI'\|X(\bar{I})_{n'}\|f_2^n(S_3I_3)e^{n'}(S_4I_4)SI')\delta(S_1S_3)\delta(I_1I_3), \quad (2.20)$$

where $X(\bar{I})_n$ and $X(\bar{I})_{n'}$ operate on the f_2 and e shell electrons respectively. These matrices can now be evaluated by means of the following general formulae the proof of which will be given in Appendix:

$$(\alpha I'_a \beta I'_b I' \| X(\bar{I})_\alpha \| \alpha' I'_a \beta' I'_b I') = (\alpha I'_a \| X(\bar{I}) \| \alpha' I'_a)(I'_a I'_b I' [\bar{I}] I'_a I'_b I') \quad (2.21)$$

and

$$(\alpha I'_a \beta I'_b I' \| X(\bar{I})_\beta \| \alpha' I'_a \beta' I'_b I') = (\beta I'_b \| X(\bar{I})_\beta \| \beta' I'_b)(I'_a I'_b I' [\bar{I}] I'_a I'_b I'), \quad (2.22)$$

where $X(\bar{I})_\alpha$ ($X(\bar{I})_\beta$) acts only on the first (second) state in the resultant coupled state, and

$$(I'_a I'_b I' [\bar{I}] I'_a I'_b I') = [(I')/(I'_a)]^{1/2} (I'_a \bar{I}'_a (I'_a) I'_b I' I'_a I'_b (I') \bar{I}'_a I'). \quad (2.23)$$

Similarly,

$$(I'_a I'_b I' [\bar{I}] I'_a I'_b I') = [(I')/(I'_b)]^{1/2} (I'_a I'_b \bar{I}'_b (I'_b) I' I'_a I'_b (I') \bar{I}'_b I'). \quad (2.24)$$

(2.23) and (2.24) are thus easily calculated from the transformation matrices between different coupling schemes which were used in the calculation of the matrices of the coulomb interaction. It is to be noted that $(I'_a I'_b I' [\bar{I}] I'_a I'_b I')$ vanishes unless all the representation $I'_a \times I'_b \times I'$, $I'_a \times I'_b \times I'$, $I'_a \times I'_a \times \bar{I}'_a$ and $I' \times I' \times \bar{I}'_a$ contain the identity representation A_1 , while $(I'_a I'_b I' [\bar{I}] I'_a I'_b I')$ vanishes unless $I'_a \times I'_b \times I'$, $I'_a \times I'_b \times I'$, $I'_b \times I'_b \times \bar{I}'_b$ and $I' \times I' \times \bar{I}'_b$ all contain A_1 .

From (2.20), (2.21) and (2.22),

$$(f_2^n(S_1I_1)e^{n'}(S_2I_2)SI\|X(\bar{I})\|f_2^n(S_3I_3)e^{n'}(S_4I_4)SI') \\ = (f_2^n(S_1I_1)\|X(\bar{I})\|f_2^n(S_3I_3)\delta(S_1S_3)\delta(S_2S_4)\delta(I_2I_4)(I_1I_2I'[\bar{I}]I_3I_4I') \\ + (e^{n'}S_2I_2\|X(\bar{I})\|e^{n'}S_2I_4)\delta(S_2S_4)\delta(S_1S_3)\delta(I_1I_3)(I_1I_2I'[\bar{I}]I_1I_4I'). \quad (2.25)$$

Similar formula for the spin-orbit interaction is obtained:

$$(f_2^n(S_1I_1)e^{n'}(S_2I_2)SI\|V(1F_1)\|f_2^n(S_3I_3)e^{n'}(S_4I_4)SI') \\ = (f_2^n(S_1I_1)\|V(1F_1)\|f_2^n(S_3I_3)\delta(S_2S_4)\delta(I_2I_4)(S_1S_2S[1]S_3S_2S')(I_1I_2I'[F_1]I_3I_4I'), \quad (2.26)$$

since

$$(e^{n'} S_2 \Gamma_2 \| \mathbf{V}(1F_1) \| e^{n'} S_4 \Gamma_4) = 0.$$

The definition of $(S_1 S_2 S[1] S_3 S_2 S')$ is similar to (2.23), namely

$$(S_1 S_2 S[1] S_3 S_2 S') = [(2S+1)/(2S_1+1)]^{1/2} (S_3 S_2 (S') 1 S | S_3 1 (S_1) S_2 S),$$

or

$$= \sqrt{(2S+1)(2S'+1)} W(S' 1 S_2 S_1; S S_3) \quad (2.27)$$

in terms of Racah's W -function.

The matrix elements of $\mathbf{X}(\overline{I})$ and $\mathbf{V}(1F_1)$ considered in this section are thus simply evaluated by multiplying several factor, e.g., $(f_2^n S_1 I_1 \| \mathbf{X}(\overline{I}) \| f_2^n S_1 I_3)$, $(\Gamma_1 \Gamma_2 \Gamma[\overline{I}] \Gamma_3 \Gamma_2 \Gamma')$ etc, once these are calculated and tabulated.

The matrices $(f_2^n S_1 I_1 \| \mathbf{X}(\overline{I}) \| f_2^n S_1 I_3)$ can be evaluated in terms of the double barred matrices for one electron by means of the following formula which is essentially (23) of RIII⁽⁴⁾.

$$\begin{aligned} & (f_2^n S_1 I_1 \| \mathbf{X}(\overline{I}) \| f_2^n S_1 I_3) \\ &= n(f_2 \| \mathbf{x}(\overline{I}) \| f_2) ((\Gamma_1)/(\Gamma_2))^{-1/2} \sum_{S_1' \Gamma_1'} (f_2^n S_1 I_1 \{ | f_2^{n-1} (S_1' \Gamma_1') f_2 \} (f_2^{n-1} (S_1' \Gamma_1') f_2 |) f_2^n S_1 I_3) \\ & \times (\Gamma_1' F_2(\Gamma_3) \overline{\Gamma} \Gamma_1 | \Gamma_1' F_2 \overline{\Gamma} (F_2) \Gamma_1). \end{aligned} \quad (2.28)$$

Similar formula can also be written down for $(e^{n'} S_2 I_2 \| \mathbf{X}(\overline{I}) \| e^{n'} S_2 I_4)$.

For the spin-orbit interaction, we have

$$\begin{aligned} & (f_2^n S_1 I_1 \| \mathbf{V}(1F_1) \| f_2^n S_3 I_3) \\ &= n(\frac{1}{2} f_2 \| \mathbf{s} \mathbf{t} \| \frac{1}{2} f_2) [(2S_1+1)(\Gamma_1)/2(\Gamma_2)]^{1/2} \sum_{S_1' \Gamma_1'} (f_2^n S_1 I_1 \{ | f_2^{n-1} (S_1' \Gamma_1') f_2 \} (f_2^{n-1} (S_1' \Gamma_1') f_2 |) f_2^n S_3 I_3) \\ & \times (S_1' \frac{1}{2} (S_3) 1 S_1 | S_1' \frac{1}{2} 1 (\frac{1}{2}) S_1) (\Gamma_1' F_2(\Gamma_3) F_1 \Gamma_1 | \Gamma_1' F_2 F_1 (F_2) \Gamma_1). \end{aligned} \quad (2.29)$$

$(f_2^n S I \| \mathbf{X}(I) \| f_2^n S I')$, $(e^{n'} S I \| \mathbf{X}(I) \| e^{n'} S I')$ and $(f_2^n S I \| \mathbf{V}(1F_1) \| f_2^n S' I')$ evaluated by these formulae are given in Table I. It is to be noted that, for half filled shells ($n=3$ and/or $n'=2$), not only the diagonal elements of $\mathbf{V}$ -operators vanish but also certain off-diagonal elements vanish. This fact is peculiar to the half filled shells and will perhaps be the cause of sharp absorption lines in the spectra of $\text{Cr}^{3+}(f_2^3)$, $\text{Mn}^{2+}(f_2^3 e^2)$ and $\text{Ni}^{2+}(f_2^6 e^2)$ complexes, since this means that the states of half filled shells are not perturbed by the nuclear motion to the first order.

In Tables II and III all the necessary matrix elements of $(\Gamma_a \Gamma_b I [\overline{I}] \Gamma_a' \Gamma_b' I')$, $(\Gamma_a \Gamma_b I [\overline{I}] \Gamma_a' \Gamma_b' I')$ and $(S_a S_b S[1] S_a' S_b' S')$ are given.

Since we do not know at present which matrix elements are needed for future analyses, we shall rather content ourselves with the preparation of these tables than proceed to the tabulation of all the matrix elements of (2.25) and (2.26).

Before leaving this section, definitions of the double barred matrices for one electron should be given. According to (2.8) and (2.10), only the followings do not vanish among the diagonal double barred matrix elements of $\mathbf{V}$ and $\mathbf{T}$ operators:

$$\begin{aligned} & (f_2 \| \mathbf{V}(E) \| f_2) = \sqrt{3} (f_2 \xi | \mathbf{v}_u(E_g) | f_2 \xi), \\ & (f_2 \| \mathbf{V}(F_2) \| f_2) = \sqrt{6} (f_2 \xi | \mathbf{v}_g(F_{2g}) | f_2 \eta), \\ & (f_2 \| \mathbf{t}(F_1) \| f_2) = \sqrt{6} (f_2 \xi | \mathbf{t}_\gamma(F_{1g}) | f_2 \eta) = \sqrt{6} i k, \\ & (e \| \mathbf{V}(E) \| e) = -2(eu | \mathbf{v}_u(E_g) | eu), \\ & (e \| \mathbf{t}(A_2) \| e) = \sqrt{2} (eu | \mathbf{t}(A_{2g}) | ev). \end{aligned} \quad (2.30)$$

Table Ia. $(f_2^n S\Gamma \| \mathbf{X}(\overline{F}) \| f_2^n S'\Gamma')$

$\mathbf{X}(\overline{F}) = \mathbf{V}(E)$

$n=1, 5 \quad (f_2 \| \mathbf{v}(E) \| f_2) = -(f_2^{5/2} F_2 \| \mathbf{V}(E) \| f_2^{5/2} F_2)$

	5/2			$\sqrt{3}/\sqrt{2}$		$\sqrt{6}/5$	$3\sqrt{7}/5\sqrt{2}$

$$(S_a \frac{1}{2} S[1] S_a' \frac{1}{2} S')$$

S_a	S	S_a' S'	0 1/2	1 1/2	3/2	S' S'	1/2 0	1	3/2 1	2
0	1/2			$\sqrt{2}/\sqrt{3}$	$2/\sqrt{3}$	1/2 1/2		$-1/\sqrt{2}$	$1/\sqrt{2}$	
1	1/2		$-\sqrt{2}/\sqrt{3}$	2/3	$-\sqrt{2}/3$	1	$1/\sqrt{2}$	1	1/2	$\sqrt{5}/2$
	3/2		$2/\sqrt{3}$	$\sqrt{2}/3$	$\sqrt{10}/3$	2/3 1	$1/\sqrt{2}$	-1/2	$\sqrt{5}/2\sqrt{2}$	$-1/2\sqrt{2}$
						2		$\sqrt{5}/2$	$1/2\sqrt{2}$	$3/2\sqrt{2}$

The off-diagonal elements are as follows

$$\begin{aligned}
 (f_2 \| \mathbf{v}(F_2) \| e) &= (e \| \mathbf{v}(F_2) \| f_2) = \sqrt{3} (f_2 \zeta | \mathbf{v}_\zeta(F_{20}) | e u), \\
 (f_2 \| \mathbf{v}(F_1) \| e) &= -(e \| \mathbf{v}(F_1) \| f_2) = -3(f_2 \zeta | \mathbf{v}_\gamma(F_{10}) | e v), \\
 (f_2 \| \mathbf{t}(F_1) \| e) &= (e \| \mathbf{t}(F_1) \| f_2) = -3(f_2 \zeta | \mathbf{t}_\gamma(F_{10}) | e v) = -2\sqrt{3} i k', \\
 (f_2 \| \mathbf{t}(F_2) \| e) &= -(e \| \mathbf{t}(F_2) \| f_2) = \sqrt{3} (f_2 \zeta | \mathbf{t}_\zeta(F_{20}) | e u).
 \end{aligned} \tag{2.31}$$

For the spin-orbit interaction operator;

$$\begin{aligned}
 (\frac{1}{2} f_2 \| \mathbf{st} \| \frac{1}{2} f_2) &= 6(\frac{1}{2} f_2 + \frac{1}{2} \zeta | \mathbf{s}_0 \mathbf{t}_\gamma | \frac{1}{2} f_2 + \frac{1}{2} \eta) = 3i \zeta', \\
 (\frac{1}{2} f_2 \| \mathbf{st} \| \frac{3}{2} e) &= (\frac{3}{2} e \| \mathbf{st} \| \frac{1}{2} f_2) = -3\sqrt{2} (\frac{1}{2} f_2 + \frac{1}{2} \zeta | \mathbf{s}_0 \mathbf{t}_\gamma | \frac{3}{2} e + \frac{1}{2} v) = -3\sqrt{2} i \zeta'.
 \end{aligned} \tag{2.32}$$

If f_2 and e are constructed from the d -functions and $\mathbf{t}(F_1) = \mathbf{I}$, $\mathbf{t} = \zeta \mathbf{I}$, then $k = k' = 1$ and $\zeta' = \zeta$ will be the spin-orbit coupling parameter for a d electron.

iii) The evaluation of the off-diagonal elements

Since the operators we are interested in are of one electron type and (2.7), (2.9) and (2.14) are still valid, we have only to calculate the double barred matrix elements of the following type in this section:

$$(f_2^n (S_1 \Gamma_1) e^{n'} (S_2 \Gamma_2) S I' \| \mathbf{X}(\bar{\Gamma}) \| f_2^{n-1} (S_3 \Gamma_3) e^{n'+1} (S_4 \Gamma_4) S I'') \tag{2.33}$$

which can be calculated by using the formula (28) of RIII as follows:

$$= \sum_{\bar{n} \bar{n}'} \sqrt{n} (f_2^n S_1 \Gamma_1 \{ | f_2^{n-1} (S_3 \Gamma_3) f_2 \rangle (e, e^{n'} (S_2 \Gamma_2) \} e^{n'+1} (S_4 \Gamma_4) \sqrt{n'+1}$$

$$\begin{aligned} & \times (S_3 I_3 f_{2n}(S_1 I_1) S_2 I_2 S I' \| \mathbf{x}_n(\bar{I}) \| S_3 I_3 e_n(\tilde{S} I') S_2 I_2 S I'') \\ & \times (S_3 I_3 \frac{1}{2} e(\tilde{S} I') S_2 I_2 S I' \| S_3 I_3 \frac{1}{2} e S_2 I_2 (S_1 I_4) S I'') . \end{aligned} \quad (2.34)$$

Now, applying (2.21) and (2.22), we obtain

$$\begin{aligned} & = \sqrt{n(2S_1+1)(I_1)} (f_2^n S_1 I_1 \{ |f_2^{n-1}(S_3 I_3) (e e^{n'}(S_2 I_2)) | e^{n'+1} S_4 I_4 \} \sqrt{(n'+1)(2S_4+1)(I_4)} \\ & \times (f_2 \| \mathbf{x}(\bar{I}) \| e) [S_1 S_2 S | S_3 S_1 S | [I_1 I_2 I' | \bar{I}] I_3 I_4 I''] , \end{aligned} \quad (2.35)$$

where

$$[S_1 S_2 S | S_3 S_4 S] = [(2S_1+1)(2S_4+1)]^{-1/2} (S_3 \frac{1}{2} (S_1) S_2 S | S_3 \frac{1}{2} S_2 (S_4) S) = W(S_3 \frac{1}{2} S S_2; S_1 S_4) \quad (2.36)$$

and

$$\begin{aligned} & [I_1 I_2 I' | \bar{I}] I_3 I_4 I'' \\ & = [(I')/(f_2)(I_1)(I_4)]^{1/2} (I_3, E\bar{I}'(F_2)(I_1) I_2 I' | I_3, E I_2 (I_4)(I') \bar{I}' I') \\ & = [(I')/(f_2)(I_1)(I_4)]^{1/2} \sum_{\tilde{I}} (I_3 E(I') \bar{I}' I_1 | I_3, E I' (F_2) \bar{I}'_1) (I' I_2 (I'') I' I' | I' \bar{I}' (I_1) I_2 I') \\ & \times (I_3 E(I') I_2 I' | I_3, E I_2 (I_4) I'') \\ & = [(I_1)(I_4)]^{-1/2} \sum_{\tilde{I}} (I_3 F_2 I_1 [\bar{I}] I_3 E I') (I_1 I_2 I' [\bar{I}] I' I_2 I'') (I_3 E(I') I' | I_3, E I_2 (I_4) I'') . \end{aligned} \quad (2.37)$$

For the spin-orbit interaction, we have similarly

$$\begin{aligned} & (f_2^n (S_1 I_1) e^{n'} (S_2 I_2) S I' \| \mathbf{V}(1 F_1) \| f_2^{n-1} (S_3 I_3) e^{n'+1} (S_4 I_4) S' I'') \\ & = \sqrt{n(2S_1+1)(I_1)} (f_2^n S_1 I_1 \{ |f_2^{n-1}(S_3 I_3) f_2 (e e^{n'}(S_2 I_2)) | e^{n'+1} S_4 I_4 \} \sqrt{(n'+1)(2S_4+1)(I_4)} \\ & \times (\frac{1}{2} f_2 \| \mathbf{st} | \frac{1}{2} e) [S_1 S_2 S | 1] S_3 S_4 S' \| [I_1 I_2 I' | F_1] I_3 I_4 I'') , \end{aligned} \quad (2.38)$$

where

$$\begin{aligned} & [S_1 S_2 S | 1] S_3 S_4 S' \\ & = (2S+1)(2S'+1) \sum_{\tilde{S}} (2\tilde{S}+1) W(S_3 \frac{1}{2} S_1; \tilde{S} \frac{1}{2}) W(S_1' S_2 S_1; S \tilde{S}) W(S_3 \frac{1}{2} S' S_2; S S_4) , \end{aligned} \quad (2.39)$$

The off-diagonal elements are thus easily evaluated by the multiplication of several factors which appear on the right hand sides of (2.35) and (2.38). The coefficients of fractional parentage are already given in (I), so that only $(e, e^n(S' I')) | e^{n+1} S I'$ which are obtained from $(e^n(S' I') e | e^{n+1} S I')$ by (3.3) of (I) are given here (Table IV). The matrices $[I_a I_b I' | \bar{I}] I_c I_d I''$, $[S_a S_b S | 1] S_c S_d S'$ and $[S_a S_b S | S_c S_d S]$ are given in Table V, VI, and VIII, respectively.

We have thus essentially finished the evalua-

tion of all the matrix elements of tensor operators among the states $\Psi (f_2^n(S_1 I_1) e^{n'}(S_2 I_2) S I' \cdot M_S \gamma)$ that will be needed in practical problems. The value of the necessary matrix elements are readily obtained simply by multiplying appropriate factors given in Table I-VII according to the formulae (2.25), (2.26), (2.35) and (2.38).*

§ 3. The Effective Hamiltonian for the Orbitally Degenerate States

The method of the spin-Hamiltonian for the non-degenerate orbital multiplets⁵⁾ has been

Table IV. $(e, e^n(S' I')) | e^{n+1} S I'$
 $(e e^n(S' I') | e^{n+1} S I') = 1$ for $n=0, 1, 3$
 for $n=2$ $(e e^2(S' I')) | e^{3/2} E)$

$S' I'$	${}^2E$
${}^1A_1$	$1/\sqrt{6}$
${}^3A_2$	$-1/\sqrt{2}$
${}^1E$	$-1/\sqrt{3}$

$(f_2^{n-1}(S' I') f_2) | f_2^n S I') = 1$ $n=1, 2, 6$

Values for $n=3, 4, 5$ are given in Table II of (I).

* It must be, however, noted that the formulae (2.25), (2.26), (2.35) and (2.38) are not to be used when $N=n+n' \geq 6$. The matrix elements of operators in this case should be evaluated by the following formula;

$$\begin{aligned} & (f_2^n(S_1 I_1) e^{n'}(S_2 I_2) S I' \| \mathbf{X} | f_2^{n''}(S_3 I_3) e^{n'''}(S_4 I_4) S' I'') \\ & = \pm (f_2^{n-n'}(S_1 I_1) e^{n'-n'}(S_2 I_2) S I' \| \mathbf{X} | f_2^{n-n''}(S_3 I_3) \\ & \quad \times e^{n'-n'''}(S_4 I_4) S' I'') , \end{aligned}$$

where $-$ sign is used for $\mathbf{X} = \mathbf{V}(\bar{I})$ or $\mathbf{V}(1 F_1)$, while $+$ sign should be taken for $\mathbf{X} = \mathbf{T}(\bar{I})$.

very useful in the semi-quantitative (in the sense that empirical parameters are introduced) analysis of paramagnetic resonance spectra⁶. Even when the ground multiplets were orbitally degenerate, the spin-Hamiltonian could be constructed and used for the final ground state (Kramers' doublet) in which we were interested in the case of paramagnetic resonance.⁷ In the case of optical spectra, however, we are rather interested in the whole levels split from a multiplet $2S+1J'$ due to the action of the field with low symmetry and of the spin-orbit

interaction than in one of them. Therefore it is of some value to point out we can also construct the effective Hamiltonian for the orbitally degenerate multiplet $2S+1\Gamma$, the correct zeroth-order wave function for the split levels and thus the behavior of these levels in the magnetic field (Zeeman effect) if it could be observed, besides the optical anisotropy. Of course, for the multiplets which are perturbed to the first order by the field of low symmetry or the spin-orbit interaction, we can discuss these properties without much labor, using the first order perturbation theory. However, for certain multiplets, especially those of half

filled shells, the first order perturbation generally vanishes, and the treatment by the effective Hamiltonian will be useful for these states.

Since we already know the form of the effective Hamiltonian for the orbitally non-degenerate multiplets $^{2S+1}A_1$ or $^{2S+1}A_2$, i.e., the usual spin-Hamiltonian, we will consider here only the multiplets $^{2S+1}\Gamma$ ($\Gamma = E, F_1, F_2$) and study how to construct the effective Hamiltonian for these. First we note that the matrix of the effective Hamiltonian for $^{2S+1}\Gamma$: $(\alpha^{2S+1}\Gamma M_S \gamma | \mathfrak{H}_{\text{eff.}} | \alpha^{2S+1}\Gamma M_S' \gamma')$ is $(2S+1) \times (\Gamma)$ dimensional and this matrix can be represented as linear combination of matrices of $(2S+1)$ irreducible spin operators: 1 , $S^{(1)} = (S_x, S_y, S_z)$, $S^{(2)} = (3S_z^2 - S(S+1)$, $\sqrt{3}(S_x^2 - S_y^2)$, $\frac{1}{\sqrt{2}}(S_y S_z + S_z S_y)$, $\frac{1}{\sqrt{2}}(S_z S_x + S_x S_z)$, $\frac{1}{\sqrt{2}}(S_x S_y + S_y S_x)$, $S^{(3)} = \dots$ up to tensors of the degree $2S$, of (Γ) irreducible orbital operators of type Γ_i ($\Gamma \times \Gamma = \sum \Gamma_i$): 1 , $T(A_2)$, $V(E)$, $T(F_1)$ ($=L$), $V(F_2)$ whose double barred matrices are

$$\begin{aligned} (\alpha E \| T(A_2) \| \alpha E) &= \sqrt{2} i, & (\alpha E \| V(E) \| \alpha E) &= \sqrt{2}, \\ (\alpha F_1 \| T(F_1) \| \alpha F_1) &= -\sqrt{6} i, & (\alpha F_1 \| V(E) \| \alpha F_1) &= \sqrt{6}, \\ & & (\alpha F_1 \| V(F_2) \| \alpha F_1) &= 3\sqrt{2}, \\ (\alpha F_2 \| T(F_1) \| \alpha F_2) &= \sqrt{6} i, & (\alpha F_2 \| V(E) \| \alpha F_2) &= \sqrt{6}, \\ & & (\alpha F_2 \| V(F_2) \| \alpha F_2) &= 3\sqrt{2}, \end{aligned} \quad (3.1)$$

and of the products of spin and orbital operators such as $S_\sigma T(A_2)$, $S_\sigma T_\gamma(F_1)$ etc. Next we note that spin-tensors of odd degree combine only with T-type orbital operators and those of even degree only with V-type orbital operators in the effective Hamiltonian. We further note that only the former types of operators, spin-tensors of odd degree and T-type orbital operators, combine with the external magnetic field. These considerations enable us to write down at once the general form of the effective Hamiltonian for ^{2S+1}E : (assuming for simplicity $S \leq 1$),

$$\mathfrak{H}_{\text{eff.}} = \mathfrak{H}_S + \mathbf{E} \cdot \mathbf{V}(E) + S^{(2)} \cdot \mathbf{E}^{(2)} \cdot \mathbf{V}(E) + S \cdot \lambda T(A_2) + \beta \mathbf{H} \cdot \mathbf{g} \cdot \mathbf{S} + \beta \mathbf{H} \cdot \mathbf{g}_0 \cdot \mathbf{T}(A_2) + \beta \mathbf{H} \cdot \mathbf{g}_{(E)} \cdot \mathbf{V}(E) \cdot \mathbf{S} \quad (3.2)$$

and for $^{2S+1}F_1$ and $^{2S+1}F_2$: (again assuming $S \leq 1$)

$$\begin{aligned} \mathfrak{H}_{\text{eff.}} &= \mathfrak{H}_S + \mathbf{E} \cdot \mathbf{V}(E) + S^{(2)} \cdot \mathbf{E}^{(2)} \cdot \mathbf{V}(E) + \mathbf{F} \cdot \mathbf{V}(F_2) + S^{(2)} \cdot \mathbf{F}^{(2)} \cdot \mathbf{V}(F_2) + S \cdot \lambda \cdot \mathbf{T}(F_1) \\ &+ \beta \mathbf{H} \cdot \mathbf{g} \cdot \mathbf{S} + \beta \mathbf{H} \cdot \mathbf{g}_0 \cdot \mathbf{T}(F_1) + \beta \mathbf{H} \cdot \mathbf{g}_{(E)} \cdot \mathbf{V}(E) \cdot \mathbf{S} + \beta \mathbf{H} \cdot \mathbf{g}_{(F_2)} \cdot \mathbf{V}(F_2) \cdot \mathbf{S}, \end{aligned} \quad (3.3)$$

where $\mathfrak{H}_S$ is the usual spin Hamiltonian constructed with the spin tensors of even degree up to $2S$, and $\mathbf{E}$, $\mathbf{F}$, λ , $\mathbf{g}$, $\mathbf{g}_0$ are parameters to be determined empirically. As in the case of the spin-Hamiltonian $\mathfrak{H}_S$ the coefficients of operators in (3.2) and (3.3) should be chosen so as to produce the invariant forms appropriate to the symmetry of the problem. It is also to be noted that the terms which contain spin-tensors of degree k : $S^{(k)}$ appear when $k \leq 2S$ and, except for the Zeeman term, they usually come from k -th (or higher) order perturbation with respect to the spin-orbit interaction as long as we neglect the spin-spin interaction.

As a simple example of the treatment by the effective Hamiltonian, we will discuss the splitting and the Zeeman effect of ^2E , $^2F_1$ and $^2F_2$ levels under the action of trigonal crystal-line field and of the external magnetic field along the trigonal axis of the octahedron. The formal considerations given below will be found useful for the analysis of the line spectra of ruby to be reported later⁸⁾.

For this purpose, it is convenient to use the following bases which are quantized in the direction of the symmetry axis, namely for $E(u, v)$,

$$u_+ = -(u + iv)/\sqrt{2}, \quad u_- = (u - iv)/\sqrt{2}, \quad (3.4)$$

for $F_1(\alpha, \beta, \gamma)$,

$$a_+ = -(\omega\alpha + \bar{\omega}\beta + \gamma)/\sqrt{3}, \quad a_- = (\bar{\omega}\alpha + \omega\beta + \gamma)/\sqrt{3}, \quad a_0 = (\alpha + \beta + \gamma)/\sqrt{3}, \quad (3.5)$$

and for $F_2(\xi, \eta, \zeta)$,

$$x_+ = -(\omega\xi + \bar{\omega}\eta + \zeta)/\sqrt{3}, \quad x_- = (\bar{\omega}\xi + \omega\eta + \zeta)/\sqrt{3}, \quad x_0 = (\xi + \eta + \zeta)/\sqrt{3},$$

where $\omega = e^{2\pi i/3}$ and $\bar{\omega} = \omega^2$.

The Wigner coefficients in this scheme are given in Table VIII.

The effective Hamiltonian for ${}^2E$ is very simple, if we drop the last term in (3.2) for simplicity

$$\mathfrak{H}_{\text{eff.}} = \lambda S_z T(A_2) + g_{//} \beta H S_z + g_{0//} \beta H T(A_2), \quad (3.6)$$

where z -axis is taken along the direction of the trigonal axis. Note that trigonal invariant does not appear from $V(E)$. The eigenfunctions and the corresponding eigenvalues are at once written down:

$$W_{1\pm}' = \frac{\lambda}{2} \pm \left(\frac{g_{//}}{2} + g_{0//} \right) \beta H \begin{cases} \Psi({}^2E_{\frac{1}{2}}u_+) \\ \Psi({}^2E_{-\frac{1}{2}}u_-) \end{cases} \quad (3.7)$$

and

$$W_{2\pm}' = -\frac{\lambda}{2} \pm \left(\frac{g_{//}}{2} - g_{0//} \right) \beta H \begin{cases} \Psi({}^2E_{\frac{1}{2}}u_-) \\ \Psi({}^2E_{-\frac{1}{2}}u_+) \end{cases} \quad (3.8)$$

Since the main contribution to the first term in (3.6) comes from the second order perturbation $V_{S0} \cdot V_{\text{trig.}}$, we may say that ${}^2E$ is split by the interplay between the spin-orbit interaction and the trigonal field. The split components show the linear Zeeman effect and the corresponding g -values are $g_{//} + 2g_{0//}$ and $g_{//} - 2g_{0//}$. Since L is quenched in E state, thus $g_{//} \sim 2$ and $g_{0//} \sim 0$, so we can predict that the sum of the g -values of the split components will be almost equal to 4. This will be really seen in the Zeeman effect of the characteristic doublet R_1, R_2 of ruby, $\text{Cr}^{3+} : \text{Al}_2\text{O}_3^9$.

Both for ${}^2F_1$ and ${}^2F_2$, the effective Hamiltonian is of the same form. Dropping again the last two terms in (3.3) for simplicity,

$$\mathfrak{H}_{\text{eff.}} = FV_0(F_2) + \lambda(S_x T_x + S_y T_y) + \lambda_0 S_z T_z + g_{//} \beta H S_z + g_{0//} \beta H T_z. \quad (3.9)$$

Moreover, the matrix elements of V are entirely same for both F_1 and F_2 , and those of T for F_1 can be obtained from those for F_2 merely changing the sign (Table VIII). Therefore, we will consider here only the case of ${}^2F_2$. (For ${}^2F_1$, change $\lambda, \lambda_0 \rightarrow -\lambda, -\lambda_0$ and $g_0 \rightarrow -g_0$ in the following.)

The matrix of the above Hamiltonian for ${}^2F_2$ is

	x_+ $\frac{1}{2}$	x_+ $-\frac{1}{2}$	x_0 $\frac{1}{2}$	x_0 $-\frac{1}{2}$	x_- $\frac{1}{2}$	x_- $-\frac{1}{2}$
$\frac{1}{2}$	$-F - \frac{\lambda_0}{2} + \beta H \left(\frac{g_{//}}{2} - g_{0//} \right)$					
x_+	$-F + \frac{\lambda_0}{2} - \beta H \left(\frac{g_{//}}{2} + g_{0//} \right)$					
$-\frac{1}{2}$	$- \lambda / \sqrt{2}$					
$\frac{1}{2}$	$- \lambda / \sqrt{2}$					
x_0	$2F + \beta H \frac{g_{//}}{2}$					
$-\frac{1}{2}$	$2F - \beta H \frac{g_{//}}{2}$					
$\frac{1}{2}$	$- \lambda / \sqrt{2}$					
x_-	$-F + \frac{\lambda_0}{2} + \frac{\beta}{2} H \left(\frac{g_{//}}{2} + g_{0//} \right)$					
$-\frac{1}{2}$	$-F - \frac{\lambda_0}{2} - \beta H \left(\frac{g_{//}}{2} - g_{0//} \right)$					

(3.10)

The eigenvalues and the corresponding eigenfunctions are:

$$W_{0\pm} = -F - \frac{\lambda_0}{2} \pm \beta H \left(\frac{g_{//}}{2} - g_{0//} \right), \quad \begin{cases} \Psi(^2F_{2\frac{1}{2}}x_+) \\ \Psi(^2F_{2-\frac{1}{2}}x_-) \end{cases} \quad (3.11)$$

and neglecting the second order Zeeman effect,

$$W_{1\pm} = -F + \frac{\lambda_0}{2} - \frac{\lambda}{\sqrt{2}} \tan \alpha \pm \beta H \left[-\frac{g_{//}}{2} \cos 2\alpha - g_{0//} \cos^2 \alpha \right],$$

$$\begin{cases} \Psi(^2F_{2\frac{1}{2}}x_0) \sin \alpha + \Psi(^2F_{2-\frac{1}{2}}x_+) \cos \alpha \\ \Psi(^2F_{2-\frac{1}{2}}x_0) \sin \alpha + \Psi(^2F_{2\frac{1}{2}}x_-) \cos \alpha \end{cases} \quad (3.12)$$

$$W_{2\pm} = -F + \frac{\lambda_0}{2} + \frac{\lambda}{\sqrt{2}} \cot \alpha \pm \beta H \left[\frac{g_{//}}{2} \cos 2\alpha - g_{0//} \sin^2 \alpha \right],$$

$$\begin{cases} \Psi(^2F_{2\frac{1}{2}}x_0) \cos \alpha - \Psi(^2F_{2-\frac{1}{2}}x_+) \sin \alpha \\ \Psi(^2F_{2-\frac{1}{2}}x_0) \cos \alpha - \Psi(^2F_{2\frac{1}{2}}x_-) \sin \alpha \end{cases} \quad (3.13)$$

where

$$\tan 2\alpha = +\sqrt{2} \lambda / \left(3F - \frac{\lambda_0}{2} \right), \quad 0 \leq 2\alpha < \pi. \quad (3.14)$$

These results may be used for the analysis of the spectra, e.g., the optical anisotropy, intensity distribution in the Zeeman pattern, assuming suitable parameters F , λ , λ_0 , g , g_0 chosen so as to fit the observed natural splitting and the Zeeman splitting. Theoretical problem is thus reduced to the explanation of these empirically determined values, just as in the case of the usual spin-Hamiltonian.

Acknowledgement

The authors wish to express their sincere thanks to Professor M. Kotani for his interest and encouragement. They are also indebted to Professor Chr. Klixbüll Jørgensen of Technical University of Denmark for his valuable suggestion and correspondence, and to Mr. S. Sugano for his helpful discussions. They further appreciate the secretary assistance of Mrs. Y. Yuminami.

Appendix

The proof of (2.21) goes as follows: by definition, we have

$$(\alpha I'_a \beta I'_b I' \gamma | \mathbf{X}_{\gamma}(\bar{\Gamma})_a | \alpha' I'_a \beta I'_b I'' \gamma') = (\alpha I'_a \beta I'_b I' | \mathbf{X}(\bar{\Gamma})_a | \alpha' I'_a \beta I'_b I'') (I')^{-1/2} (I' \gamma | I'' \gamma' \bar{\Gamma} \bar{\gamma}), \quad (A.1)$$

while

$$\begin{aligned} &= \sum_{\gamma_a, \gamma'_a, \gamma_b} (I' \gamma | I'_a \gamma_a I'_b \gamma_b) (\alpha I'_a \gamma_a | \mathbf{X}_{\gamma}(\bar{\Gamma})_a | \alpha' I'_a \gamma'_a) (I'_a \gamma'_a I'_b \gamma_b | I'' \gamma') \\ &= (\alpha I'_a | \mathbf{X}(\bar{\Gamma}) | \alpha' I'_a) (I'_a)^{-1/2} \sum_{\gamma_a, \gamma'_a, \gamma_b} (I' \gamma | I'_a \gamma_a I'_b \gamma_b) (I'_a \gamma_a | I'_a \gamma'_a \bar{\Gamma} \bar{\gamma}) (I'_a \gamma'_a I'_b \gamma_b | I'' \gamma'). \end{aligned} \quad (A.2)$$

Using the definition of the transformation matrix

$$\begin{aligned} &(I'_a \bar{\Gamma}(\Gamma_a) I'_b \Gamma' | I'_a \Gamma'_b(\Gamma') \bar{\Gamma} \Gamma) \delta(I' \Gamma'') \delta(I' \gamma'') \\ &= \sum_{\gamma_a, \gamma'_a, \gamma_b, \bar{\gamma}} (I' \gamma | I'_a \gamma_a I'_b \gamma_b) (I'_a \gamma_a | I'_a \gamma'_a \bar{\Gamma} \bar{\gamma}) (I'_a \gamma'_a I'_b \gamma_b | I'' \gamma') (I' \gamma' \bar{\Gamma} \bar{\gamma} | I'' \gamma''), \end{aligned} \quad (A.3)$$

the summation in (A.2) can be transformed in the following way:

$$= (\alpha I'_a | \mathbf{X}(\bar{\Gamma}) | \alpha' I'_a) (I'_a)^{-1/2} (I'_a \bar{\Gamma}(\Gamma_a) I'_b \Gamma' | I'_a \Gamma'_b(\Gamma') \bar{\Gamma} \Gamma) (I' \gamma | I'' \gamma' \bar{\Gamma} \bar{\gamma}). \quad (A.3)$$

Thus (2.21) has been proved. (2.22) may be proved in the same way.

Note added in proof. Equation (2.3), which is the basic formula for the present calculation, has been used without proof. Recently, G. F. Koster has given the proof including more general cases. *Phys. Rev.* **109** (1958) 227.

A new Probe Method for Measuring Ionized Gases

By Takayoshi OKUDA and Kenzo YAMAMOTO

Faculty of Engineering, Nagoya University, Nagoya

(Received December 18, 1957)

A new probe method is proposed. This method is based upon the idea that the end of a cylindrical probe affects the surface area of the sheath. The first stage of this method is to measure the sheath radius by using a variable-length structure. The procedure is to extrapolate the probe current to $l=0$ along the straight line of the plot of current vs. length of probe and to measure the slope of the straight line and thus to derive the radius of the sheath. Experimental results of ion sheath for Ar are fairly well consistent with the theoretical radius expected from simple theories, except for low plasma density. The discrepancy between the theory and the experiment is caused by the disturbance.

By taking into account a correction factors, namely, depletion in ion collection due to elastic scattering, plasma density can be exactly estimated by measuring the radius of ion sheath without having any knowledge of the adequate space charge equation. Thus, the reliability of the probe method is increased.

§ 1. Introduction

In Langmuir's probe theory,¹⁾ the conditions to be satisfied are (i) no collisions between charged particles and gas atoms; (ii) both energy distribution and density of charged particle at the plasma-sheath boundary being the same as in undisturbed plasma, in other words, behavior of plasma near probe unchanged by insertion of probe into plasma.

The first is obviously not fulfilled for plasma of such high pressure that thickness of the sheath is greater than the mean free path of the charged particle. From this point of view,

expressions in which velocity of ion is defined by use of the term "mobility" have been suggested and developed by some investigators.²⁻⁷⁾

The second is concerned with investigations on the boundary between plasma and sheath. This is one of the most interesting problems of the probe theory today. It arises primarily from a need to overcome the contradiction that application of the ordinary probe theory results in an ion temperature which is larger than or is of the order of electron temperature. Body solved the boundary problem on the

criterion that ion sheath can not be formed stably unless it fulfills a certain condition, and he obtained an expression for ion current independent of ion temperature.⁸⁾ Other aspects of the problem were suggested by F. Wenzel⁹⁾ and D. Bohm,¹⁰⁾ who gave ion collection formulae independent of ion temperature by analyzing the density distribution of the charged particle under the assumption that density distribution is governed by orbital motion around the probe through the effect of probe potential.

In addition to the situation of the plasma-sheath boundary in the probe measurement, a complicated condition develops at high pressure. This is a depletion of collected charged particle due to elastic scattering, which was emphasized by B. Davydov and L. Zimadovskaya,¹¹⁾ D. Bohm,¹⁰⁾ Y. M. Kagan,¹²⁾ G. J. Schulz and S. C. Brown.⁵⁾

In practical use, besides such a depletion, there is a disturbing effect, i.e. formation of a disturbed region near the probe because of penetration of probe voltage into the plasma. This phenomena was touched upon in previous papers,¹³⁾ so we will not go into it further here.

We consider it essential to determine sheath radius for probe measurement exactly, i.e. to verify the conduction equation in sheath and to find both behavior of plasma-sheath boundary and disturbance due to penetration of probe voltage into plasma. Of course, sheath radius is an important quantity to estimate plasma density.

Nevertheless, a method for determining the radius of ion sheath exactly has not yet been developed. The cathetometer method usually provides only crude estimation because the sheath is thin and the boundary between it and the plasma is not clearly observed; consequently, it is difficult to determine the exact boundary between the plasma and the sheath of a probe having the usual negative potential. Also this method is not applicable for electron sheath which is not visible. Turning to the ion sheath, a high negative voltage must be used to make it visible. At high negative voltage, there are secondary processes, such as ejection of secondary electrons by positive ion or metastable atom which complicate the situation and finally lead to a breakdown of the ion sheath. From the fact that the critical

voltage for such secondary processes is lowered with rising pressure, at high pressure especially there is no experimental method for determining radius of the ion sheath free from such secondary processes.

We propose here a new method using a cylindrical probe of variable-length. The end of the probe as well as the side of cylinder collect currents of ions or electrons from the plasma. The current flowing into the end is a function of the sheath radius and can not be neglected so far as a finite dimension of the sheath is concerned, even when the probe is thin.

After verifying the principle of our method by preliminary experiment in this paper, we apply the results of our measurement to a criterion for the most suitable space charge equation as well as to the correction necessary to eliminate the disturbing effect from the measurement of the plasma density. In this way we can increase the reliability of the measured plasma density.

§ 2. Preliminary Experiment

We first consider the end effect quantitatively. Whatever the shape of the end sheath of the cylindrical probe may be, the additional collection through the end sheath can be written in the term of equivalent extension Δl of the probe length l . Thus, total collection is given by

$$i = i_0(l + \Delta l), \quad (1)$$

where i_0 is the ion current per cm of length of the side of cylinder of the probe, and Δl must be a function of both the probe radius r_p and the sheath radius a . The latter radius can be found by experiment as follows. Under the conditions that secondary processes do not occur and that the sheath radius is large

Fig. 1. Probe structure for examining end effect,

enough in low pressure so that we can determine it by visual observation, the ion current flowing through the end sheath is measured as a function of the radius of the sheath covering the side of cylinder. We prepare a device (see Fig. 1) in which there is an end plane probe separated from the main cylindrical probe. The same negative potential as applied to the main probe is, through a dif-

ferent probe voltage source, applied to the end plane probe. The radius of sheath a is then measured by means of the cathetometer and the ion current flowing into the end probe is simultaneously measured. The thickness of the end sheath is nearly equal to that of the main probe, although slightly curved in shape, as shown in Fig. 1.

As an example, in Table I we tabulate the

Table I. Preliminary test for end effect in cylindrical probe. Mercury vapour plasma at room temperature, discharge current 50 mA. i_{end} denotes ion current flowing into end plane probe.

Probe Voltage (V)	i_{end} (μA)	a (mm)	i_0 ($\mu\text{A}/\text{mm}$)			
			from main probe	(a) $i_{\text{end}}/1.5a-r_p$	(b) $i_{\text{end}}/a-r_p$	(c) i_{end}/a
200	42	7.0	5.6	5.7	10.5	6.0
300	50	7.4	6.1	6.1	11.4	6.7
400	56	8.0	6.3	6.2	11.2	7.0
500	62	8.5	6.4	6.4	11.3	7.3
600	68	9.1	6.6	6.4	11.1	7.5
800	82	10.0	6.9	6.8	11.7	8.2

(a), (b) and (c) represent that Eq. (2), (3) and (4) are used, respectively.

experimental data for Hg vapour at room temperature and for the discharge current of 50 mA. We assume the three shapes for the end sheath as indicated in Fig. 2 where (a) represents a cylindrical and (b) and (c) represent semi-spherical shapes. In such assumed forms, Δl in each case can be

(a) $\Delta l = 1.5a - r_p,$ (2)

(b) $\Delta l = a - r_p,$ (3)

(c) $\Delta l = a.$ (4)

Fig. 2. Assumed shapes of ion sheath at end. (a) a cylindrical end, (b) and (c), hemi-spherical end.

The equivalent ion current per unit length $i_{\text{end}}/\Delta l$ for the three forms is computed from the experimental results given in Table I where i_{end} is the ion current flowing into the end probe. Values of $i_{\text{end}}/\Delta l$ with various negative voltages in the case of (a) fairly agree with i_0 which is deduced from the current flowing into the main probe. Thus the validity of the form (a) is confirmed.

Thus equation (1) for determining sheath radius can be rewritten as

$i = i_0(l + 1.5a - r_p).$ (5)

A more convenient way for evaluating the radius of the sheath is to estimate the ion current i_0 at $l = 0$ by extending line i vs. l having a slope of $i_0 = di/dl$ (see Fig. 4). Then, instead of equation (5), we can write

$i_0 = i_0(1.5a - r_p).$ (6)

This is valid not only for an ion sheath, but also for an electron sheath, of course.

§ 3. Experiment and Results

Here, we use two probes of different diameters with lengths that can be varied by using an external magnet, as shown in Fig. 3. A large spherical vessel is used to eliminate

the asymmetric disturbance usually arising in the ordinary cylindrical tube, which is long with a small cross-section. Here the asymmetric disturbance is a phenomenon in which plasma densities and potentials are different on the cathode and anode sieves of the probe. Special precaution must be taken to completely eliminate any excess collection of ions coming through the small gap between probe and glass envelope.

Fig. 3. Variable-length probes for measuring radius of ion sheath.

Examples of plots of ion current vs. probe length are given in Fig. 4. Except for the range of small l the plot is a straight line. Deviation from the straight line for small l seems to be due to the disturbance caused by the very thin glass envelope.

To verify validity of this method, we compare the sheath radius calculated by equation (6) with that measured by visual observation, at a particular condition. The sheath radius is made visible when the probe is set at a

very high negative potential and in such a low pressure that no secondary processes occur on the probe surface. Table II gives results for Ar in pressure of 4.10^{-3} mm Hg, indicating that there is good agreement between calculated and measured radius when form (a) is assumed, while if form (b) or (c) is assumed there is no agreement between them.

Sheath radii a for Ar measured in this method are tabulated in Table III. The pressure of gas is from 10^{-3} mm Hg to 5 mm Hg, and discharge current from 0 to 200 mA.

We now compare the measured sheath radius with the theoretical radius derived from various space charge equations. According to Y. Watanabe and H. Kobayashi,⁴⁾ following three different equations are applicable.

Fig. 4. Plots of ion current vs. probe length at various negative potentials.

Table II. Comparison of radius of ion sheath measured by variable-length probe method with that by visual observation, in the case of Ar of pressure of 4.10^{-3} mm Hg.

Discharge current (mA)	Probe voltage (V)	i_0 (μ A/cm)	i_{00} (μ A)	probe radius r_p (cm)	sheath radius a (cm)			
					Variable-length probe method			Visual obser- vation
					(a)	(b)	(c)

"	200	200	70	0.075	0.28	0.42	0.35	0.35
"	400	250	140	"	0.42	0.63	0.64	0.43

(a), (b) and (c) represent that Eq. (2), (3) and (4) are used, respectively.

- (a) Langmuir's law
- $$3.43 \cdot 10^{-7} M^{-1/2} V^{3/2} (r_p \beta^2)^{-1} = i. \quad (7)$$
- (b) μ -law
- $$5.56 \cdot 10^{-13} p^{-1/2} \mu_0 V^{3/2} (\phi_0 r_p)^{-3/2} = i. \quad (8)$$
- (c) b -law
- $$5.55 \cdot 10^{-13} p^{-1} b_0 V^2 (\phi_0 r_p)^{-2} = i. \quad (9)$$

Notations used are as follows:

- i : collecting ion current per cm (A/cm)
- V : negative voltage (volts)
- a : radius of ion sheath (cm)
- r_p : radius of probe (cm)
- M : atomic weight, e.g., for O_2 , $M=16$
- j_p : random ion current density (A/cm²)
- v : velocity of ion (cm/sec)
- β^2 , ϕ_0 and ϕ_c : geometrical factors corresponding to Langmuir's law, μ - and b -laws, respectively, being functions of a/r_p
- p : pressure (mm Hg)
- μ_0 : mobility coefficient of ion at 1 mm Hg (cm^{3/2}. mm Hg^{1/2}/V^{1/2}. sec) by which the velocity of ion is defined as $v = \mu_0 (E/p)^{1/2}$, where E is field strength, e.g., for Ar and Ne, μ_0 's are 0.8×10^4 , and 1.6×10^4 , respectively
- b_0 : mobility of ion at 1 mm Hg (cm². mm Hg/V. sec) by which velocity of ion is defined as $v = b_0 (E/p)$, i.e., for Ar and Ne, b_0 's are $1.24 \cdot 10^3$ and $3.34 \cdot 10^3$, respectively.¹⁴⁾

- In Table III, theoretical values of ion sheath radius evaluated from Langmuir's, μ - and b -laws are denoted as a_2 , a_3 and a_4 , respectively. From the experimental results, we may come to the following conclusions:
- A) At pressures lower than 10^{-2} mm Hg, measured a_1 approximates evaluated a_2 based upon Langmuir's law;
- B) At moderate pressures of the order of $10^{-1} \sim 1$ mm Hg, measured a_1 approximates evaluated a_3 based upon μ -law.
- C) At pressures higher than several mm Hg, measured a_1 approximates evaluated a_4 based upon b -law;
- D) In each case, measured a_1 agrees with or is less than evaluated a ;
- E) In each case, the discrepancy between measured a_1 and evaluated radius increases with decreasing discharge current or with plasma density.

From the above measurements, we have increased our knowledge of negative probe, e.g., we can now understand qualitatively the conditions under which each space charge equation is applicable.

Now the question arises as to where the discrepancy between the sheath radius measured by are variable-length probe method and the evaluated radius based upon the corresponding simple space charge equation comes from.

Table III. Measured and evaluated sheath radii, sheath voltage, R , α , β and evaluated plasma density for Ar.

Pressure (mm Hg)	Discharge current (mA)	Probe radius (cm)	Negative Voltage (V)	i_0 (μ A/cm)	i_{00} (μ A)	a_1 (cm)	a_2 (cm)	a_3 (cm)	a_4 (cm)	V' (V)	R	α	β	n (10^{10} /cm ³)

We first consider how the simple space charge equation must be modified when various other processes are to be considered. If the ion at the sheath-plasma boundary possesses an initial velocity, the sheath radius would be large (Malter and Webster),¹⁰⁾ which is a fact contrary to measurements. Also, an addition to the diffusion term in the equation of current flow leads to a large sheath radius, an effect contrary to the measurement.

Ion sheath radius is usually evaluated from space charge equation by using the value of ion current, which is measured to be small because of elastic scattering sideways and backwards. Consequently the sheath radius is estimated to be large. Such loss through elastic scattering might be considered the source of the discrepancy. In general, elastic scattering is increased with increasing gas pressure. However elastic scattering is not a possible source because of the experimental fact that the discrepancy does not depend upon the pressure. Moreover, the range in which the plot i vs. l is not linear is too large to be explained by elastic scattering.¹²⁾

Another probable source may come from an estimation of the true sheath voltage. If the negative voltage penetrates into plasma to some degree, it can be expected that sheath voltage is lower than applied voltage deduced from the probe characteristic.

Assuming the penetration, we can expect the sheath voltage V' from the measured sheath radius and the corresponding space charge equation, to be as given in Table III. For example, with a pressure of 2.6×10^{-2} mm Hg and a discharge current of 200 mA, using a probe having a diameter of 1.5 mm in the tube, as shown in Fig. 3, expected sheath voltages of 24, 35 and 60 volts can be obtained for an applied negative voltage of 30, 60 and 90 volts, respectively. Also, the experiment indicates that the difference between the sheath voltage and the applied voltage increases as the discharge current or the plasma density decreases. Such a penetration is characterized by formation of a penetrating sheath outside the ion sheath. Disturbance due to penetration will be described in another paper.

§ 4. Determination of Plasma Density

To determine plasma density, it is essential

that elastic scattering effect must be taken into account.

The elastic scattering occurring near a probe leads to depletion of the collection of ions or electrons, which has been discussed by Brown and Schultz,⁶⁾ Bohm¹⁰⁾ and Kagan.¹²⁾ This effect has a tendency to become pronounced with increasing gas pressure.

Analogous to Bohm's theory for spherical probe stood on an idea that collection is determined by the diffusion flow at the point which is one mean free path distant from the probe, we get the expression of the collection on a cylindrical probe in terms of the probe radius r_p , the mean free path λ , and probe length l as follows;

$$R_1 = j/j_0 = \lambda / \{ \lambda + r_p \log l / (r_p + \lambda) \}, \quad (10)$$

where j and j_0 are electron current densities flowing into the probe, with and without the depletion, respectively.

Thus, such a depletion depends upon the mean free path of the charged particle as well as on both the radius and length of probe, but is independent of plasma density. Kagan¹²⁾ found that this depletion becomes effective in the vicinity of the probe within several times the radius of the probe. Equation (10) applies also for ion or electron sheath.

Eq. (10) is derived by assuming that no sheath is formed around the probe. So far as ion collection in negative probe is concerned, it is necessary to consider the effect of the existence of an ion sheath on the depletion.

According to our analysis which is analogous to Kagan's theory of spherical probe, the density distribution as a function of distance r from a cylindrical probe is expressed by

$$n_v = (F_v / 2\pi r_p v) \{ (r_p / r) \cos \theta_r + (2r_p / \lambda) \log (r / r_p) + \pi / 2 \}, \quad (11)$$

where F_v is total flow to the probe, v velocity of charged particle and $\theta_r = \sin^{-1} r_p / r$.

Setting $r = r_p$, we find the density at probe surface as follows:

$$n_v(r_p) = F_v / 4r_p v. \quad (12)$$

Since scattering does not occur in the ion sheath, as we shall discuss in detail in another paper, the existence of an ion sheath increases collection of ion determined by the density outside the sheath. Consequently, ion collection with ion sheath is greater than that without ion sheath; the condition of the latter can

not be found in the usual probe method.

Considering the effect of ion sheath having radius a , the resultant expression of the depletion factor can be given by

$$R' = R\alpha, \tag{13}$$

and

$$\begin{aligned} \alpha &= n_v(a)/n_v(r_p) \\ &= (2/\pi)\{(r_p/a) \cos \theta_{r_p} + (2r_p/\lambda) \log(a/r_p) + \pi/2\}, \end{aligned} \tag{14}$$

where $\theta_{r_p} = \sin^{-1} r_p/a$.

Finally, the correct plasma density can be found by the following equation:

$$n = \frac{i}{2\pi ae} \frac{1}{R'} \left(\frac{2\pi M'}{kT_p} \right)^{1/2} \tag{15}$$

where e is elementary charge, K Boltzmann constant, M' mass of ion and T_p ion temperature.

The plasma densities obtained by Eq. (15) are given in Table III. It is found that numerical values of plasma density obtained at different negative voltages agree fairly well with each other. Without above correction, there is a poor agreement.

Finally, we may add following description concerning to the disturbance. The disturbance accompanying with negative probe is characterized by formation of penetrating sheath and "transition region" which appears outside the penetrating sheath. The transition region is formed as a result of loss of charged particles near the probe. Owing to such disturbance, the plasma density near the probe is decreased. In fact, the extent of the dis-

turbance observed as a range in which the plot of probe current vs. probe length is not linear, increases with decreasing plasma density. Also, the ratio β of the measured ion current at $l=0$ to the ion current extrapolated to $l=0$ along the straight line, increases with increasing plasma density, as shown in Fig. 5 in which measured β as well as the electron current flowing into the probe holding at the space potential as a measure of plasma density are plotted against pressure.

Those non-linearity can not be caused by the scattering effect because the scattering effect is located so close to the glass envelope that its range is usually covered by the ion sheath around the probe. Therefore it is seen that the formation of transition region results in the non-linearity and consequently the transition region expands with decreasing plasma density.

§ 5. Conclusion

We propose a new method for determining sheath radius and plasma density. This method has the merit that it is not necessary in principle to use the space charge equation and that error due to disturbance can be eliminated. Also it offers information of the most adequate space charge equation and clarifies how disturbance in negative probe leads to error in the measurement.

It especially emphasizes that the disturbance must not be ignored even in low pressure plasma where the elastic scattering effect can be neglected, and that the boundary problem should be interpreted basing upon the disturbance.

Oscillation of the Wake behind a Flat Plate parallel to the Flow

By Sadatoshi TANEDA

Kobe University of Mercantile Marine

(Received December 27, 1957)

Oscillation of the pure laminar wake behind a flat plate placed in a uniform stream at zero incidence angle was investigated experimentally at Reynolds numbers between 10^2 and 10^5 . (The Reynolds number R is Ul/ν , where U is the model speed, l is the plate length and ν is the kinematic viscosity.)

For a sufficiently small R the corresponding wake was perfectly laminar and vortex filament was seen nowhere. But when R of about 700 was reached, the wake began to oscillate sinusoidally some distance downstream. As R was increased further the oscillation became more and more conspicuous and discrete vortex filaments appeared in the loop of the sinusoidal wave. Frequency N was measured by the hot-wire technique and it was found that the Strouhal number Nl/U is nearly proportional to $1/2$ power of R . On the other hand, wave length λ was determined from the photographs taken by aluminium dust method, and the relation between l/λ and R was obtained. Spacing ratio and velocity of the vortex filaments were also estimated.

These experimental results were compared with those of the wakes behind various bluff bodies, and some knowledges about the origin of oscillation of the wake were obtained. The value of wake Strouhal number was nearly constant for all shapes of body, while the wave velocity changed remarkably with the shape of the body.

§ 1. Introduction

It has long been recognized that the wake behind a bluff cylindrical body oscillates and arranges itself in a regular vortex street in the intermediate Reynolds number range. Though an appropriate explanation of the geometry of the vortex street was provided by the well known theory of von Karman¹⁾, the reason why the wake should oscillate or why a vortex street must appear, has not yet been made clear.

In the case of a bluff body, the flow sepa-

rates from the surface of the body and twin vortices are formed immediately behind the body at the beginning of motion. Then they become more and more elongated in the flow direction, take up an asymmetrical position and move away from the body. In this way a regular vortex street is set up. These experimental results seem to indicate that the oscillation of a wake is due to the instability of twin vortices.

On the other hand, it should be noticed that the wake behind a bluff body is a separated

wake, and is composed of two parts, the twin vortices and the laminar wake. Therefore the laminar wake can also be considered as the origin of oscillation, and it is still a matter of speculation which of the twin vortices or the laminar wake is to be looked upon as the true origin of oscillation. In order to make clear this point, the investigation about a pure laminar wake is needed. However, literatures in which the pure laminar wakes were dealt with seem to be scanty. The pure laminar wake can be produced by a flat plate placed parallel to the flow, since separation does not occur and twin vortices do not appear in the flow. Though several authors (Fage and Johansen²⁾; Tyler³⁾; Blenk, Fuchs and Liebers⁴⁾) have investigated the wake behind an inclined flat plate in the past, little work has been done for the case of zero incidence angle. A careful measurement about the pure laminar wake behind a flat plate parallel to the flow was first made by Hollingdale⁵⁾. He has obtained several valuable results about the stability and the configuration of the pure laminar wake, but his observation was made

only for R lower than about 2×10^3 and the results seem to be inadequate to draw any general conclusion as to the variation of the frequency, wave length and wave velocity with the Reynolds number.

In the present report, further observations on the pure laminar wake behind a flat plate parallel to the flow, at various Reynolds numbers from about 10^2 to 10^6 , are described, together with some remarks on the experimental method and possible significance of the results.

§ 2. Apparatus and Experimental Method

All the experiments were made with a research water tank of 300 cm in length, 20 cm in width and 20 cm in depth. A small carriage, to which a model was fixed upright, was towed, by a steel wire uniformly along rails mounted over the water tank, using a 100 watt a. c. motor. The velocity of the carriage could be varied smoothly from 1 to 20 cm/s by controlling a friction gear fitted to the motor. General arrangement of the apparatus is shown in Fig. 1.

Fig. 1. Schematic diagram of the apparatus.

Thin flat plates of five different sizes, all of which were tapered carefully and smooth to sharp edges, were used as models. Sizes of the models are given in Table I. All ratios of the thickness to length of the plates used were less than 125^{-1} , and no influence of the thickness was detected in the wake measurement.

Wave length and spacing ratio of the vortex street were determined, by examining photographs taken by aluminium dust method⁶⁾. The central horizontal plane of the tank was illuminated from a side by a sheet of intense

Table I.

light from incandescent lamps behind a narrow slit, and photographs showing the movement of aluminium dust suspended in the water were taken from above with a camera fixed to the water tank.

The frequency was measured with a hot-wire speed meter. Hot-wire technique has usually been applied only to air stream because its use in water is met with a great difficulty due to electrolysis, air bubbles in, or a large conductivity of water etc. We used the technique, however, in the water and succeeded in measuring the frequency after a considerable amount of study. In order to eliminate the influence of electrolysis, a. c. was used to heat the hot wire. Two Pt-wires, each 30μ in diameter and about 5 mm in length, were used, one in the wake, and the other outside the wake. They were heated by 250 cycle a. c. from an audio frequency oscillator, and the change of electric resistance of the hot wires, caused by a fluctuating flow, was amplified and recorded on the photographic paper of an electromagnetic oscillograph. The velocity of the carriage and the time mark were also recorded on the same paper. Fig. 2 shows the block diagram of the electronic set-up used in the frequency determination.

Fig. 2. Block diagram of the electronic set-up used in the frequency determination.

The velocity of the wave form was determined from the photographs of one part of the field taken successively by measuring the distance the wave had travelled in the known time interval between two consecutive exposures.

§ 3. Flow pattern of the Wake

Many photographs were taken, of the flow pattern behind a flat plate moving in the water at various Reynolds numbers between 10^2 and 10^6 . Some of them are shown in Fig. 3.

The change of the flow pattern which occurs in the wake when R is increased stepwise is as follows. For R lower than about 700, the wake is perfectly laminar. When R of about 700 is reached, however, a very faint oscillation appears some distance downstream of the flat plate, as was clarified already in the previous paper⁷⁾. This value of 700 is in approximate accordance with the value of 600 observed by Hollingdale. For R from about 700 to 1000 the oscillation is not regular. Frequently the oscillation persists for a few wave lengths, then dies out, and the wake becomes sensibly laminar again. For R higher than about 10^3 , however, the oscillation does not show any tendency to die away, and the wake shows a regular sinusoidal form. The whole sinusoidal wave form is observed to move slowly in the direction of motion of the body. When R is slightly higher than 10^3 , the sinusoidal wave form extends far downstream but discrete vortex filament does not appear in the whole wake. On increasing R further, the oscillation becomes more and more noticeable, and discrete vortices appear in the hollows of the sinusoidal wave form. They arrange themselves for some distance in a configuration corresponding to that of a Karman vortex street. The vortices do not arrange themselves on two parallel rows with a definite spacing ratio (the ratio of lateral spacing between the rows to the distance between two consecutive vortices in the same row), but the wake tends to widen out downstream, and the spacing ratio changes. At the beginning of the wake the spacing ratio is about 0.3, while far downstream it is about 0.6. These values are much larger than the theoretical value 0.28 obtained by von Karman.

For higher R the regular vortex street is soon deformed and destroyed into pieces. But it was frequently observed that these scattered vortices were soon united and arranged themselves again to a new regular vortex street, the dimension of which was much larger than that of the primary one.

(a) $R=1861$ (b) $R=3550$ (c) $R=15800$ (d) $R=15800$; continued from (c)

Fig. 3. Photographs showing flow pattern in the oscillating wake behind flat plate moving in the water.

§ 4. Measurement of the Frequency

The frequency of the oscillating wake was measured with a hot wire speed meter. When R is lower than about 700, the wake is sensibly laminar and no oscillating signal can be detected. Then it follows a range of R in which the frequency is very irregular. In the range from about 700 to 1000 of R , the commencement of the oscillation seems to depend largely on a very small residual motion of the water. Consequently it is very difficult to determine the frequency. At R higher than about 10^3 , however, a regular frequency is observed. Of course even for R higher than 10^3 , any signal of oscillation can be detected in the immediate rear of the plate, since the flow is always laminar there. There-

fore a hot wire should be placed always at some distance behind a plate. The frequency increases with the model speed, while for a fixed model speed frequency is constant throughout the whole field of the wake. The best signal was obtained when the hot wire was located about 1 to 2 plate length behind the plate and about 5 mm off the centre of the wake. As the direction of the flow cannot be detected with a single hot wire, the frequency of the fluctuation in the middle of the vortex street is always double that outside. The double frequency component decreased rapidly with distance from the centre of the wake, and disappeared almost completely at about 5 mm from the wake centre. The typical oscillographs are shown in Fig. 4.

Fig. 4. Velocity fluctuation records.

The results are expressed in terms of the dimensionless Strouhal number $S=Nl/U$, where N is the frequency, l is the plate length and U is the model speed. The Strouhal number S is considered to depend on R as well as external disturbances. The present measurements of $S(R)$ are given in Fig. 5.

From this figure it will be seen that there exists a functional relation

$$\frac{Nl}{U} = \text{const.} \left(\frac{Ul}{\nu} \right)^{1/2} \quad (1)$$

Hence

$$N = \text{const.} (\nu l)^{-1/2} U^{3/2} \quad (2)$$

Namely, the frequency N is nearly propor-

tional to $3/2$ power of the flow speed. It should be noticed that this relation is in accordance with that observed in the case of a laminar half jet (Sato²³).

As is seen from Fig. 5, the scatter of observed values is fairly large for the whole range of R . It seems that this is not due to the inaccuracy of experiment, but to the essential properties of the pure laminar wake.

§ 5. Measurements of the Wave Length and the Wave Velocity

The wave length and the wave velocity were determined from the photographs of the flow pattern. When R is lower than about

10^3 , it was rather difficult to measure the wave length owing to the irregularity of the wave form, so all measurements were made only for R higher than 10^3 . Even for R higher than 10^3 the measurement was very difficult, because the amplitude of the wave was very small immediately behind the flat plate. The wave length varied in different places, i.e. the wave length showed a tendency to increase downstream. For these reasons measurements were all made at the place where a distinct sinusoidal wave form appeared first in the wake. The curve of l/λ against

R is given in Fig. 6. As is seen from the figure the functional relation

$$\frac{l}{\lambda} = \text{const.} \left(\frac{Ul}{\nu} \right)^{1/2} \tag{3}$$

can be established. A large scattering of the observed values is similar to that in the case of the frequency measurements.

The wave velocity was determined from the successive photographs of the vortex street. If we know the time between the two successive exposures, then the wave velocity V can be calculated by measuring the distance the

Fig. 5. Plot of $\log S$ against $\log R$.

Fig. 6. Plot of $\log l/\lambda$ against $\log R$.

wave had travelled during that time interval. From many observations it was found that the value of V/U is nearly 0.08 and does not vary greatly with the Reynolds number. It should be noted that this value of 0.08 is much less than that for the bluff body. In the case of a circular cylinder the value of V/U is about 0.14 (Karman and Rubach⁹; Richards¹⁰). The value of V/U shows a weak tendency to decrease downstream.

§ 6. Discussion

In the case of a flat plate, N is, as is shown in § 4, nearly proportional to $U^{3/2}$, while in the case of a bluff body, N is proportional to U^1 (Karman and Rubach⁹; Fage and Johansen²; Tyler³; Blenk, Fuchs and Liebers⁴). Thus there is a conspicuous difference between the two cases of a flat plate and a bluff body. But if we use the wake width δ , instead of the plate length l in equation (1), we get

$$\frac{N\delta}{U} = \text{const.} \quad (4)$$

for a flat plate, because δ is proportional to $R^{-1/2}$ from the boundary layer theory.

On the other hand in the case of a bluff body

$$\frac{Nd}{U} = \text{const.} \quad (5)$$

where d is the breadth of the bluff body across the stream. Since the wake width δ is nearly proportional to d , we have

$$\frac{N\delta}{U} = \text{const.} \quad (6)$$

Thus the wake Strouhal number $N\delta/U$ remains practically constant in both wakes, those behind a flat plate and behind a bluff body. Moreover if δ is the wake width at the position where the difference between the velocities at the centre and the outside of the wake is equal to U , the value of the constant is found to be nearly universal for bodies in any shape.

The reasoning mentioned above leads us to the conclusion that there is no essential difference between the two wakes, the pure laminar wake and the separated wake. The frequency seems to be the function of only U and δ , and is independent whether twin vortices are present or not. Though the viscosity is effective in producing a wake, it has little relation to the frequency.

On the other hand it should be noticed that

the scattering in the observed frequency for the flat plate is much larger than that for the bluff body. In the case of the bluff body scattering is very small when Reynolds number is comparatively low (Roshko¹¹; Kovasznay¹²). These facts give us an important suggestion as to the origin of oscillation of the wake and the behaviour of the twin vortices.

As was described above the value of $N\delta/U$ is nearly independent of the shape of the body producing the wake, while the wave velocity V/U changes conspicuously with the shape of the body (§ 5). That is, V is a function of not only U and δ , but also the shape of the body. It seems that the shape of a body has an influence upon the velocity distribution in a wake and consequently the wave velocity changes according to the shape. But the wave velocity is not affected greatly by the viscosity.

As for the spacing ratio of the vortex street behind a bluff body, there has been many investigations made and it is believed that the initial value of the spacing ratio near the body is about 0.3, and it increases up to about 0.5 downstream. This is in agreement with the results obtained for the flat plate (§ 3). That is, as for the spacing ratio there is no significant difference between both cases of the pure laminar wake and the separated wake. The observed spacing ratio is always larger than the value 0.28 of von Karman obtained theoretically.

Though the wake Strouhal number $N\delta/U$ is nearly constant and is independent of the Reynolds number for bodies in any shape and form, the wake Reynolds number at which oscillation first appears in the wake, changes with the shape of the body. In the case of a flat plate parallel to the flow, the critical wake Reynolds number is about 200, while in the case of a circular cylinder it is about 100. There seems to be a general relation that the smaller the bluntness of a body, the higher is the critical Reynolds number.

In conclusion, the author wishes to express his thanks to Professor Hikoji Yamada for constant advice and encouragement in the course of this work.

Transport Phenomena in Monovalent Metals

By Mikio TSUJI

General Education Department,
Kyushu University, Fukuoka

(Received January 16, 1958)

Taking into account the departure of the distribution function for phonons from its thermal equilibrium value, Hanna and Sondheimer¹⁾ have calculated the electrical and thermal conductivities and the absolute thermoelectric powers of monovalent metals based on the quasi-free electron model. Their expressions have been obtained by interpolation from the solutions at high temperatures and those at low temperatures, and the latter have been obtained by the assumption that the change of the distribution function for electrons due to the impurity scattering is larger than that due to the lattice scattering. Therefore it is not obvious whether their results are applicable for the case of intermediate temperature range and for the pure metals at low temperatures.

We have obtained the formulae which are approximately correct at all temperatures and for any concentration of impurities including the case of pure metals. The Boltzmann equations for the electrons and phonons are written in the form:

$$\frac{1}{\hbar K} \frac{dE}{dK} E^{n-1} \frac{\partial f_0}{\partial E} = \mathcal{L}_1(c^{(n)}) + \sum_j \mathcal{L}_{2,j}(b_j^{(n)}), \quad (1)$$

$$(n-1) \frac{\hbar u_0^2}{kT} \frac{\partial N_0}{\partial z} = \mathcal{L}_{3,j}(c^{(n)}) + \mathcal{L}_{4,j}(b_j^{(n)}), \quad (2)$$

where $\mathcal{L}$'s are the collision operators and $c^{(n)}$ and $b_j^{(n)}$ are the functions related to the distribution for electrons and phonons. (See reference (1) and (4).) If we put

$$c^{(n)} = c_0^{(n)} + c_1^{(n)} \eta, \quad (3)$$

and insert (3) into (2), $b_j^{(n)}$ are obtained as linear functions of $c_0^{(n)}$ and $c_1^{(n)}$. Putting these $b_j^{(n)}$ into (1), we have an integral equation of the type

$$\mathcal{L}_1(c^{(n)}) = \frac{1}{\hbar K} \frac{dE}{dK} E^{n-1} \frac{\partial f_0}{\partial E} + c_0^{(n)} A_0(E) + c_1^{(n)} A_1(E) + B^{(n)}(E). \quad (4)$$

Using the well known symmetricity of the integral operator $\mathcal{L}_1$, we can solve (4) by a modification of Kohler's variational method²⁾. We have assumed the general spherical energy band model for electrons and the Debye model for phonons. The results are as follows:

$$\frac{1}{\sigma} = \rho = \rho_e - \rho_g \quad (5)$$

$$\rho_g = \frac{3\pi^2 \hbar}{e^2} q_0^2 \left(\frac{T}{\Theta} \right)^5 \sum_j A_j^{-1} P_{j,0}, \quad (6)$$

$$\kappa = \kappa_e + \kappa_g, \quad (7)$$

$$\kappa_g = \frac{(kT)^2}{3\pi^2 \hbar} \left(\frac{T}{\Theta} \right)^2 K_0^4 q_0^{-2} \alpha^2 \sum_j A_j P_{j,4}, \quad (8)$$

$$S = S_e(1+\delta) + S_g, \quad (9)$$

$$S_g = -\frac{k}{e} \left(\frac{T}{\Theta} \right)^3 \sum_j P_{j,5} \quad (10)$$

where $\alpha = (dE/dK)_\zeta$, q_0 is the maximum wave number of phonons and other symbols have the same meanings as those used by Hanna and Sondheimer. For the quasi-free electron model, the expressions for σ and κ coincide completely with those obtained by Hanna and Sondheimer, and thus the interpolation formulae of Hanna and Sondheimer have been justified. For the absolute thermoelectric power S , Eq. (9) differs from the expression of Hanna and Sondheimer in the point that the latter have not the term δS_e . δ is a complicated function of temperature, and at low temperatures and for ideally pure metals, if we assume the phonons are scattered only by electrons, the value of δ reaches to 1/2. However, in many cases, δ is small compared to unity, and so the results of Hanna and Sondheimer are justified practically except for certain special cases.

We have also shown that a general variational principle of Ziman³⁾ and Dorn⁴⁾ gives the same results if we put

$$c^{(n)} = c_0^{(n)} + c_1^{(n)} \eta, \quad (11)$$

$$b_j^{(n)} = \frac{b_{j,0}^{(n)}}{z + \Gamma_j} + \frac{z}{z + \Gamma_j} b_{j,1}^{(n)}, \quad (12)$$

where Γ_j has the same meaning as reference (1). The author believes, however, that his new method above described is more convenient in the point that the best forms of the trial functions of $b_j^{(n)}$ are automatically and uniquely determined if the trial function of $c^{(n)}$ is given. The details will soon appear in Memoirs of the Faculty of Science, Kyushu University, Series B Vol. 2, No. 4.

Observation of a Beryllium
Hyperfragment

By Shigeo MATSUMOTO

Institute of Polytechnics, Osaka City University,
Osaka

(Received January 10, 1958)

A beryllium hyperfragment has been found in 600 microns thick Ilford G5 emulsions which were flown at 70,000 feet during four hours from Bristol. The fragment was emitted from a nuclear disintegration of the type $20+1_p$. After traveling 6×10^{-12} seconds, it came to rest and gave rise to a four prong star. The track of the fragment exhibited the "thin-down", and it was not accompanied by delta rays near the secondary star. The residual ranges of the fragment and its decay products are given in Table I. The masses of particles 1 and

Table I. Characteristics of the hyperfragment and its decay products.

Track	Residual range	Identity	Energy*(Mev)
Fragment	137 μ	$\Delta\text{Be}^8(\Delta\text{Be}^9)$	53
1	6.5 ± 0.21 mm	p	41.5 ± 0.8
2	218 ± 7 μ	$t(\text{or } d)$	8.9 (or 7.7)
3	34 ± 1.7 μ	p, d, t	1.8, 2.3, 2.6
4	29 ± 1.6 μ	p, d, t	1.6, 2.0, 2.3

2 were found to be $(1.0 \pm 0.24)M_p$ and $(3 \pm 1.1)M_p$ ** respectively by making use of the constant sagitta method, where M_p represents the protonic mass. The former agrees well with the result obtained by the range-ionization method. If particle 2 is an alpha particle, the detectable number of delta rays longer than 2 microns along the track are expected to be four. Since even such a delta ray could not be observed, the particle seems to be singly charged. The identifications of 3 and 4 could not be established, but they appear to be singly charged. The emitted angles of decay products indicate that one or more neutrons should be emitted.

When we assume various identities of 2, 3, and 4, a number of hypothetical disintegration schemes are made. Assuming that only one neutron, indicated as 5, has carried away the residual momentum from charged particles, the binding energy of a Δ^0 particle in the hyperfragment— B_Δ —

* The range-energy relation of Fay et al.¹⁾ was used for shorter tracks, and that of Barkas et al.²⁾ for longer one. We have employed the value of stopping power which was measured by Imaeda and Kazuno³⁾ for the same emulsions as those used here.

** If particle 2 is doubly charged, the value is changed to $(2.3 \pm 0.9)M_p$.

can be calculated for the disintegration schemes. Most of the disintegration schemes except for the three shown in Table II can be excluded, because B_Δ are too large or too small. The mass

Table II. Probable disintegration schemes of the beryllium hyperfragment.

Fragment	Decay products					$B_\Delta(\text{Mev})$
	1	2	3	4	5	
(a) ΔBe^8	p	t	d	p	n	7.2 ± 2.0
(b) ΔBe^9	p	d	t	d	n	5.8 ± 2.0
(c) ΔBe^9	p	t	d	d	n	2.2 ± 2.0

measurement of particle 2 indicates that it was perhaps a triton, so scheme (b) is less probable than (a). Scheme (c) is also less probable, because the B_Δ is a little smaller as compared with the values reported by other authors.⁴⁾⁵⁾ Scheme (a) seems to be the most probable, because the identities of each particle fit to observation and the binding energy— $B_\Delta=7.2 \pm 2.0$ Mev—agrees fairly well with the values obtained by other authors⁶⁾⁶⁾. Tati and Tati⁷⁾ and Kwon et al.⁸⁾ have indicated that B_Δ increases gradually with increasing mass number of hyperfragment. Their theoretical prediction is compatible with the B_Δ in (a). In conclusion, we would like to take note of the following. When a beryllium hyperfragment decays, a helium or heavier recoil nucleus is usually involved in the decay products. It acquires interest from the fact that such a nucleus has not been observed in the present example.

The author wishes to express his cordial thanks to Prof. Y. Watase for his interest and encouragement, and to Prof. Y. Yamaguchi for some criticisms. Thanks are also due to Mr. S. Kaneko for his constant guidance, and to Mr. O. Kusumoto for his valuable advice.

Asymptotic Expansions of Weber's Functions

By RYOZO YAMADA
Faculty of Science and Engineering
Meijo University, Nagoya, Japan

(Received January 20, 1958)

In our previous paper³⁾, we obtained the asymptotic expansions of the solutions of modified Weber's equation $y''+(\gamma+x^2/4)y=0$, whose validity was limited to the range $\pi/4 > \arg x > -\pi/4$. This paper deals with the expansions of the solutions of Weber's equation $y''+(\gamma-x^2/4)y=0$, valid for $\pi/4 > \arg x > -\pi/4$. By these two sets of asymptotic expansions, we can evaluate $D_n(x)$, $D_{-n-1}(ix)$ for arbitrary order and argument in the whole complex domain, together with Whittaker's expression of these functions in Kummer's function and the asymptotic expansions of Whittaker^{2),3)}. The integral representation of the functions are²⁾

$$D_n(x) = -\frac{\Gamma(n+1)}{2\pi i} e^{-1/4 \cdot x^2} \int_0^\infty e^{-xt - 1/2 \cdot t^2} (-t)^{-n-1} dt$$
$$= \frac{\Gamma(n+1)}{2\pi i} x^{-n} e^{in\pi} \int_0^\infty e^{-x^2 f(w)} dw,$$

$$D_{-n-1}(ix) = \frac{e^{-1/2(n-1)\pi}}{\sqrt{2\pi}} x^{-n} e^{in\pi} \int_0^\infty e^{-x^2 f(w)} dw$$

where $f(w) = 1/4 + \exp w + \frac{1}{2} \exp 2w - (w/4) \sinh^2 w_0$, $t = x \exp w$, and

$$(w_1) = -\sqrt{\frac{2\pi}{x \cosh w_0}} \exp \left[-\frac{x}{4} \left\{ \cosh w_0 + \frac{1}{2} \sinh^2 w_0 - \sinh^2 w_0 \log \sinh^2 \frac{1}{2} w_0 \right. \right. \\ \left. \left. + \frac{2}{x^2} \log (x \sinh^2 \frac{1}{2} w_0) \right\} \right] \left(1 + \frac{1}{24x^2} \frac{8 \cosh^2 w_0 - 11 \cosh w_0 - 5}{\sinh^2 \frac{1}{2} w_0 \cosh^3 w_0} - \dots \right),$$
$$(w_1 + 2\pi i) = -\sqrt{\frac{2\pi}{x \cosh w_0}} \exp \left[-\frac{x^2}{4} \left\{ \cosh w_0 + \frac{1}{2} \sinh^2 w_0 - \sinh^2 w_0 (\log \sinh^2 \frac{1}{2} w_0 + 2\pi i) \right. \right. \\ \left. \left. + \frac{2}{x^2} \log (x \sinh^2 \frac{1}{2} w_0) \right\} \right] \left(1 + \frac{1}{24x^2} \frac{8 \cosh^2 w_0 - 11 \cosh w_0 - 5}{\sinh^2 \frac{1}{2} w_0 \cosh^3 w_0} - \dots \right),$$
$$(w_2) = \sqrt{\frac{2\pi}{x \cosh w_0}} \exp \left[\frac{x^2}{4} \left\{ \cosh w_0 - \frac{1}{2} \sinh^2 w_0 + \sinh^2 w_0 (\log \cosh^2 \frac{1}{2} w_0 - i\pi) \right. \right. \\ \left. \left. - \frac{2}{x^2} \log (x \cosh^2 \frac{1}{2} w_0) \right\} \right] \left(1 + \frac{1}{24x^2} \frac{8 \cosh^2 w_0 + 11 \cosh w_0 - 5}{\cosh^2 \frac{1}{2} w_0 \cosh^3 w_0} - \dots \right).$$

Considering the integral representations and the end points of contours, we can construct the tables of $D_n(x)$, $D_{-n-1}(ix)$ in terms of (w_1) , $(w_1 + 2\pi i)$ and (w_2) when w_0 lies in the subdomain 1, 2, 3, 1', 2', 3'.

$-n = (x^2/4) \sinh^2 w \equiv (x^2/4) \sinh^2 (\alpha + i\beta)$.

The stationary points of this integrand are

$w_1 = \log \sinh^2 \frac{1}{2} w_0, \quad w_2 = \log \sinh^2 \frac{1}{2} (w_0 + i\pi)$.

If we write

$\phi_1 = \text{Im} \{ f(w) - f(w_1) \}, \quad \phi_2 = \text{Im} \{ f(w) - f(w_2) \},$

the contours of integration that pass through w_1 and w_2 are determined by $\phi_1(w) = 0, \phi_2(w) = 0$. These contours have different shapes by the signs of $\phi_1(w_2), \phi_1(w_2 - 2\pi i)$, i.e.,

$$\frac{\phi_1(w_2)}{\phi_1(w_2 - 2\pi i)} = \frac{\sinh \alpha \sin \beta}{\sinh \alpha \sin \beta}$$
$$= \frac{\sinh 2\alpha \sin 2\beta}{4} \log \frac{\cosh \alpha + \cos \beta}{\cosh \alpha - \cos \beta}$$
$$+ \frac{\cosh 2\alpha \cos 2\beta - 1}{2} \left(\tan^{-1} \frac{\sin \beta}{\sinh \alpha} \mp \frac{\pi}{2} \right).$$

We divide the domain of values of complex w_0 into six subdomains named 1, 2, 3, 1', 2', 3' as shown in Fig. 1. By the method of the steepest

Fig. 1. w_0 -plane. $\phi_1(w_2)$ is negative in 1, 1' and 2' and is positive in 2, 3 and 3'. $\phi_1(w_2 - 2\pi i)$ negative in 3, 2' and 3' and is positive in 1, 2 and 1'.

descents¹⁾, the integral $\int \exp(-x^2 f(w)) dw$ along the contours that pass through $w_1, w_1 + 2\pi i$ and w_2 which are denoted as $(w_1), (w_1 + 2\pi i)$ and (w_2) are

	1	2	3	1'	2'	3'
$\frac{2\pi i}{\Gamma(n+1)}e^{-in\pi}x^n D_n(x)$	$\begin{pmatrix} w_1 \\ -(w_1+2\pi i) \end{pmatrix}$	$-(w_1+2\pi i)$	$\begin{pmatrix} w_2 \\ -(w_1+2\pi i) \end{pmatrix}$	$\begin{pmatrix} w_2 \\ -(w_1+2\pi i) \end{pmatrix}$	(w_1)	$(w_1)-(w_2)$
$\sqrt{2\pi}e^{-1/2(n-1)\pi i}x^n D_{-n-1}(ix)$	$(w_1)+(w_2)$	(w_2)	(w_2)	$(w_1)+(w_2)$	$(w_1)+(w_2)$	(w_1)

Asymptotic expansions in the transitional region are also obtained by a similar method;

$$D_n(x) \approx \frac{\Gamma(n+1)e^{i(n+1/6)\pi}}{x^{(n+2/3)(12)^{1/6}}} \exp \left[\frac{x^2}{4} \left(\frac{1}{2} + \log 2 - i\pi \right) + \varepsilon (\log 2 - i\pi) \right] \left(\frac{v}{2} \right)^{1/3} H_{1/3}(1)(v e^{-i\pi}) ,$$

$$D_{-n-1}(ix) \approx \frac{\sqrt{2\pi}e^{i(1/2 \cdot n + 1/6)\pi}}{x^{(n+2/3)(12)^{1/6}}} \exp \left[\frac{x^2}{4} \left(\frac{1}{2} + \log 2 - i\pi \right) + \varepsilon (\log 2 - i\pi) \right] \left(\frac{v}{2} \right)^{1/3} H_{1/3}(1)(v) ,$$

where $\varepsilon=n-x^2/4$, and $v=4\varepsilon^{3/2}/3x$. These asymptotic expansions are valid for $|\arg x|<\pi/4$. $D_n(-x)$, $D_{-n-1}(-ix)$ can be obtained by the circuit relations²⁾.

Excitation Curve for the Reaction $P^{31}(n, p) Si^{31}$

By Susumu MORITA

*Department of Physics, Faculty of Science,
Kyushu University, Fukuoka, Japan*

(Received February 6, 1958)

The excitation curve for the reaction $P^{31}(n, p)Si^{31}$ was measured in the energy range of neutron from 3.0 MeV to 5.2 MeV by activation method. A large resonance peak of 160 mb was found at the neutron energy of 4.9 MeV.

§ 1. Introduction

Paul and Clarke¹⁾ found that the cross sections for (n, p) reactions with 14 MeV neutrons were considerably larger than the theoretical values predicted by the assumption of compound nucleus formation. Then, it has been attempted by several authors to measure the excitation function, and energy spectrum and angular distribution of the emitted protons in these reactions^{2), 3)}. We obtained also the preliminary result for the excitation function of the reaction $P^{31}(n, p)Si^{31}$ for neutron energies of 3.0 MeV to 5.2 MeV by the activation method. The reaction $P^{31}(n, p)Si^{31}$ has the threshold energy of 0.9 MeV and the resultant Si^{31} decays by emitting a beta ray with the maximum energy of 1.5 MeV and has a half life of 159 min.⁴⁾. Accordingly, this reaction has proved to be a valuable "threshold detector" for the measurement of continuous neutron spectrum, particularly, the fast neutron flux in a nuclear reactor⁵⁾.

The cross section of this reaction has been measured for neutron energies up to 3.6 MeV with good energy resolution⁶⁾, and the behavior of the cross section is primarily determined by the Coulomb barrier penetrability for the emitted proton in the energy region near the threshold⁷⁾. As the neutron energy gets higher, the existence of resonance structure has been shown. We tried in the present work to extend the cross section measurement to somewhat higher energy.

§ 2. Experimental Procedures and Results

The reaction $D(d, n)He^3$ was used as the neutron source. The change of energy of incident deuteron, as well as the variation of neutron energy with angle of emission, were used in order to get the neutrons of various energies. The deuteron beam, accelerated by

the Van de Graaff generator at Kyushu University, entered the target chamber of 4 cm in length through a nickel foil. The bombardments with deuterons of 1.93 MeV and 2.28 MeV were made with a nickel foil of 1.59 mg/cm² thick and deuterium gas of 43.5 cm Hg and those with deuterons of 1.70 MeV and 2.13 MeV were undertaken with a nickel foil of 1.09 mg/cm² thick and deuterium gas of 10.21 cm Hg. The energy loss and spread of deuteron beam in the nickel foil and deuterium gas was estimated by the data given by Allison and Warshaw⁸⁾ and Segre⁹⁾.

The samples of red phosphor were arranged in the directions of 0, 20, 40, 60 and 80 degrees relative to the deuteron beam and the distances between the center of target chamber and the centers of the surface of samples were 138 mm.

Each sample was made by pressing the red phosphor into a circular vessel of 35 mm diameter. The thickness of red phosphor was enough to get the saturation of self absorption for the beta-ray of Si^{31} , and the densities of induced activity were measured.

After the bombardment of about four hours by deuteron beam of a few microamperes, the activity induced in these samples by the neutrons were followed with a G.M. counter of thin mica window. The samples were placed closely against the window of the counter to give 2π counting geometry. For example, the decay curves for five samples obtained with deuteron of 2.28 MeV are shown in Fig. 1. In this figure, the straight lines A, B, C, D and E, with the half life of 159 min.⁴⁾, correspond to the activity of samples placed at 0, 20, 40, 60 and 80 degrees, respectively. As these lines are well fitted with our experimental data, all the counting rates of each sample were followed back to the

initial activity assuming the above value of half life, and the weighted mean of these values was obtained for each sample. The counting rate of initial activity divided by the neutron intensity incident on the sample was taken as the measure of the relative cross section of this reaction at the corresponding

Fig. 1. Decay curves of activity of Si^{31} induced by d - d neutrons, obtained with deuteron beam of 2.28 MeV. The lines A, B, C, D and E, with half life of 159 min., correspond to the activity of samples placed at 0, 20, 40, 60 and 80 degrees, respectively.

neutron energy. As the geometrical extent of target chamber and those of samples were rather large in our arrangement, the intensity of neutron impinging on each sample and its uncertainty were estimated by the following procedures. The target chamber of 4 cm in length was divided into four sections of 1 cm in length and each section was approximated by a point neutron source situated at their center. The neutron intensities incident on samples from these point sources were estimated, considering the deuteron energies at these points, angle of emission of neutron and the solid angles for each sample subtended by these point sources. The values of cross section for the d - d reaction as a function of deuteron energy and angle of emission of neutron was referred to the summary given by Fowler and Brolley¹⁰.

The uncertainties in neutron intensity are considerably large for the samples placed at the directions of 20 and 40 degrees, owing to the rapid change of the angular distribution

of d - d neutrons in these directions. Also, the energy spread of neutrons becomes larger with the increase of angle of emission and their spreads for the samples placed at 80 degrees were estimated to be 3.26 ± 0.17 MeV, 3.25 ± 0.23 MeV, 3.13 ± 0.22 MeV and 3.10 ± 0.20 MeV, corresponding to the four values of bombarding energy of deuterons. As these values are well overlapped, the average of the cross section was obtained for the average value of these neutron energies. This average value is normalized to the absolute value of the cross section obtained by Ricamo¹¹. The values of cross section for a certain energy of neutron, obtained with different deuteron energies but overlapped energy region of neutron, were also averaged. The result thus obtained is shown in Fig. 2. The values of

Fig. 2. Excitation curve of the reaction $\text{P}^{31}(n, p)\text{Si}^{31}$. Present result was normalized to the absolute cross section obtained by Ricamo at the neutron energy of 3.2 MeV.

the absolute cross section, shown in the ordinate, has an uncertainty of about 15 per cent, owing to the difference in the energy resolution between Ricamo's experiment and ours.

As can be seen in Fig. 2, a remarkable resonance of about 160 mb was found at neutron energy of 4.9 MeV. A small resonance at neutron energy of 3.7 MeV is probable but not certain. The dotted curve in Fig. 2, shows the theoretical excitation curve calculated by assuming the compound nucleus for-

mation with the value of $R=(1.4 \times A^{1/3}) \times 10^{-13}$ cm for nuclear radius and the value of 0.9 MeV for the threshold energy of this reaction. The general behavior of the theoretical curve, in the region below the barrier height of 5.4 MeV, is determined by the penetrability of emitted proton against the Coulomb barrier. This theoretical curve is well fitted with the experimental points in the energy range below 3.0 MeV, but seems somewhat too large in the range above 3.0 MeV, as was suggested by Grimeland⁷⁾. But the value of 3.3 MeV, suggested by Grimeland for the barrier height of Si^{31} , will be too small. On the other hand, the theoretical curve was obtained with the assumption that the available energy of this reaction is small compared with the threshold energy and this assumption is not valid in our energy range. Accordingly, the excitation curve in these energy range will not be conclusive to estimate the barrier height. The excitation curve in the range above the barrier height, where the theoretical curve becomes nearly flat and the direct interaction will become important, will be desirable.

The author wishes to express his cordial thanks to Prof. I. Nonaka and all staff of the nuclear laboratory of Kyushu University. This work has been supported by the Scientific Research Expenditure of the Ministry of Education.

Note added in proof; After this paper was received by the Physical Society of Japan, measurements of the excitation curve of the reaction $P^{31}(n, p)Si^{31}$ in the more extended range of neutron energies than our's were reported by J. A. Grundl et al in Phys. Rev. 109 (1958) 425. Their results are consistent with the present one in general behavior, although the resonance peak in their result is not so remarkable as in our result. This may be due to the difference in the energy resolution of neutron.

Electronic Structure of Bismuth Type Crystals

By Shoichi MASE

Department of General Education, University of Nagoya

(Received December 17, 1957)

A study is made of calculating the electronic energy bands in bismuth type crystals by making use of the Bloch method (with the inclusion of spin-orbit interaction) for the purpose of clarifying the relation between the low temperature diamagnetic susceptibility and the energy bands. The peculiar feature of the de Haas-van Alphen effect in bismuth type crystals (the small effective mass tensor) is explained by our calculated energy bands but the ordinary main term of the Landau-Peierls susceptibility expected from the energy bands is considerably small compared with the experimental value. Then, unlike Jones theory, the most part of the extraordinary large constant susceptibility seems to be attributed to the non-diagonal term which is usually neglected.

§ 1. Introduction

As is well known, the electronic and magnetic properties of bismuth type crystals, particularly bismuth, are extremely anomalous and they have been studied by many workers. On the consideration of the magnetic property and others, Jones¹⁾ deduced that the energy surfaces of electrons are extremely oblong spheroids, the longest axis of which is parallel to the trigonal axis, and that of holes is oblate spheroid, the shortest axis of which is in trigonal axis. On the analysis of the de Haas-van Alphen effect of bismuth, Blackman²⁾ and Shoenberg³⁾ deduced that, besides Jones' ellipsoids, there are another three ellipsoids with 120° symmetry about the trigonal axis.

According to Shoenberg's study, the contribution to the susceptibility by the de Haas-van Alphen electrons in bismuth is less than 10% of the experimental value, the detail of which is shown in Table I. One object in the present paper is to study whether the

90% of the experimental value minus the ion core part is contributed by other ellipsoids which do not show periodic phenomena as appreciable.

Morita⁴⁾ investigated the electronic structure of bismuth crystal with use of the tight binding approximation and tried to explain Jones' and Shoenberg's results. We extend his theory with the inclusion of the spin-orbit interaction in an approximate manner.

§ 2. The Symmetry Properties of Energy Bands

Bismuth type crystal has the space group symmetry $D_{3d}^5 - R\bar{3}m$ but the crystal structure is very similar to that of simple cubic lattice. The crystal is composed of sublattices A and B. We take here the binary and trigonal axis as x - and z -axis respectively, then the

observed anisotropic small effective mass tensor in the de Haas-van Alphen effect is reasonably explained from the view point of the energy bands. The other object is to investigate whether or not the susceptibility of about

Fig. 1. The lattice structure of bismuth type crystal.

atom configuration projected to the perpendicular plane to z -axis becomes as shown in

$$a_0 = (0, 0, 0)u,$$

$$a_1 = \left(\frac{\sqrt{2}}{2}, -\frac{\sqrt{6}}{6}, \frac{2\sqrt{3}}{3}(1+3\omega) \right)u,$$

$$a_2 = \left(0, \sqrt{\frac{2}{3}}, \frac{2\sqrt{3}}{3}(1+3\omega) \right)u,$$

$$a_3 = \left(-\frac{\sqrt{2}}{2}, -\frac{\sqrt{6}}{6}, \frac{2\sqrt{3}}{3}(1+3\omega) \right)u,$$

$$a_p = (2, 0, 0)u,$$

In the case of bismuth ω , ε and u take the following values*,

$$\omega = 0.0173,$$

$$\varepsilon = 0.0548,$$

$$u = 3.24 \text{ \AA}.$$

u is approximately the nearest neighbour distance. The primitive translation vectors of the lattice are $\vec{a}_0a_1$, $\vec{a}_0a_2$ and $\vec{a}_0a_3$, hence the first Brillouin zone is such as indicated in Fig. 2.

Fig. 2. First Brillouin zone.

The effect of the crystal symmetry on the energy bands can be derived by well known Bouckaert, Smoluchowski and Wigner's method⁵⁾ or Elliot's method⁶⁾ in double group. The typical elements of symmetry operations which make the lattice invariant are as follows:

(i) E is the unit element,

Fig. 1. The positions of atoms in the figure are

$$b_1 = \left(0, -\sqrt{\frac{2}{3}}, \frac{\sqrt{3}}{3}(1+3\omega+3\varepsilon) \right)u,$$

$$b_2 = \left(\frac{\sqrt{2}}{2}, \frac{\sqrt{6}}{6}, \frac{\sqrt{3}}{3}(1+3\omega+3\varepsilon) \right)u,$$

$$b_3 = \left(-\frac{\sqrt{2}}{2}, \frac{\sqrt{6}}{6}, \frac{\sqrt{3}}{3}(1+3\omega+3\varepsilon) \right)u,$$

$$b_1' = \left(0, \sqrt{\frac{2}{3}}, -\frac{\sqrt{3}}{3}(1+3\omega-3\varepsilon) \right)u.$$

(ii) C_3^+ and C_3^- are $\pm 120^\circ$ rotation around the trigonal axis,

(iii) S_1 , S_2 and S_3 are the reflections in the planes through a_0a_2 , a_0a_3 , a_0a_1 and z -axis respectively,

(iv) J is the inversion at the origin followed by the non-primitive translation $\tau \equiv \vec{a}_0b_2$,

(v) JC_3^+ and JC_3^- ,

(vi) JS_1 , JS_2 and JS_3 .

By the operations (i), (ii) and (iii), the atoms A-site are transformed into A-site and by the operations (iv), (v) and (vi), the atom of A-site into B-site. The characters of irreducible representations of the double groups of wave number k are given in Table II. The plus and minus signs attached on some characters in (a) and (c) mean that the upper sign corresponds to the representation without dash sign and the lower sign corresponds to the other. Additional degeneracies due to time reversal symmetry are also shown in Table II. In Table III is shown the compatibility relations.

If we neglect ω and ε , Bragg reflections from hexagonal faces in Fig. 2 disappear and symmetry lines T and A extend to the point which is equivalent to Γ . In the real crystal, however, the energy band should split at the faces through the middle points A and C along T and A , and nearly full and nearly empty bands should be separated by small energy gap. Then we should expect electrons or holes with very small effective mass at A or C . From the crystal symmetry alone, A is the point with zero slope along T , Σ and M . C is the point with zero slope along A , Σ' and D . B is also the point with zero slope along three directions similar as the

point C . T is the line with zero slope (T_4, T_5) or finite slope ($^2T_6$) in directions perpendicular to the T . A and A' are points of zero slope in two directions perpendicular to the A and A' axis. M is the line of zero slope in two directions perpendicular to the line. W is not special symmetry point on M and then generally a point of finite slope along M . These considerations are useful to study some detail of the band structure in the following sections.

§ 3. Calculation of Energy Bands

Bismuth, antimony and arsenic atoms have five valency electrons and the upper most p states are halfly occupied by the electrons. In crystals, the atomic levels become broad and overlap. Since, however, the cohesive energy of bismuth metal is comparatively small, we may expect from Wigner's theory⁷⁾ of cohesion that the overlapping of p - and d -bands is presumably not so large. Then we neglect here the d state. As seen from Fig. 1, each half of six neighbouring atoms is slightly different in the atomic distances and this is taken into account to obtain the matrix elements. Here we take the two centre approximation and further for the two centre integrals take the following approximation:

$$\begin{aligned} & (pp\sigma)_{R+\Delta R}, (pp\pi)_{R+\Delta R}, (ss\sigma)_{R+\Delta R}, (sp\sigma)_{R+\Delta R} \\ & = (pp\sigma)_R, (pp\pi)_R, (ss\sigma)_R, (sp\sigma)_R \left(1 - r_i \frac{\Delta R}{R}\right), \end{aligned} \quad (3.1)$$

where $r_i = r_1, r_2, r_3, r_4$ for the first... and the fourth respectively. Neglecting the higher power than second of ε, ω to unity, matrix elements in the case without spin are given in Appendix A.

Now we consider the spin-orbit interaction. For arsenic, antimony and bismuth atoms, the spin-orbit coupling parameter λ for p^3 electron configuration are the order of 0.2 eV, 0.4 eV and 1.3 eV⁸⁾ respectively. If the values of these are not considerably reduced in metals, we should take account of the spin-orbit interaction Hamiltonian H_{so} in zeroth order approximation, not as small perturbation, because λ is the same order of magnitude as the nearest neighbour energy integrals for the electro static potential. H_{so} , however, may be very small in the middle of lattice points where wave functions particularly well overlap. Then even the nearest neighbour integral for H_{so} is certainly small compared

with the energy integral in the same atom, which is the order of λ , and the former should be also small compared with the nearest neighbour integrals for the electro static potential. Then it may be not so bad to neglect the migration of atomic wave functions into neighbouring atoms and approximate H_{so} as spherically symmetrical about each nucleus. In such a approximation the matrix element for H_{so} is independent of k . Because of the periodic potential term, however, the magnitude may be somewhat different from that is appeared in the theory of atomic spectra.

Noting that spin functions transform by the spinor representation, Bloch functions which belong to the irreducible representations are obtained by group theoretical method⁹⁾. The results are listed in Appendix B. α and β show two spin functions. The bar on the subscript means that the wave functions are constructed from atomic functions located at B-site. We can set up secular equations for each representation as shown in Appendix C.

Now we determine the values of parameters to obtain energy curves. Many knowledge are obtained from soft X-ray emission band but unfortunately no experiment is made for this type of lattice. Then we determine the parameters in rough manner. With use of approximately determined two centre integrals with reference to the existing calculations of energy bands for germanium and others and estimated value of $E_{xx}(0) - E_{ss}(0)$, we found that the overlapping of s and p bands is small. Therefore we neglect the s state in numerical calculation. We evaluate the energy eigenvalue with use of ε and ω for bismuth and several values of λ and with the assumption of the following values for the other parameters,

$$\begin{aligned} (pp\sigma) &= 1.1 \text{ eV}, \\ (pp\pi) &= -0.35 \text{ eV}, \\ r_1 &= 3, \quad r_2 = 6. \end{aligned} \quad (3.2)$$

The energy *versus* k curves are shown in Fig. 3. This figure was drawn by performing numerical calculation for only a few points on the secular equations in Appendix C. In the case of $\lambda > 0.7$ eV, the energy of A_4' becomes higher than that of $^2T_6'/a$ and the band structure becomes similar as that of good conductor. Then we deduce that λ is fairly small compared with that of atom in bismuth.

Along the line A , the energy extremum does not occur in the case of $\lambda=0$. With the inclusion of spin-orbit interaction, qualitative feature of energy curve will be unchanged.

Fig. 3. Energy versus k curve. The origin of the energy is arbitrary. (Units eV.).

Although the lattice constants are almost the same in bismuth, antimony and arsenic, the values of parameters in (3.2) will be generally different in three cases and the energy curves in three cases will be unable to obtain only by changing the value of λ . We can say, however, that the pocket of holes does not occur at A in antimony and arsenic, since the energies for A_4' and ${}^2\Gamma_6'$ are considerably reduced and raised respectively by diminishing the value of λ and on the other hand the values of C_3 , C_3' and ${}^2A_6$ are more insensitive on the value of λ , as far as λ is not so small. Apart from the kind of charge carriers, however, we should expect the points A and C for possible points where electrons or holes are located.

§ 4. The Shape of the Energy Surfaces of Electrons and Holes

We proceed to investigate finer details of the band structure and discuss the comparison

with experiments of susceptibility. Total susceptibility consists of the diamagnetic and paramagnetic susceptibility of conduction electrons and the contribution from ion core. The latter part is $-0.14 \times 10^{-6}/\text{gr}$ in bismuth¹⁰⁾ and this value is about 10% of total value. On the other hand the spin paramagnetic susceptibility of conduction electrons is very small compared with Landau susceptibility in bismuth. Then we may consider that about 90% of the experimental value of χ in bismuth is orbital diamagnetism (or sums of orbital diamagnetism and paramagnetism) of conduction electrons. In antimony and arsenic the percentage of the orbital part to total susceptibility becomes much smaller.

To calculate the energy surfaces in the neighbourhood of A and C , we expand the matrix elements as power series of $k-k_A$ or $k-k_C$ and solve the secular equations with keeping up to the second order of wave number. Further we retain only the leading term in expansion of ε and ω .

First we consider the energy surface at C . The energy surface connected with C_3 is given by

$$E_C(k) = E(C_3) + \frac{\hbar^2}{2m} (\alpha_{11}(C_3)k_x^2 + \alpha_{22}(C_3)k_y^2 + \alpha_{33}(C_3)k_z^2 + 2\alpha_{23}(C_3)k_yk_z). \quad (4.1)$$

The energy surface connected with C_3' is quite similar as that of C_3 . The expression of $\alpha_{ij}(C_3)$ is shown in Appendix D. The other two ellipsoids are obtained from (4.1) by $\pm 120^\circ$ rotation about the trigonal axis. We subsequently correspond these ellipsoids to the de Haas-van Alphen ellipsoids. The magnitude of all $\alpha_{ij}(C_3)$ or $|\alpha_{ij}(C_3')|$ are generally the same order. We note, however, the numerators of α_{22} , α_{33} and α_{23} are composed of the sum of terms with plus and minus signs of comparable order but α_{11} is composed of only terms with same sign.

Secondly we study the structure of the energy surface at A . In the neighbourhood of this point, the energy connected with the representation A_4' is given by

$$E_A(k) = E(A_4') + \frac{\hbar^2}{2m} (\alpha_{11}(A_4')k_x^2 + \alpha_{11}(A_4')k_y^2 + \alpha_{33}(A_4')k_z^2). \quad (4.2)$$

The energy surface connected with ${}^2A_6$ is quite similar as that of A_4' . The expression of $\alpha_{ij}(A)$ is shown in Appendix D. The

magnitude of $|\alpha_{33}(A)|$ is generally not so large, because $(pp\sigma)+2(pp\pi)$ in numerator is small positive quantity and the denominator is not so small. On the other hand the magnitude of $|\alpha_{11}(A)|$ is generally large if the energy gap between $^2A_6^8$ and A_4' is small.

Along the line M and D , the energy gap between occupied and unoccupied bands may be as small as at the points A and C . Since W and W' are not the points with zero slope, we must study in detail whether or not energy extremum occurs somewhere along the line. This is very tedious and here we do not pursue this problem. But we wish to point out that the energy surfaces at the points along these lines have not the same symmetry properties as those of the de Haas-van Alphen ellipsoids Shoenberg have found.

Now we compare theoretical values of α_{ij} with the experimental values evaluated from the de Haas-van Alphen effect. Table IV (a) is the experimental values for bismuth, antimony and arsenic and IV (b) is theoretical values of $\alpha_{ij}(C_3)$ and $\alpha_{ij}(A_4')$ with use of the values of parameters in (3.2) and the value $\lambda=0.6$ ev. The characteristic feature of the experimental results are that all α_{ij} is fairly larger than unity except α_{22} in bismuth and

any principal axis of ellipsoids is not in the direction of the trigonal axis but inclines by some degree ($\alpha_{23}\approx 0$). Then we can correspond the energy surface at C with the de Haas-van Alphen ellipsoids. The discrepancy between theoretical and experimental values of α_{22} , α_{33} and α_{23} can be attributed to improper cancelation in numerator of (D.2) but the discrepancy of α_{11} can not be interpreted in such manner. To explain the extremely large value of α_{11} in bismuth, we must suppose that the energy gap between C_3 and C_3' should be the order of one half or one third of the present calculation, in which the energy gap is 0.025 ev. On the other hand, if we assume that the energy gap in antimony is the order of 0.1~0.2 ev, then we can understand that the experimental values of all α_{ij} are the order of ten in antimony. The single energy surface pocket at A_4' is extremely oblong ellipsoid. In order to explain that the de Haas-van Alphen effect by the holes is not perceptible in bismuth, we must consider that the energy gap between $^2A_6$ and A_4' is larger than two times of 0.05 ev in present calculation and then $|\alpha_{11}(A_4')|$ is <70 . On the other hand two types of period are observed in arsenic¹¹⁾. We correspond one type of period

Table IV. Effective mass tensor coefficients. (a) experimental values, (b) theoretical values.

(a)					(b)				
	α_{11}	α_{22}	α_{33}	α_{23}		α_{11}	α_{22}	α_{33}	α_{23}
Bi	417	0.8	40	4.0	C_3	136	-3.0	112	-4.6
Sb	20	5.3	10	6.7	A_4'	-148	-148	-1.3	0
As	5.2	13	7.9	9.8					
	32	32	4.3	0					

(the longer period part) with the energy surface at $^2A_6^8$ in accordance with the shape of the energy surface derived from experiments.

According to Abeles and Meiboom's experiment of galvanomagnetic effect of bismuth¹²⁾, the number of conduction electrons per atom is the order of 1.6×10^{-6} at 80°K. This is almost equal as the value 1.5×10^{-6} per atom evaluated from the de Haas-van Alphen effect. This fact shows that the de Haas-van Alphen electrons themselves are majority carriers. Thus we suppose that electrons and holes are located at the points C and A respectively.

The present theory predicts that the electrons at C are depleted by alloying antimony in bismuth by the effect from large change of λ . This depletion should cause remarkable change in electronic phenomena as conductivity.

Since the contribution to the susceptibility $\chi_{\perp}$ from holes at A is very small compared with that of de Haas-van Alphen ellipsoids, the contribution to the ordinary main term of Landau-Peierls diamagnetism from all electrons and holes in bismuth is clearly smaller than two times of the contribution from the

de Haas-van Alphen electrons, i.e. 20% of experimental value of $\chi_{\perp}$. We can obtain similar conclusion of $\chi_{\parallel}$. Then we obtain at most 30% of the experimental value from ionic and Landau susceptibilities.

§ 5. Conclusion

To summarize, it is most plausible that three ellipsoids of electrons (or holes) at C are responsible for the de Haas-van Alphen effect. The shape of the energy surface we found here is in accord with Shoenberg's model. Extreme anisotropy of α_{ij} in bismuth can be understood as accidental approach of two energy bands at C , the energy gap of which is estimated to the order of 0.01 eV, and proper cancelation in numerator of α_{22} , α_{33} and α_{23} . The energy surface pocket of holes (or electrons) which is expected to occur at A is extremely oblong single ellipsoid and we expect longest period of the de Haas-van Alphen oscillation in the magnetic field parallel to the trigonal axis. Such oscillation is observed only in arsenic. If we supposed that $\alpha_{11}(A'_4)$

$= -50 \sim 70$ in bismuth and then $E(A_6^B) - E(A_4) \sim 0.1$ eV, the longest period by the holes is the same order with $\chi_{\parallel}$ component of Shoenberg's ellipsoids and these are both too short compared with $\chi_{\perp}$ component of Shoenberg's ellipsoids. The calculated value of $\alpha_{11}(A'_4)$ is fairly accord with but $|\alpha_{33}(A'_4)|$ is considerably small compared with the value derived from galvanomagnetic effect or cyclotron resonance¹³⁾ of bismuth. This inevitable discrepancy may be due to crude approximation in the present paper.

In the present paper one remarkable point to be noted is that total contribution to the ordinary Landau-Peierls susceptibility from possible ellipsoids of electrons and holes in bismuth may be less than 20% of the experimental value. Such a unexpected result in Landau-Peierls theory was also met in the theory of diamagnetic susceptibility of graphite¹⁴⁾. We suppose that the small energy gap at C in bismuth should be related to the particular importance of the non-diagonal term which was pointed out by Adams¹⁵⁾.

Appendix A. Matrix Elements in the Case without Spin

We take into account of only six nearest neighbours.

$$H_{ss} = E_{ss}(0),$$

$$H_{xx} = H_{yy} = H_{zz} = E_{xx}(0),$$

$$H_{ss} \exp i\mu = 2c\{(X+Y+Z) + ir_3\varepsilon(P+Q+R)\},$$

$$H_{xx} \exp i\mu = \{(a+b) - 2\omega(a-b)\}(X+Y) + 2bZ + 2ir_2\varepsilon bR + i\varepsilon\{(r_1+2)a + (r_2-2)b\}(P+Q),$$

$$H_{yy} \exp i\mu = \frac{1}{3}\{(a+5b) - 2\omega(a-b)\}(X+Y) + \frac{2}{3}\{(2a+b) - 4\omega(a-b)\}Z \\ + \frac{1}{3}i\varepsilon\{(r_1+2)a + (5r_2-2)b\}(P+Q) + \frac{2}{3}i\varepsilon\{2(r_1+2)a + (r_2-4)b\}R,$$

$$H_{zz} \exp i\mu = \frac{2}{3}\{(a+2b) + 4\omega(a-b)\}(X+Y+Z) - \frac{2}{3}i\varepsilon\{(4-r_1)a - 2(r_2+2)b\}(P+Q+R),$$

$$H_{xy} \exp i\mu = \frac{\sqrt{3}}{3}(1-2\omega)(a-b)(X-Y) + \frac{\sqrt{3}}{3}i\varepsilon\{(2+r_1)a - (r_2+2)b\}(P-Q),$$

$$H_{zx} \exp i\mu = \frac{\sqrt{6}}{3}(1+\omega)(a-b)(X-Y) - \frac{\sqrt{6}}{3}i\varepsilon\{(1-r_1)a + (r_2-1)b\}(P-Q),$$

$$H_{zy} \exp i\mu = \frac{\sqrt{2}}{3}(1+\omega)(a-b)(X+Y) - \frac{2\sqrt{2}}{3}(1+\omega)(a-b)Z - \frac{\sqrt{2}}{3}i\varepsilon\{(1-r_1)a + (r_2-1)b\}(P+Q) \\ + \frac{2\sqrt{2}}{3}i\varepsilon\{(1-r_1)a + (r_2-1)b\}R,$$

$$H_{sz} \exp i\mu = -\sqrt{2}i(1-\omega)d \cdot (P-Q) - \sqrt{2}\varepsilon(r_4+1)d \cdot (X-Y),$$

$$H_{sy} \exp i\mu = -\frac{\sqrt{6}}{3}i(1-\omega)d \cdot (P+Q) + \frac{2\sqrt{6}}{3}i(1-\omega)d \cdot R - \frac{\sqrt{6}}{3}\varepsilon(r_4+1)d \cdot (X+Y) \\ + \frac{2\sqrt{6}}{3}\varepsilon \cdot (r_4+1)d \cdot Z,$$

$$H_{ss} \exp i\mu = -\frac{2\sqrt{3}}{3} i(1+2\omega)d \cdot (P+Q+R) + \frac{2\sqrt{3}}{3} \varepsilon(2-r_4)d \cdot (X+Y+Z),$$

where

$$X = \cos(\xi + \eta + \zeta), \quad Y = \cos(-\xi + \eta + \zeta), \quad Z = \cos(-2\eta + \zeta),$$

Appendix C. Secular Equations

We give secular equations for some representations. The s state is neglected.

(i) $T(0, 0, \zeta)$: $\zeta = 0 \sim \pi/2$.

The secular equations are

$$\begin{vmatrix} E_{xx}(0) + \frac{\lambda}{2} - E(T_4 + T_6) & H_{x\bar{x}} \\ H_{x\bar{x}} & E_{xx}(0) + \frac{\lambda}{2} - E(T_4 + T_6) \end{vmatrix} = 0,$$

$$\begin{vmatrix} E_{xx}(0) - \frac{\lambda}{2} - E(^2T_6) & -\frac{\sqrt{2}}{2}\lambda & H_{x\bar{x}} & 0 \\ & E_{xx}(0) - E(^2T_6) & 0 & H_{\bar{x}\bar{x}} \\ \text{compl. conj.} & & E_{xx}(0) - \frac{\lambda}{2} - E(^2T_6) & -\frac{\sqrt{2}}{2}\lambda \\ & & & E_{xx}(0) - E(^2T_6) \end{vmatrix} = 0.$$

These equations split into two parts respectively at Γ and A , as known from Table III.

(ii) $A(0, 2\zeta, \zeta)$: $\zeta = 0 \sim \pi/6$,

$A(0, -\zeta, \zeta)$: $\zeta = 0 \sim \pi/3$,

$\Sigma\left(0, \eta, \frac{\pi}{2}\right)$: $\eta = 0 \sim \frac{\pi}{4} \left\{ 1 + \frac{\omega(2+3\omega)}{(1+3\omega)^2} \right\}$.

The secular equation is

$$\begin{vmatrix}
 E_{xx}(0)-E & H_{y\bar{y}} & -\frac{i}{2}\lambda & H_{y\bar{z}} & \frac{i}{2}\lambda & 0 \\
 & E_{xx}(0)-E & H_{yz} & -\frac{i}{2}\lambda & 0 & \frac{i}{2}\lambda \\
 & & E_{xx}(0)-E & H_{z\bar{z}} & \frac{\lambda}{2} & 0 \\
 \text{compl. conj.} & & & E_{xx}(0)-E & 0 & \frac{\lambda}{2} \\
 & & & & E_{xx}(0)-E & H_{x\bar{x}} \\
 & & & & & E_{xx}(0)-E
 \end{vmatrix} = 0.$$

This equation splits into two parts at B and C , as known from Table III.

$$\begin{aligned}
 \text{(iii)} \quad M\left(\xi, 0, \frac{\pi}{2}\right): \quad \xi=0 \sim \frac{\pi}{2} \left\{ 1 + \frac{\omega(2+3\omega)}{(1+3\omega)^2} \right\}, \\
 D\left(\xi, \frac{\pi}{3}, \frac{\pi}{6}\right).
 \end{aligned}$$

The secular equation is

$$\begin{vmatrix}
 E_{xx}(0)-E & iH_{xy}e^{i\mu} & iH_{zx}e^{i\mu} + \frac{\lambda}{2} & iH_{xx}e^{i\mu} & -\frac{i}{2}\lambda & 0 \\
 & E_{xx}(0)-E & 0 & -\frac{i}{2}\lambda & -iH_{yz}e^{i\mu} & -iH_{yz}e^{i\mu} - \frac{i}{2}\lambda \\
 & & E_{xx}(0)-E & 0 & -iH_{xy}e^{i\mu} + \frac{i}{2}\lambda & -iH_{zx}e^{i\mu} \\
 & & & E_{xx}(0)-E & iH_{xy}e^{i\mu} & iH_{zx}e^{i\mu} - \frac{1}{2}\lambda \\
 \text{compl. conj.} & & & & E_{xx}(0)-E & 0 \\
 & & & & & E_{xx}(0)-E
 \end{vmatrix} = 0.$$

Effects of Impurities on Nuclear Quadrupole Resonance in *p*-Dichlorobenzene

By Shoji KOJIMA, Shizuko OGAWA, Midori MINEMATSU
and Makoto TANAKA

Department of Physics, Tokyo University of Education, Otsuka, Tokyo

(Received December 27, 1957)

The resonance of Cl^{35} in α phase *p*-dichlorobenzene containing various impurities was studied. The used impurities were *p*-Br ϕ Cl, *p*-Br $_2\phi$, *p*-I $_2\phi$, *p*-OH ϕ Cl, *p*-CH $_3\phi$ Cl, *p*-NH $_2\phi$ Cl, *p*-NO $_2\phi$ Cl, *p*-NO $_2\phi$ CH $_3$ and *p*-(CH $_3$) $_2\phi$. The characteristic number which represents the number of resonant nuclei which is affected by an impurity molecule was measured. This characteristic number depends on the volume difference of the resonant and impurity molecules and independent on the difference in dipole moment. The results of the theoretical discussions supported the experiment.

The height, width, shape and the integrated intensity of the resonance line were also measured. The integrated intensity was almost constant in the range of small concentration of impurity and then decreased.

1. Introduction

Duchsene and Monfils¹⁾ and Dean²⁾ found in their experiments on *p*-dichlorobenzene that presence of impurities in the sample leads to a broadening of the quadrupole resonance line. Segel and Lutz³⁾ gave a brief report on the decrease in the line height as a result of presence of impurities. Recently Monfils and Grosjean⁴⁾ studied the decrease of the line height in detail. They indicated that the effectiveness of an impurity molecule in reducing the line height depends on both the difference in volume and the difference in electric dipole moment of the resonant and impurity molecules. Michel and Spence⁵⁾, however, found in their experiment on monochlorobenzene no evidence for the dependence on dipole moment. In the present work the effects of impurities have been studied with a larger number of impurities than those used by Monfils and Grosjean.

It was mentioned by Segel and Lutz that the integrated intensity of the line was independent on the impurity concentration³⁾. Michel and Spence, however, mentioned that the main effect of impurities on the resonance was to reduce its intensity without appreciable broadening⁵⁾. The height, the width and the integrated intensity of the line have been carefully measured in the present experiments.

2. Experimental Procedures

The resonance of Cl^{35} in α phase *p*-dichloro-

benzene containing the various impurities was studied. The frequency of the resonance was about 34.23 Mc.

The spectrometer used was a signal feed back oscillator which was described by Wang⁶⁾. The working level of oscillation was about 5.8 volt in all the experiments. The height of resonance line was observed with a video amplifier and an oscilloscope. In order to measure the width and the shape of the resonance line a set of a narrow band amplifier and recorder was used. In this case, adopting frequency modulation of small amplitude, the derivative curve of the resonance line was recorded. The width was determined from the recording as the difference of the frequen-

Fig. 1. Recording of the nuclear quadrupole resonance of Cl^{35} in *p*-Cl $_2\phi$ with impurities of *p*-Br ϕ Cl 0.1%. Kicks are frequency markers.

cies corresponding to the extreme points of the derivative curve. An example of recordings is reproduced in Fig. 1.

The samples were produced by melting the mixture of pure *p*-dichlorobenzene and impurities of known molar percent with the aid of a hot water bath. The produced samples in the hot water bath were let cool naturally and its temperature reached to room temperature during 24 hours.

3. The height of the Resonance Line

The studied samples were those containing the impurities of *p*-Br ϕ Cl, *p*-Br $_2\phi$, *p*-I $_2\phi$, *p*-OH ϕ Cl, *p*-CH $_3\phi$ Cl, *p*-NH $_2\phi$ Cl, *p*-NO $_2\phi$ Cl, *p*-NO $_2\phi$ CH $_3$ and *p*-(CH $_3$) $_2\phi$. The height of the resonance line decreased when the concentration of impurity was increased. Monfils and Grosjean deduced from a simple assumption a theoretical equation expressing the relation between the intensity and the concentration of impurity. If we apply their equation for the height of resonance, *A*, we obtain

$$A = A_0 \exp(-NC) \quad (1)$$

where *C* is the molar concentration of impurity and *N* is a characteristic number. This characteristic number represents the number of resonant nuclei per impurity molecule whose resonances have been so shifted that they can no longer contribute to the central portion of the line.

The observed height was plotted logarithmically against the concentration of impurity. The plots are reproduced in Figs. 2, 3 and 4, where the plotted height is normalized as the height on the pure sample is unity. For small impurity concentrations the experimental data fit to the straight lines which

Fig. 2. The height of the resonance line vs. impurities of *p*-Br ϕ Cl, *p*-Br $_2\phi$ and *p*-I $_2\phi$.

Fig. 3. The height of the resonance line vs. impurity concentration for the impurities of *p*-OH ϕ Cl, *p*-CH $_3\phi$ Cl and *p*-NO $_2\phi$ Cl.

Fig. 4. The height of the resonance line vs. impurity concentration for the impurities of *p*-(CH $_3$) $_2\phi$, *p*-NH $_2\phi$ Cl and *p*-NO $_2\phi$ CH $_3$.

Table I.

Impurity	<i>N</i>	<i>N'</i>	<i>N</i> (M. G)
<i>p</i> -Br ϕ Cl	105	100	87
<i>p</i> -Br $_2\phi$	190	200	164
<i>p</i> -Br ϕ I			330
<i>p</i> -I $_2\phi$	510		
<i>p</i> -OH ϕ Cl	100	60	135
<i>p</i> -NH $_2\phi$ Cl	160		435
<i>p</i> -NH $_3\phi$ Cl	230		204
<i>p</i> -(CH $_3$) $_2\phi$	380		
<i>p</i> -NO $_2\phi$ Cl	600	500	
<i>p</i> -NO $_2\phi$ CH $_3$	830		

* Monfils and Grosjean⁴⁾

are expressed by Eq. (1). From the slope of the straight line, the characteristic number *N* was determined. The values obtained are

listed in the second column of Table I. Those reported by Monfils and Grosjean are also listed in the fourth column of the table. It indicates close agreement between their results and the present results except for the case of impurity of $p\text{-NH}_2\phi\text{Cl}$. This sample, however, showed in the experiment an appreciable change with time. The present data were measured after one day from solidification. Measurements after a few weeks showed further decrease in height for the sample of impurity concentration of about 0.05, 0.1 and 0.2 percent and no appreciable change for the pure sample and those of large impurity concentrations. So that these measurements give a greater characteristic number than the mentioned above. We have used the data of the measurement on the fresh sample which was considered to be free from chemical change.

Figs. 2, 3 and 4 indicate that the plots deviate from the straight lines for large concentration. In these range of concentration it seems that the volumes influenced by an impurity molecule are overlapping. The critical concentration C_c , above which the overlapping begins, is estimated from the equation of

$$C_c \approx 1/N. \quad (2)$$

The critical concentrations obtained from the knick points of the curves and those calculated from Eq. (2) are listed in Table II.

Table II.

Impurity	C_c (percent)	$1/N \times 100$
$p\text{-Br}\phi\text{Cl}$	1.0~1.3	0.95
$p\text{-Br}_2\phi$	0.6~0.7	0.55
$p\text{-I}_2\phi$	0.2	0.20
$p\text{-OH}\phi\text{Cl}$	1.2	1.00
$p\text{-CH}_3\phi\text{Cl}$	0.6	0.43
$p\text{-(CH}_3)_2\phi$	>0.1	0.27
$p\text{-NH}_2\phi\text{Cl}$	1.0~1.3	0.63
$p\text{-NO}_2\phi\text{CH}_3$	0.2	0.17
$p\text{-NO}_2\phi\text{Cl}$	0.3	0.12

The agreement between them is satisfactory. This means that the linear relation in the logarithmic plot of the height holds until the height decreases to $1/e$ of the initial value, where e is the base of natural logarithm.

For the samples mixed with $p\text{-OH}\phi\text{Cl}$, $p\text{-CH}_3\phi\text{Cl}$, $p\text{-(CH}_3)_2\phi$ and $p\text{-NH}_2\phi\text{Cl}$ the decrease

of height stopped at the concentration of 1.5, 1.5, 0.1 and 1.5 percent respectively, which are shown by dotted lines in Figs. 3 and 4. They presumably arise from nonmixing of the impurity above those concentration. These data are omitted from the plots.

4. The Line Width

The line width, Γ , was measured for the samples containing impurities of $p\text{-OH}\phi\text{Cl}$, $p\text{-Br}\phi\text{Cl}$, $p\text{-Br}_2\phi$ and $p\text{-NO}_2\phi\text{Cl}$. On the contrary to the case of Michel and Spence the broadening of the line was always observed. The relative broadening defined by $(\Gamma - \Gamma_0)/\Gamma_0$, where Γ_0 is the width for the pure sample, was plotted against the impurity concentration C , as shown in Fig. 5. It indicates that the

Fig. 5. The broadening of the resonance line vs. impurity concentration for the impurities of $p\text{-Br}\phi\text{Cl}$, $p\text{-Br}_2\phi$, $p\text{-OH}\phi\text{Cl}$ and $p\text{-NO}_2\phi\text{Cl}$.

relative broadening is proportional to the concentration in the range of small concentration. This linear relation can be expressed

$$(\Gamma - \Gamma_0)/\Gamma_0 = N' C \quad (3)$$

where N' is again the characteristic number. The N' , however, is defined slightly differently from N . It means the number of resonant nuclei whose resonance has been shifted to produce observable broadening. The characteristic number N' was determined from the initial slope of the curve. The obtained results are listed in the third column of Table I. The characteristic numbers obtained from both methods, N and N' , are in close agreement.

When the concentration increased the plots of broadening deviate from the straight lines. The effective value of characteristic number, which is determined from the tangent of the

curve, decreased as the impurity concentration increased. The origin of decrease of N' is the same as the previous case.

5. The Integrated Intensity

The shape of the resonance line was determined by graphical integration of the recording. The obtained patterns of the resonance lines for the various concentration of impurities of $p\text{-Br}\phi\text{Cl}$ are reproduced in Fig. 6, where the

Fig. 6. The shape of resonance line (the left half is shown) for various concentration of $p\text{-Br}\phi\text{Cl}$ impurity.

Fig. 7. The integrated intensity *vs.* impurity concentration for the impurity of $p\text{-Br}\phi\text{Cl}$. $\circ$ obtained from the area of the resonance line. $\times$ obtained from the product of the height and the width.

all patterns are normalized as the intensity maximum is unity. It indicates that the patterns are similar to Gaussian curve. The integrated intensity, I , was obtained as the area

of pattern. The plots of the integrated intensity against the impurity concentration is reproduced in Fig. 7.

If the shape of the line is expressed by $A \exp(-2\nu^2/\Gamma^2)$, the area is obtained by $(\pi/2)^{1/2} A\Gamma$. The product $A\Gamma$ is also plotted in the Fig. 7. Both plots fit excellently.

The curve shown in Fig. 7 indicates that the integrated intensity is constant below the impurity concentration of 0.2 percent. For such small concentration Eqs. (1) and (3) give

$$A\Gamma = A_0\Gamma_0\{1 + (N - N')C\}. \quad (4)$$

The previous result that N' is equal to N leads to the constancy of the integrated intensity.

When the impurity concentration was increased above 0.2 percent, the integrated intensity decreased gradually. This is presumably arisen from that the tails of the resonance curve sink below the noise level.

6. Interpretation of Characteristic Number

Monfils and Grosjean connected the characteristic number N with difference in volume and difference in electric dipole moment. For the impurities of monoatomic substituents the difference in volume of the resonant and impurity molecules is calculated as the difference of the van der Waals volumes of corresponding atoms. For the impurities of radical substituents the volume is not so clearly defined as the previous case. The shape of the radical is determined by giving the spheres of van der Waals radii for each atoms, whose center is located at the known bond distance and the known bond angle. At first the volume of such shape of the radical is calculated (V_a). At room temperature, however, the radicals may rotate around its axis. The volume taking into account rotation around one axis is then calculated (V_b). Another definition of the volume is given by the circumscribed sphere of the above mentioned static shape of the radical (V_c). The differences in volumes of resonant and impurity molecules calculated on these three definitions are listed in Table III with the notation of ΔV_a , ΔV_b and ΔV_c , respectively.

The relation between the characteristic number N and the volume difference is shown in Fig. 8 for the impurities of monoatomic substituents and in Fig. 9 for the impurities of the radical substituents. In Fig. 9 the

Table III.

Impurity	<i>N</i>	ΔV_i (10^{-24} cm ³)	ΔV_b (10^{-24} cm ³)	ΔV_o (10^{-24} cm ³)	ΔV_{exp} (10^{-24} cm ³)
<i>p</i> -OH ϕ Cl	100	-8.89	4.75	-0.9	6.8
<i>p</i> -NH ₂ ϕ Cl	190	-4.23	5.87	11.7	13.0
<i>p</i> -CH ₃ ϕ Cl	220	0.31	7.00	14.4	15.0
<i>p</i> -(CH ₃) ₂ ϕ	380	0.62	14.00	28.8	26.8
<i>p</i> -NO ₂ ϕ Cl	600	1.02	23.03	41.0	40.7
<i>p</i> -NO ₂ ϕ CH ₃	830	1.33	30.0	55.4	56.2

Fig. 8. The characteristic number *vs.* the volume difference for the impurities of monoatomic substituents. $\times$ is the value measured by Monfils and Grosjean.

crosses denote the plot of *N* against ΔV_b and the full circles denote the plot of *N* against ΔV_o . Figs. 8 and 9 indicate that the characteristic number is proportional to the volume difference. The straight line in Fig. 8 is expressed by an equation:

$$N = k\Delta V, \quad (5)$$

where *k* is 14.5×10^{24} cm⁻³. This relation accords with the result of Monfils and Grosjean not only qualitatively, but also quantitatively.

If the definition of volume V_o is used, the straight line II in Fig. 9 is obtained. This straight line is just expressed by Eq. (5). On the other hand, if the definition V_b is used, the obtained straight line, which is shown by the line I in Fig. 9, has a larger slope than that expressed by the equation. Then the difference between them may attribute to the

Fig. 9. The characteristic number *vs.* the volume difference for the impurities of radical substituents. $\times$ based on the volume difference defined as ΔV_b , $\circ$ based on the volume difference defined as ΔV_o .

effect of the dipole moment of molecule. The difference between the observed characteristic number and the number calculated from the volume difference by using the Eq. (5), *ie*, $N - k\Delta V_b$, was plotted against the difference in dipole moment of the resonant and impurity molecules*. The plot is reproduced in Fig. 10. It shows no correlation between the characteristic number and the difference in dipole moment. In view of the present result the definition of the volume V_o seems to be adequate. And if this definition is used the

* The values of dipole moment used are almost the same as those used by Monfils and Grosjean. But for the *p*-OH ϕ Cl 2.27 Debye is used instead of 1.62 Debye.⁷⁾

Fig. 10. The characteristic number *vs.* the difference in dipole moment. The plotted characteristic number is subtracted the number corresponding to the volume difference.

dependency of characteristic number on the volume difference is expressed by the same equation as the case of the monoatomic impurities.

7. Theoretical Estimations

a) Effect of the dipole moment

When a molecule possess a dipole moment P , the field gradient produced by it at a distance r is expressed by

$$q_{zz} = \frac{\partial}{\partial z} \frac{3(\mathbf{Pr})_z - rP_z}{r^5} = \alpha \frac{P}{r^4}, \quad (6)$$

where numerical factor α is $2 \sim 3$ in usual cases. Since the shift of resonance frequency due to the effect of dipole field, $\Delta\nu$, is equal to $eQq_{zz}/2h$, then we obtain

$$\Delta\nu \approx 6 \times 10^{19} P r^{-4} \quad (\text{c/s}) \quad (7)$$

Putting $P=1$ Debye and $\Delta\nu=400$ c/s, which is the half of width of the resonance line on pure sample, we obtain $r=6.4 \times 10^{-8}$ cm. The resonant nuclei in the sphere of this radius do not contribute to the central portion of the resonance line. Since the density of molecule is about $5.28 \times 10^{-21}/\text{cm}^3$, this sphere contains only six molecules. This number is very small with respect to the observed characteristic number N . If the dipole moment of a part of the molecule in place of the dipole moment of whole molecule were ac-

counted, the situation would not be altered. Therefore, the difference in dipole moment of the resonant and impurity molecules is not responsible for the characteristic number.

b) Effect of volume

An impurity molecule whose volume is different from that of surrounding molecules produces strain on the surrounding medium. For simplicity we assume that the impurity molecule is spherical and the radial displacement alone is produced. Then the nonvanishing strain tensors in polar coordinate are given by

$$e_{rr} = \frac{\partial u}{\partial r} \quad e_{\theta\theta} = e_{\varphi\varphi} = u/r, \quad (8)$$

where u is the radial displacement. Generally u is expressed by the form $ar + br^{-2}$. In the present case, however, a vanishes as the case of point imperfection. If the volume change ΔV is introduced on the surface of the spherical molecule whose radius is r_0 , then $(u)_{r_0} = \Delta V / 4\pi r_0^2$. From this condition b is determined. So that,

$$u = \Delta V / 4\pi r^2 \quad (9)$$

Since the dilatation $e_{rr} + e_{\theta\theta} + e_{\varphi\varphi}$ vanishes by Eqs. (8) and (9), the stress tensors are expressed by

$$\left. \begin{aligned} S_{rr} &= 2\mu e_{rr} = -\frac{4}{3}\mu \frac{\Delta V}{V} \\ S_{\theta\theta} &= 2\mu e_{\theta\theta} = \frac{2}{3}\mu \frac{\Delta V}{V} \\ S_{\varphi\varphi} &= 2\mu e_{\varphi\varphi} = \frac{2}{3}\mu \frac{\Delta V}{V} \end{aligned} \right\} \quad (10)$$

where μ is Lamé constant or the rigidity and $V = (4\pi/3)r^3$. These equations give the stresses on the surface of the sphere of volume V .

The relation between the frequency shift and the stress was measured by Kushida, Benedeck and Bloembergen on *p*-dichlorobenzene.⁸⁾ Their result is $\frac{\partial\nu}{\partial p} = 28$ c/s/kg/cm² at 24.8°C. This figure was obtained by applying simple hydrostatic pressure p . In the present case, however, radial compression and tangential tensions are applied. Therefore the shift may be different from the homogeneous deformation. Since such data are not available, we use tentatively above figure. The rigidity μ is estimated to be 2.7×10^4 kg/cm² from the volume compressibility used by Kushida *et al.* and Poisson ratio to be 0.3 as

usual substances have. Then the frequency shift of the resonant molecules which located on the surface of the sphere of volume V is

$$\Delta\nu = 28 \times \frac{4}{3} \mu \frac{\Delta V}{V} \quad (11)$$

For the impurity of *p*-dibromobenzene, ΔV is equal to $13 \times 10^{-24} \text{ cm}^3$. Then the Eq. (11) gives V of $3.3 \times 10^{-20} \text{ cm}^3$ in order to yield the shift of 400 c/s. The volume contains about 174 molecules. This figure fits to the observed characteristic number. The estimations above mentioned supports the experimental evidence that the effect of impurity is interpreted with the volume effect alone.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 13, No. 5, MAY, 1958

Origin of the Magnetic Anisotropy Energy of Antiferromagnetic Cr_2O_3

By Masashi TACHIKI and Takeo NAGAMIYA

Department of Physics, Osaka University, Osaka, Japan

(Received January 27, 1958)

The magnetic anisotropy constant Cr_2O_3 arising from the dipolar interactions among the chromic ions was calculated to be -0.059 cm^{-1} per ion at absolute zero, and the magnetic anisotropy constant due to the crystalline field combined with the spin-orbit coupling was estimated from the fine-structure coupling constant of ruby and compared with that deduced from the antiferromagnetic resonance experiment by Dayhoff. The value from ruby is too large. The temperature dependence of the anisotropy constant and that of the antiferromagnetic resonance frequency at zero field are discussed.

§ 1. Introduction

Since Honda and Soné¹⁾ first made measurements of the powder susceptibility of chromium sesquioxide, Cr_2O_3 , there appeared a number of experimental studies of the magnetic properties of this substance.²⁻⁵⁾ The neutron diffraction study by Brockhouse²⁾ has indicated that an antiferromagnetic arrangement of the spins of the chromic ions occurs below 308°K (Fig. 1). The spins align along the unique crystallographic axis according to the single crystal measurements of the magnetic susceptibility by McGuire *et al.*,³⁾ and recently this has been supported also by a neutron diffraction study.⁴⁾ Information about the

magnetic anisotropy energy can most conveniently be obtained from measurements of the antiferromagnetic resonance absorption, and Dayhoff,⁵⁾ carrying out such an experiment, determined the anisotropy energy as a function of temperature in the neighbourhood of the Néel point, 308°K.

The origin of the magnetic anisotropy energy in chromium sesquioxide may consist of three parts: the magnetic dipolar interactions among the chromic ions, the fine-structure coupling of the individual chromic ion, i.e., the spin-orbit interaction combined with the interaction between the orbital angular momentum and the crystalline electric field,

and the anisotropic exchange interactions. The purpose of this paper is to calculate the first of these three and to give some considerations on the other two.

§ 2. Anisotropy Energy arising from the Magnetic Dipolar Interactions among the Ions

Chromium sesquioxide has a corundum structure of rhombohedral symmetry. Chromic ions lie on the $[111]$ body diagonal of the rhombohedral unit cell, and the magnetic structure deduced from neutron diffraction measurements is as shown in Fig. 1. Since

Fig. 1. The rhombohedral unit cell of Cr_2O_3 after Brockhouse; only Cr ions with spins are indicated.

the crystal has a three-fold symmetry about the $[111]$ axis, the anisotropy energy arising from the dipolar interactions has uniaxial symmetry about the same axis. We calculated this anisotropy energy using the Fourier method developed Nagamiya *et al.*⁶⁾ Assuming an isotropic g -factor and using Eqs. (4.1), (4.3) and (4.5) of their paper, the following expression is obtained for this anisotropy energy:

$$E = \left[g^2 \mu_B^2 S^2 \frac{4\pi}{V} \sum_{hkl} \{1 + (-1)^{h+k+l}\}^2 \times \{\sin 2\pi(h+k+l)u\}^2 \{3 \cos^2 \theta_{hkl} - 1\} \times \sigma^2_{hkl} \right] \cos^2 \theta, \quad (1)$$

where θ is the angle between the spin axis and the $[111]$ axis, V the volume of the rhombohedral unit cell, θ_{hkl} the polar angle of the reciprocal lattice vector (hkl) , σ_{hkl} means the form factor of the spherical charge distribution placed at each position of the

chromic ion (given by Eq. (6.4) of the paper quoted above) and u is the parameter indicating position of the chromic ions. As we could not find the observed value of u , we assumed $u=0.105$, referring to those for $\alpha\text{-Al}_2\text{O}_3$ and $\alpha\text{-Fe}_2\text{O}_3$ ($u=0.105$ for both). With the use of $g=1.97$ obtained from the paramagnetic resonance experiment,⁸⁾ the following numerical result is obtained:

$$E = -0.059 \cos^2 \theta \text{ cm}^{-1} \text{ per ion at absolute zero.} \quad (2)$$

It is interesting to compare this negative small value of the coefficient of $\cos^2 \theta$ with corresponding value, 1.15 cm^{-1} , of $\alpha\text{-Fe}_2\text{O}_3$.⁹⁾ The crystalline structure is the same for these two compounds but the spin superstructure is different. The trivalent metallic ions, which are located at the interstices of the approximately hexagonal close-packed lattice of the oxygen ions, form slightly uneven honey-comb nets. In $\alpha\text{-Fe}_2\text{O}_3$, spins on each honey-comb net plane point in the same direction, and alternate nets of opposite spins are piled up, so that a strong dipolar anisotropy energy favouring the magnetization direction in the plane of the nets is expected. On the other hand, each of the honey-comb nets in Cr_2O_3 consists of plus and minus spins, arranged in an antiferromagnetic way as shown in Fig. 2. The negative sign in Eq. (2) indicates a stronger coupling between

Fig. 2. Nearly hexagonal net planes of Cr ions in Cr_2O_3 .

neighbours in the same honey-comb net plane of Cr_2O_3 and it favours the spin direction along the body diagonal, [111]. This is consistent with the experimental results mentioned in section 1.

§ 3. Other Anisotropy Energies

Geusic¹⁰⁾, and Zaripov and Shamonin¹¹⁾ observed by paramagnetic resonance measurements in ruby (Al_2O_3 contaminated with Cr_2O_3) that the fine-structure coupling constant D of Cr^{3+} is -0.19 cm^{-1} , the negative sign having been known from the optical Zeeman effect¹²⁾. We might expect approximately the same fine-structure coupling constant for the Cr^{3+} ions in Cr_2O_3 . The corresponding anisotropy energy is $-0.29 \cos^2 \theta \text{ cm}^{-1}$ per ion at absolute zero ($DS(S-1/2) = -0.29 \text{ cm}^{-1}$, S being $3/2$) which is about five times as large as that arising from the dipolar interactions. However, we shall see in the next section that such a large anisotropy energy is incompatible with the results of the experiment of antiferromagnetic resonance absorption, which gives a value about one third of it.

The anisotropy constant arising from the anisotropic exchange interaction may have a magnitude of $K_{f-s} \cdot \Delta E_{ez} / \Delta E_{orv}$ if one denotes by K_{f-s} the fine-structure anisotropy constant (-0.29 cm^{-1} in case the above argument were valid), by ΔE_{ez} the change of energy when the spin of a chromic ion changes its component in the direction of the Weiss molecular field by one, and by ΔE_{orv} the separation between the ground and excited orbital levels in the crystalline field. ΔE_{ez} is $3kT_N/(S+1)$ in the approximation of molecular field ($T_N = 308^\circ \text{K}$, $S = 3/2$) and ΔE_{orv} is known to be of the order of 20000 cm^{-1} ¹²⁾ from the optical absorption spectrum of ruby, so that $K_{f-s} \cdot \Delta E_{ez} / \Delta E_{orv} \sim 10^{-2} \cdot K_{f-s}$, which is negligibly small compared with K_{f-s} . A closer analysis will show that this underestimates the anisotropy constant arising from the anisotropic exchange interaction by a factor of about 4, but it is still negligible compared with K_{f-s} .

§ 4. Discussion

Antiferromagnetic resonance studies by Dayhoff⁶⁾ show that the temperature dependence of the anisotropy energy, represented by $-K \cos^2 \theta$ in the temperature range of 18°

below the Néel point, is given through

$$K = 8300 (T_N - T)^{0.87 \pm 0.03} \text{ erg/cm}^3. \quad (3)$$

In order to compare this with the theoretical anisotropy constant based on the arguments in section 2 and 3, we first derive the theoretical temperature dependence of the dipolar and fine-structure anisotropy constants. Taking the approximation of the molecular field, they are expressed as

$$K_{dp} = -NC \langle S_z^2 \rangle / S^2, \quad C = -0.059 \text{ cm}^{-1}, \quad (4)$$

$$K_{f-s} = -ND \{ 3 \langle S_z^2 \rangle - S(S+1) \} / 2, \quad (5)$$

where S_z is the component of the spin angular momentum operator of each ion in the direction of the internal field and N the number of ions in one cubic centimeter. For (5), the spin Hamiltonian DS_z^2 has been assumed for each ion, z being the direction of [111]. The molecular field approximation gives the following expression:¹³⁾

$$\langle S_z^2 \rangle = S^2 B_s^2(z), \quad (6)$$

$$\frac{1}{2} \{ 3 \langle S_z^2 \rangle - S(S+1) \} = S(S+1) - \frac{3}{2} S B_s(z) \coth \frac{z}{2S}, \quad (7)$$

$$z = g \mu_B S H / kT, \quad (8)$$

where B_s is the Brillouin function and H the magnitude of the internal field. Further, there is a relation between z and T :

$$\frac{T}{T_N} = \frac{3S}{(S+1)} \cdot \frac{B_s(z)}{z}. \quad (9)$$

Expanding (6), (7) and (9) in powers of z in the vicinity of the Néel temperature, we obtain

$$\begin{aligned} \langle S_z^2 \rangle &= \frac{(S+1)^2}{9} z^2, \\ \frac{1}{2} \{ 3 \langle S_z^2 \rangle - S(S+1) \} &= \frac{1}{15} \frac{(S+1)}{S} \left(S - \frac{1}{2} \right) \left(S + \frac{3}{2} \right) z^2, \\ z^2 &= \frac{30 S^2}{(S+1)^2 + S^2} \frac{T_N - T}{T_N}. \end{aligned} \quad (10)$$

Inserting (10) into (4) and (5), and putting $S = 3/2$, we get

$$K_{dp} = 3.84 \times 10^3 (T_N - T) \text{ erg/cm}^3, \quad (11)$$

$$K_{f-s} = -2.65 \times ND (T - T_N) / T_N. \quad (12)$$

Both are proportional to $(T_N - T)$ and so that they cannot give the temperature dependence of (3). The deviation from 1 of the power of $(T_N - T)$ in expression (3) may probably

arise from changes in the lattice parameters in the neighbourhood of the Néel temperature. Greenwald¹⁴) observed by X-ray diffraction method that the c -axis (in hexagonal setting) elongates and the a -axis contracts as the crystal is cooled through the antiferromagnetic transition region. These changes would make the trigonal part of the crystalline field acting on Cr^{3+} decrease and hence would lower the value of D . If so, one would expect a milder dependence on temperature of the anisotropy constant. Also, the exchange coupling constants would be affected by these changes; if they are diminishing with lowering temperature, one would also expect a milder dependence.

If we replace (3) simply by $8300 (T_N - T)$ and combine it with (11), we obtain $K_{T-s} = 4.46 \times 10^3 (T_N - T) \text{ erg/cm}^3$. The corresponding value of D is -0.063 cm^{-1} per ion, which is about one third of that deduced from experiments on ruby. Considering a possible difference in the crystalline field in Cr_2O_3 and in ruby, this factor of $1/3$ may not be improbable. The corresponding critical magnetic field (H_c , the field at which the spin axis turns from the easy axis to the direction perpendicular to it when the field is applied along the easy axis) at absolute zero is calculated to be 136 kilo gauss. Dayhoff ex-

trapolated expression (3) to absolute zero and obtained 110 kilo gauss. With dipolar interactions only it would turn out to be 85 kilo gauss.

Fig. 3 shows the dependence on temperature of $2K/\chi_\perp$, which is the square of antiferromagnetic resonance frequency ω/γ in the absence of external magnetic field, for the case (A) where the anisotropy energy arises solely from the dipolar interaction and for the case (B) where it arises solely from the fine-structure coupling, using experimental values of $\chi_\perp$ given by McGuire *et al.*⁹⁾. The latter is also plotted in the same figure. To get an accurate estimate of the anisotropy constant due to the fine-structure coupling, extension of the measurements of antiferromagnetic resonance to lower temperature will be valuable.

Anisotropy of Hot Electrons in *n*-type Germanium

By Wataru SASAKI, Motoichi SHIBUYA and Kanji MIZUGUCHI

Electrotechnical Laboratory, Nagatacho, Tokyo

(Received February 8, 1958)

Electromotive force perpendicular to the current flowing in *n*-type germanium samples is observed. The deviation angle of electric field vector from current vector is a function of current orientation, temperature, and field strength, and in some cases exceeds 20°. This effect can be attributed to the anisotropy in electric conduction due to the ellipsoidal energy surfaces.

§ 1. Introduction

Electric conduction in cubic crystals is isotropic so long as Ohm's law is applicable. However, under high electric field, where Ohm's law fails, cubic crystals do not always conduct isotropically. If anisotropy occurs in conduction, and the current direction does not lie on any of the symmetry axes of the crystal, electric field vector deviates from current vector. This deviation produces electric field transverse to the current and could be detected by transverse electrodes attached to the crystal in the same way as the Hall effect.

This effect was considered theoretically by one of us, M. S., for semiconductors with spheroidal energy surfaces¹⁾. Preliminary experiment carried out by us²⁾ showed that this effect occurs in *n*- and *p*-type germanium, and that the deviation observed in *n*-type germanium agrees qualitatively with Shibuya's calculation.

In this paper details of the experiment on *n*-type germanium are described and the experiment is compared with the above-mentioned theory, and mechanisms are suggested to explain the quantitative disagreement between the theory and experiment.

§ 2. Experimental

n-type germanium samples with room-temperature resistivity of 6~15 ohm-cm were chosen from crystals prepared by M. Kikuchi of our Laboratory. Slices of about 3 mm thick were cut along (110) plane of the crystal lattice, and filaments with large current electrodes and transverse potential electrodes, as shown in Fig. 1, were prepared by a magnetostriction cutter. Filaments lying along various direction between $\langle 001 \rangle$ and $\langle 110 \rangle$ were prepared. The angle θ defining the fila-

ment direction is chosen as shown in Fig. 1.

Filaments were etched with CP 4 to minimize spurious effects caused by hole injection from surface imperfections under high electric field.

Fig. 1. Shape of specimen.

In order to avoid temperature rise in filaments under high electric field, measurements were carried with pulsed current. The apparatus arrangement is shown in Fig. 2. The voltage applied on the filament was measured through terminals A, the current through terminals B, and the transverse voltage through terminals C. These voltages were measured by measuring the pulse height on the cathode-ray tube of a synchroscope. Fig. 3 shows the wave form of these pulses on the synchroscope. For minimizing the temperature rise the duration time of the pulse must be chosen as small as possible, while too short pulse makes the estimation of the pulse height uncertain due to transient phenomena caused by the floating capacities of the pulse transformer. In many cases pulses of 0.3~0.5

Fig. 3. Wave form of voltage pulses.

microsecond duration and repetition rate of 50 pulses per second were used.

The pulse transformer was loaded with 1 k Ω resistor in order to obtain the best wave form. This impedance is rather low and the electric field in the filament is disturbed by insertion of this transformer when transverse electric field is produced. Thus, though the transverse voltage measured at terminals C is proportional to the transverse field without the transformer, the absolute amount of the field

should require a method of calibration. This was done as follows. When magnetic field is applied the electric field vector deviates from the current vector by an angle ε , the Hall angle, in the plane perpendicular to the magnetic field. Hall angle is given by

$$\varepsilon = \mu_R B$$

where μ_R is the Hall mobility, a function of temperature and the purity of the specimen, and B is the magnetic induction. When the transverse electrodes of our specimen are used as Hall electrodes and magnetic field is applied, the Hall field caused by magnetic field is disturbed by the insertion of the input transformer in the same way as the anisotropy field caused by the high electric field, and the measured transverse voltage at terminals C caused by magnetic induction B corresponds to the deviation of electric field vector from current vector by an angle ε , given by the above equation, when there is no such disturbance as is caused by insertion of pulse transformer. Thus the angle of deviation of electric field vector from current vector is estimated from the pulse voltage measured at terminals C. This estimation becomes underestimation when electric field is so high that the resistivity of the filament becomes higher than the low field resistivity; however, the effect is smaller than 10 per cent at the highest field.

The measurement was carried at temperatures of 290°K, 200°K and 90°K

§ 3. Results of Experiment

Fig. 4 shows the field dependence of the current density and the transverse voltage, observed at terminals C, of an n -type germa-

nium filament whose direction deviates by 30° from $\langle 001 \rangle$ axis, at 90°K . Three regions are seen in the current-density curve as has been pointed out by Ryder and Shockley³⁾⁻⁶⁾. In the first region Ohm's law is valid, in the second Ohm's law fails and the current is nearly proportional to the square root of electric field, and in the third current is almost constant.

Fig. 4. Electric field dependence of current density and transverse voltage for an *n*-type germanium filament with $\theta=30^\circ$. Broken line corresponds to spurious voltage due to probe asymmetry.

Spurious transverse voltage proportional to longitudinal electric field, caused by asymmetry in transverse probes, appears in the first region. Another component of transverse voltage, which differs from that in the first region in regard to its dependence on longitudinal field, appears in the second region. This component grows rapidly and attains its maximum value before the third region begins.

In order to estimate the transverse field due to anisotropy of hot electrons, the spurious component due to probe asymmetry, which is proportional to longitudinal field and is easily estimated from the low field data, is subtracted from the observed voltage. Thus the

tangent of the angle ϵ between current and electric field vectors due to anisotropy of hot electrons is calculated and is shown in Figs. 5 and 6.

In Fig. 5 $\tan \epsilon$ is plotted against longitudinal electric field for filament whose direction deviates 30° from $\langle 001 \rangle$ axis measured at three temperatures are shown. It is seen that the lower the temperature the lower is the field

Fig. 5. Electric field dependence of $\tan \epsilon$ for an *n*-type germanium specimen with $\theta=30^\circ$.

Fig. 6. Electric field dependence of $\tan \epsilon$ for specimens with various values of θ .

where the angle becomes observable, the lower the field E_a where the angle attains the maximum value, and the larger the maximum angle. It seems that these three curves tend asymptotically to a single curve for the field higher than E_a .

In Fig. 6 $\tan \varepsilon$ curves for various filaments

Fig. 7. Dependence of ε on θ .

with different direction of crystal axis measured at 90°K are shown. The direction of deviation of the electric field vector from the current vector is such that the electric field lies nearer to $\langle 111 \rangle$ axis in (110) plane than the current vector in every case. Fig. 7 shows the angle ε at longitudinal field of 750 v/cm as a function of θ . The sign of ε was taken positive for specimens with θ smaller than 50° .

The shapes of the curves in Fig. 6 are very similar to one another, and the curves do not seem to tend asymptotically to a single curve in the highest field, in contrast to the curves in Fig. 5.

§ 4. Discussions

The anisotropy of hot electrons in cubic semiconductors with spheroidal energy surfaces was calculated by Shibuya¹⁾. He considers the different contributions to the current shared by the electron groups from different energy valleys in k -space, caused by different temperature rise and hence the difference in mobility of the electrons in these groups at high electric fields. His calculation hence results in anisotropy angle which is constant over the electric field where current is proportional to the square root of electric field and is also independent of temperature. The angle of anisotropy thus obtained is shown in Fig. 6 by broken line, which is in good qualitative agreement with experiment.

This effect may be understood with a sim-

Fig. 8. Simplified spheroidal energy surface model for explaining high field anisotropy.

plified model in Fig. 8. Only two spheroids A and B are considered. An electric field E is applied in the direction nearer to the rotation axis of spheroid A. Electric current produced by electrons with prolate-spheroidal energy surfaces lies farther from the axis of rotation, and such current components as shown in Fig. 8 are produced. These components make an electric current vector parallel to electric field when Ohm's law holds. The magnitude of effective mass of an electron with prolate energy surfaces is a function of the direction of the electric field relative to the axis of rotation of the spheroid, and is the larger the smaller the angle between electric field and the rotation axis. When the electric field becomes larger, the temperature of electrons in valley B, with smaller effective mass, becomes higher than that of A, and this difference of electron temperatures makes the current shared by A group larger than that by B group at higher electric field. These situations are shown in Fig. 8. In *n*-type germanium eight spheroids lying on $\langle 111 \rangle$ axes make the situation more complicated.

The disagreement in quantitative respects including the field and temperature dependence of ε seems to suggest other mechanisms involved in this problem.

In Shibuya's calculation it is assumed that the number of electrons in a valley does not change from that at thermal equilibrium in spite of the difference between the temperatures of the electrons in different energy valleys. There must be a natural tendency, however, that the electrons in a valley at higher temperature are scattered to a valley at lower temperature, and the electron number in high temperature valleys become smaller than that

in low temperature valleys. This tendency will make the current carried by electrons in high temperature valley less and that in low temperature valleys more than the case calculated by Shibuya, thus the angle of deviation will become larger. This situation in a simplified model is also shown in Fig. 8. If it is taken into account that the frequency of intervalley scattering is dependent on the lattice and electron temperatures the field and temperature dependence of the angle of deviation will be realized.

The existence of maximum in ε versus field curve suggests that the difference in number of electrons in different valleys becomes smaller in field higher than E_a probably due to occurrence of very frequent intervalley transitions of electrons, which depends little on the thermally excited intervalley phonons as may be supposed from the asymptotic character of the curves in Fig. 5.

Quantitative calculation for explaining the phenomenon described above is being carried.

We wish to represent our thanks to M. Kikuchi for preparation of germanium single crystals, to Z. Ishii for X-ray determination of crystal axes of the specimen, and to G. M. Hatoyama for interests and discussions to this work.

Magnification Calibration of Electron Microscopes by Crystal Lattice Spacings

By Ryozi UYEDA,

Physical Institute, Nagoya University, Nagoya, Japan

Tatsunosuke MASUDA, Hiroshi TOCHIGI,

Akashi, Ltd., Naka 8th Bldg., Marunouchi, Tokyo, Japan

Kazuo ITO and Haruo YOTSUMOTO

Japan Electron Optics Lab. Co. Ltd., Kamirenjaku, Mitaka, Tokyo, Japan

(Received January 30, 1958)

By an electron microscope Brindley, Comer, Uyeda and Zussman (*Acta Cryst.* **11** (1958), 99) found fringes corresponding to superlattice of about 90 Å spacing in antigorite. We tried to use the fringes for magnification calibration of electron microscopes. In this paper the trial and new observations in the course of the trial are shortly described.

§ 1. Introduction

The magnification of electron microscopes is usually calibrated by replicas of optical gratings. Since, however, the smallest spacing of optical gratings is about one micron, calibration at magnification over 10,000 times is very difficult. Although for this purpose other methods are known¹⁾, they are not so convenient as using grating replicas. Therefore, gratings of smaller spacings are required. It is well known that Menter²⁾ observed direct images of crystal lattice of phthalocyanines. Since, however, the spacing of phthalocyanine is about 12 Å, it is too small for the magnification calibration. Recently, Brindley, Comer, Uyeda and Zussman³⁾ reported direct images of superlattice spacing of about 90 Å in an antigorite*, a lamellar variety of serpentinite. We tried to use this spacing for the magnification calibration. In this note, we report on our trial and give some interesting observations made in the course of the experiment.

§ 2. Magnification Calibration

We determined the superlattice spacing by the superposed specimen method of electron diffraction as follows: Thallium chloride (TlCl) was deposited on an antigorite specimen by vacuum evaporation and then electron diffraction patterns and electron micrographs of the superposed specimen were taken (Fig. 1). In the diffraction pattern (Fig. 1a) Debye-rings

of TlCl are appearing superposed on the diffraction pattern of an antigorite single crystal. Taking the spacing of TlCl ($a=3.834$ kx) as the standard⁴⁾, we determined the superlattice spacing to be 89.7 Å*. In the micrograph (Fig. 1b) fringes corresponding to the superlattice spacing are appearing and we used them for the magnification calibration. The fringes usually appeared undistorted and we found that they are adequate for our purpose. Since, however, the specimen of antigorite with the superlattice structure is rare, we must look for another appropriate specimen. We believe that the use of moiré patterns⁵⁾ is worthy of consideration.

§ 3. New Observations

In Figs. 2-7 some of the most interesting micrographs are reproduced. Fringes generally appeared with better contrast by under focussing. In Fig. 2 fringes are sharper than those in other pictures and a weak line is appearing between two strong ones. Fig. 3 gives an example of fringes with spacings one-half those in other figures. Broad and curved bands are observed where two crystal sheets are overlapping. They may be moiré pattern on overlapping sheets⁵⁾. In Fig. 4 a micrograph of a distorted crystal is reproduced. Dark bands are appearing along or between which we can observe stepped structures of the fringes. We thought at first that the dark bands are of the same origin as those

* Specimen from Manchuria, called *Yu Yen Stone* (U.S. National Museum, No. 94356).

* The x-ray value of the same specimen is not available.

of Fig. 3 and called them broadly "screw dislocations". Hashimoto⁶⁾ and Cowley⁷⁾, however, have advanced different interpretations. We recognized that the dark bands have moved during observation (Fig. 5). In some parts of Fig. 4, superlattice fringes split into two and the split distance sometimes amounted to one-half the superlattice spacing (Fig. 6).

It is also worth noting that a few edge dislocations were observed (Fig. 7). We must, however, be deliberate in *deciding whether or not apparent imperfections represent those actually in the crystal*.

(Received February 6, 1958)

Although the covalency character has been found even in the normal complexes by the analyses of the paramagnetic resonance spectra and optical absorption experiments recently performed, any reliable model for the electronic structures of complex ions has not yet been established. To clarify this problem, the electron distribution in a complex ion $[\text{Co}(\text{NH}_3)_6]^{3+}$ is determined by means of the Thomas-Fermi method. To avoid the difficulty of multi-centre problem, the smoothing approximation is adopted. The Thomas-Fermi equation is reexamined from the standpoint of the variation principle, in order to investigate the validity of this approximation. In this paper, by the use of a trial function of spherical symmetry, the charge distributions for the total, valence- and core-electrons are calculated. Among these charge distributions, the charge distribution for valence-electrons seems most reliable and to approximate well the real situation in the complex ion. All faults brought by the smoothing approximation are discussed. In Appendix, the treatment of a trial function including an angle-dependent term is discussed.

§ 1. Introduction

As is well known, the binding between constituents of a complex ion is fairly strong so that we can treat it as a structural unit just like a single "molecule". A typical one of such ions is the so-called octahedral complex XY_6 , in which the central metallic ion X is surrounded by a (nearly) regular octahedron composed of six "ligands" Y's. The electronic structure or the bond property of such a complex has been a long-pending problem for many physicists and chemists.

Since in complex salts the behaviour of electrons responsible for the magnetic properties is different from that of free metallic ions, a good deal of information on the electronic structure of these complexes has been

obtained from their magnetic properties, i.e. magnetic susceptibilities and paramagnetic resonance spectra. For instance, magnetic susceptibility of the ferricyanide ion $[\text{Fe}(\text{CN})_6]^{3-}$ is much smaller than that of the ferric ion in the simple salts. Pauling¹⁾ has explained this peculiar property by his famous model in which covalent bondings are assumed between σ orbitals of ligands and the d^2sp^3 hybridized orbitals of the Fe^{3+} ion, while Van Vleck has pointed out that the same result can be predicted assuming that extremely strong cubic electric field due to six CN ions acts on the Fe^{3+} ion. These models correspond to the two limiting cases of the charge distribution between the central atom and ligands: i.e. $[\text{Fe}^{3-}(\text{CN})_6]$ and $[\text{Fe}^{3+}(\text{CN})_6^-]$.

Van Vleck²⁾ has also shown that these two can be derived as special cases of the charge distribution if one uses the molecular orbital method. In the molecular orbital picture, the

* Present address: H. H. Wills Physics Laboratory, University of Bristol, Royal Fort, Bristol 8, England.

orbitals of the incomplete shell electrons may spread all over the complex ion.

The recent detailed analyses of the paramagnetic resonance and optical absorption experiments have shown that there exists the above-mentioned effect (conventionally called "covalency") even in the normal complexes which had been considered to be described by the ionic or crystalline field model.^{3,4)} From these standpoints, it seems appropriate to treat the electronic structure of complexes by the molecular orbital method. In fact, several attempts in the LCAO MO approximation have been made in order to analyze the experimental data. In most of these analyses, however, the basic approximation is the ionic model and the quantitative results are restricted at most to the semi-empirical determination of the degree of covalency. After all, at present we have no reliable model which can be a starting point of our further investigations.

In view of these circumstances, it is highly desirable to obtain accurate MO wave functions, e.g. LCAO SCF wave functions. But this requires first of all some knowledge of the charge distribution in these complex ions. For such a complex ion as treated here $[\text{Co}(\text{NH}_3)_6]^{3+}$, the ionic model $[\text{Co}^{3+}(\text{NH}_3)_6]$ will not be adequate as well as Pauling's covalent model $[\text{Co}^{3-}(\text{NH}_3)^+_6]$. The real situation may be between these two. In fact, recently Pauling⁶⁾ proposes "the neutrality principle" that the central atom should be regarded as neutral on an average. In MO treatments, one may start either with the $[\text{Co}^{3+}(\text{NH}_3)_6]$ or $[\text{Co}^{3-}(\text{NH}_3)^+_6]$ model if LCAO SCF calculations were carried out to the final stage, varying not only the coefficients of linear combination of atomic orbitals but also the orbital exponent of the central atomic orbital. The labour of finding the correct wave function is, however, greatly dependent on the Hartree field assumed at the beginning of the calculations, and it is thus necessary to have a reliable model for the charge distribution in advance.

We shall, therefore, adopt the Thomas-Fermi method to infer the charge distribution between the central atom and ligands. The main difficulty in applying this method to a polyatomic system arises from the lack of spherical symmetry. Fortunately, the geo-

metrical shape of an octahedral complex is of good symmetry, and March⁷⁾ has shown that in such molecules the smoothing or spherical approximation gives fairly good results, especially for the distribution of valence electrons. In the present paper, therefore, we shall try as the first step to find the radial charge distribution of valence electrons under this approximation.

Before presenting the results, the Thomas-Fermi equation will be reexamined from the standpoint of the variational principle, in order to investigate the validity of this approximation (§ 2). § 3 is devoted to the elucidation of the method. Numerical results obtained for $[\text{Co}(\text{NH}_3)_6]^{3+}$ using the smoothing approximation will be shown and discussed in § 4.

§ 2. The Thomas-Fermi Equation and the Variational Principle

The purpose of the present investigation is to obtain the charge distribution $e\rho(r)$ and the potential $V(r)$ in the octahedral molecular ion $[\text{Co}(\text{NH}_3)_6]^{3+}$ by means of the Thomas-Fermi (T.F.) method. It is, however, quite difficult to solve the TF equation directly in this case, for lack of spherical symmetry. In order to avoid this difficulty, March et al.⁶⁾ have considered the similar problem using the so-called smoothing approximation in which the potential due to nuclei is averaged over angles. It is not easy, however, to estimate the contribution from the angle-dependent terms of the TF potential neglected in this approximation.

We will, therefore, try to reduce the TF equation to an equivalent variational problem and to solve the latter. While usual derivation of the TF equation by the variational method is based on the principle of energy minimum,⁷⁾ we will show here that the TF equation can also be derived from the principle of "complementary energy" minimum.⁸⁾

Let us consider a molecular system consisting of several nuclei (charge Zie and position $\mathbf{R}_i$) and of N electrons. Using the conventional notations, the total energy of such a system in the statistical treatment is given by the expression:

$$E\left(\frac{1}{4\pi} \nabla^2 V_e, e\rho, T\right)$$

$$= \int d\tau \left\{ \frac{1}{8\pi} (\nabla V_e)^2 + \frac{1}{4\pi} \nabla V_e \cdot \nabla V_N \right\} + \int_T d\tau \kappa \rho^{5/3} \quad (1)$$

where

$$\kappa = (3h^2/10m)(3/8\pi)^{2/3},$$

V_e and V_N are electrostatic potentials due to the electrons and nuclei respectively and T is the region occupied by electrons. The first term on the right hand side of Eq. (1) represents the energy of repulsion between electrons, the second the interaction energy between electrons and nuclei, and the last term expresses the kinetic energy of N electrons.

As is readily seen, the well-known relation between the charge density $e\rho$ and the potential $V(=V_e+V_N)$

$$4\pi e\rho = \mu(V-V_0)^{3/2}, \quad \mu = 4\pi e(3e/5\kappa)^{3/2} \quad (2)$$

can be derived by minimizing the above expression (1) under the following subsidiary conditions

$$\nabla \cdot \frac{1}{4\pi} \nabla V_e = \begin{cases} e\rho & \text{in } T \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

and

$$\int_T e\rho d\tau = Ne, \quad (4)$$

where $-eV_0$ is the maximum energy of an electron in the complex ion. Applying the Friedrichs' or involutory transformation to (1), (3) and (4), one can prove that our problem is equivalent to the procedure of minimizing the complementary energy $-I$ expressed by the following function

$$-I(U, T') = \int d\tau \frac{1}{8\pi} (\nabla U - \nabla V_N)^2 + \int_{T'} d\tau \frac{1}{4\pi} \frac{2}{5} \mu U^{5/2} - NeU(\infty). \quad (5)$$

Here T' is the region where $U > 0$, and $U(\infty)$ stands for the value of U at infinity. No subsidiary condition is imposed on this function $U(\mathbf{r})$. Applying the variational principle to the function U , one can obtain the TF equation

$$\Delta U = \begin{cases} \mu U^{3/2} - 4\pi \sum_i Z_i e \delta(\mathbf{r} - \mathbf{R}_i) & \text{in } T' \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

and the conditions

$$U(\mathbf{r}) \sim U(\infty) + (\sum Z_i - N)e/r, \text{ as } r \rightarrow \infty$$

and

$$\frac{1}{4\pi} \int_{T'} d\tau \mu U^{3/2} = Ne.$$

Comparing (6) with (2) (3) (4), one can see that for the correct U and V ,

$$U = V - V_0, \quad U(\infty) = -V_0.$$

Equivalence between these two procedures to minimize (1) and (5) can be confirmed by proving the following inequalities

$$I(U, T') \leq E_0 < E\left(\frac{1}{4\pi} \nabla V_e, T\right), \quad (7)$$

where E_0 denotes the minimum value of the expression (1), i.e. the correct TF energy. The equalities in (7) hold only when the correct solutions of V_e and of U are substituted. We will therefore restrict our discussion to the verification of the inequalities (7).

If we express the function E in terms of $(1/4\pi)\nabla V_e$, then

$$E - I = \int d\tau \left\{ \frac{1}{8\pi} (\nabla V_e)^2 + \frac{1}{4\pi} \nabla V_e \cdot \nabla V_N \right. \\ + \int_T d\tau \frac{3}{5} \left(\frac{4\pi}{\mu} \right)^{2/3} \left(\nabla \cdot \frac{1}{4\pi} \nabla V_e \right)^{4/3} \\ + \int d\tau \frac{1}{8\pi} (\nabla U - \nabla V_N)^2 \\ \left. + \int_{T'} d\tau \frac{1}{4\pi} \frac{2}{5} \mu U^{5/2} - NeU(\infty) \right\}. \quad (8)$$

The sum of the first- and the third term on the right hand side can be transcribed as

$$\int d\tau \left\{ \frac{1}{8\pi} (\nabla V_e)^2 + \frac{1}{4\pi} \nabla V_e \cdot \nabla V_N \right\} \\ + \int d\tau \frac{1}{8\pi} (\nabla U - \nabla V_N)^2 \\ = \int d\tau \frac{1}{8\pi} (\nabla U - \nabla V_e - \nabla V_N)^2 \\ - \frac{1}{4\pi} \int_T d\tau U \Delta V_e + NeU(\infty). \quad (9)$$

Substituting this into (8), we get

$$E - I = \int d\tau \frac{1}{8\pi} (\nabla U - \nabla V_e - \nabla V_N)^2 \\ + \frac{\mu}{4\pi} \left[\int_{T'} d\tau \frac{2}{5} U^{5/2} + \int_T d\tau \frac{3}{5} \left(\frac{\Delta V_e}{\mu} \right)^{5/3} \right. \\ \left. - \int_T d\tau U \frac{\Delta V_e}{\mu} \right]. \quad (10)$$

Evidently the first term cannot be negative and vanishes only when $\nabla U = \nabla(V_e + V_N)$. The second term can be written as

$$\int_{T \times T'} d\tau \left[\frac{2}{5} U^{5/2} + \frac{3}{5} \left(\frac{\Delta V_e}{\mu} \right)^{5/3} - U \frac{\Delta V_e}{\mu} \right] \\ + \int_{T' - T \times T'} d\tau \frac{2}{5} U^{5/2} \\ + \int_{T - T \times T'} d\tau \frac{3}{5} \left(\frac{\Delta V_e}{\mu} \right)^{5/3} - \int_{T - T \times T'} d\tau U \frac{\Delta V_e}{\mu}, \quad (11)$$

where $T \times T'$ expresses the common region of T and T' . If we utilize the well-known inequality for $x, y > 0$

$$\frac{1}{p} x^p + \frac{1}{q} y^q - xy \geq 0, \quad \frac{1}{p} + \frac{1}{q} = 1,$$

where the equality holds only when $x^p = y^q$, then we can readily see that the first term on the right hand side of (11) is non-negative and becomes zero only when

$$\Delta V_e = \mu U^{3/2}. \quad (12)$$

Then second- and the third term are obviously non-negative. The last term also cannot be negative, since $-U \Delta V_e / \mu$ is positive in the region $T - T \times T'$. All these terms become zero when $T = T'$. Thus we ultimately get

$$E \left(\frac{1}{4\pi} \Delta V_e, T \right) \geq I(U, T'). \quad (13)$$

If we substitute the correct solution in V_e and U alternately, we obtain the inequalities of (7).

Let us denote the correct solution by V_e^0 and U^0 , then (10) becomes

$$E \left(\frac{1}{4\pi} \nabla V_e, T \right) - I(U, T') \\ = E \left(\frac{1}{4\pi} \nabla V_e, T \right) - I(U^0, T^0) \\ + E \left(\frac{1}{4\pi} \nabla V_e^0, T^0 \right) - I(U, T') \\ > \int d\tau \frac{1}{8\pi} (\nabla U - \nabla V_e^0 - \nabla V_N)^2 \\ + \int d\tau \frac{1}{8\pi} (\nabla U^0 - \nabla V_e - \nabla V_N)^2. \quad (14)$$

One can thus estimate the mean square errors of the approximate ∇V_e or ∇U by calculating the left hand side of this expression.

§ 3. Application of the Method to a Complex Ion

Now we will apply the above-mentioned variational principle to an octahedral complex ion $[\text{Co}(\text{NH}_3)_6]^{3+}$. The reasons why we choose this ion as the object of our study are

that it is a diamagnetic cation with the ligands of well-known character and that its high symmetry and the small distance between the metal ion and the ligands are considered to be favourable for the smoothing approximation adopted below.

As the first step, we try to minimize the expression (5) taking a spherical variation function:

$$U = U_0(r), \quad (15)$$

where r is the distance measured from the Co nucleus*. From the physical point of view, this is equivalent to the procedure to smooth out the positive charges of the nitrogen and hydrogen nuclei over the spherical surfaces of radii R_1 and R_2 respectively, where R_1 is the distance Co-N and R_2 that of Co-H (smoothing approximation).** Starting from (1), (3) and (4), March has made similar justification of the smoothing approximation.⁹⁾

Substituting (15) into (5) and taking the variation with respect to the radial function $U_0(r)$, one obtains the Euler equation

$$\frac{1}{r^2} \frac{d}{dr} \left(r^2 \frac{d}{dr} U_0(r) \right) \\ = \begin{cases} \mu \{U_0(r)\}^{3/2} & r < R_0 \\ 0 & r > R_0 \end{cases}, \quad (16)$$

together with the boundary conditions

- (a) $U_0^{(1)}(r) \rightarrow Ze/r$ as $r \rightarrow 0$,
(b) $U_0^{(1)}(R_1) = U_0^{(2)}(R_1)$,

* It is unfortunate, however, that the inequality (14) cannot be used directly to judge the accuracy of U_0 obtained in this way. When this U_0 is substituted for U in the expression (5), $I(U, T)$ becomes infinite, because U_0 does not show correct (singular) behavior near the position of the ligand nuclei. The infinity of $I(U, T)$, however, does not imply infinite error in V_e or the electronic charge distribution. In fact, the appearance of infinity may be avoided by adopting $U_0 - V_{N0} + V_N$ as U instead of U_0 , where V_{N0} is the spherical part of V_N , but then the evaluation of the integral

$$\frac{1}{4\pi} \cdot \frac{2}{5} \int_{T'} \mu U^{5/2} d\tau$$

will be rather difficult. At present we confine ourselves to such qualitative discussions as given below.

** R_1 is taken as 1.99 Å which is approximately equal to the sum of covalent radii of Co and N, while R_2 is taken as 2.55 Å assuming that the molecular constants of the ligand NH_3 are equal to those of a free NH_3 molecule.

$$\begin{aligned}
(c) \quad & U_0^{(2)}(R_2) = U_0^{(3)}(R_2), \\
(d) \quad & -\left(\frac{dU_0^{(1)}}{dr}\right)_{R_1} + \left(\frac{dU_0^{(2)}}{dr}\right)_{R_1} = -\frac{N_1 e}{R_1^2}, \quad (17) \\
(e) \quad & -\left(\frac{dU_0^{(2)}}{dr}\right)_{R_2} + \left(\frac{dU_0^{(3)}}{dr}\right)_{R_2} = -\frac{N_2 e}{R_2^2}, \\
(f) \quad & U_0^{(3)}(R_0) = 0, \\
(g) \quad & \frac{1}{4\pi} \int_{\tau'} d\tau \mu U^{3/2} = N_2 e,
\end{aligned}$$

where Ze is the charge of Co nucleus, $N_1 e$ and $N_2 e$ are the nuclear charges of nitrogen and hydrogen respectively. R_0 represents the finite radius of the positive complex ion, exactly as in the case of atomic ions, and $U_0^{(1)}$, $U_0^{(2)}$ and $U_0^{(3)}$ represent U_0 for $r \leq R_1$, $R_1 \leq r \leq R_2$ and $R_2 \leq r$ respectively. If we set

$$U_0 = \frac{Ze}{r} \phi_0, \quad r = bx, \quad (18)$$

where

$$b = (3/32\pi^2)^{2/3} (\hbar^2/2me^2 Z^{1/3}),$$

then (16) is transformed into its usual dimensionless form

$$\frac{d^2 \phi_0}{dx^2} = \sqrt{\frac{\phi_0^3}{x}} \quad (19)$$

and the boundary conditions (17) become correspondingly,

$$\begin{aligned}
(a) \quad & \phi_0^{(1)}(0) = 1, \\
(b) \quad & \phi_0^{(1)}(X_1) = \phi_0^{(2)}(X_1), \\
(c) \quad & \phi_0^{(2)}(X_2) = \phi_0^{(3)}(X_2), \\
(d) \quad & \left(\frac{d\phi_0^{(1)}}{dx}\right)_{x_1} - \left(\frac{d\phi_0^{(2)}}{dx}\right)_{x_1} = \frac{N_1}{X_1 Z}, \quad (20) \\
(e) \quad & \left(\frac{d\phi_0^{(2)}}{dx}\right)_{x_2} - \left(\frac{d\phi_0^{(3)}}{dx}\right)_{x_2} = \frac{N_2}{X_2 Z}, \\
(f) \quad & \phi_0^{(3)}(X_0) = 0, \\
(g) \quad & \frac{z}{Z} = -X_0 \left(\frac{d\phi_0^{(3)}}{dx}\right)_{x_0},
\end{aligned}$$

where z is number of excess positive charge 3 of this ion, $\phi_0^{(1)}$, $\phi_0^{(2)}$ and $\phi_0^{(3)}$ correspond to $U_0^{(1)}$, $U_0^{(2)}$ and $U_0^{(3)}$, and X_1 , X_2 and X_0 are R_1 , R_2 and R_0 in dimensionless unit. As is well-known, the condition (20g) is easily derived from (17g), using the equation (16) and the other conditions (a) ~ (f).

According to March, the smoothing approximation seems to give fairly good results in certain cases. However, in order to take the actual arrangement of nuclei in complex ions into account, it will, of course, be more adequate to assume a trial function including the

angle-dependent terms, in addition to the term of spherical symmetry. For instance, if the cubic term of potential is added as the second step, the form of a trial function becomes

$$U(r) = U_0(r) + C(\theta, \varphi) U_4(r), \quad (21)$$

where

$$C(\theta, \varphi) = \sqrt{7/12} \{Y_4^0 + \sqrt{5/14} (Y_4^4 + Y_4^{-4})\}. \quad (22)$$

Substituting (21) into (5) and then taking variation for U_0 and U_4 , a set of differential equations for U_0 and U_4 are obtained together with their boundary conditions. The purpose of this paper is, however, to discuss the results of the smoothing approximation, which could also be used as initial solution to these equations. We shall, therefore, content ourselves only with the derivation of these equations (which will be given in Appendix), and now proceed to the discussion of the present results.

§ 4. Results and Discussion

We solved numerically the equation (19) under the boundary condition (20). Numerical integration was performed using the electronic digital computer FUJIC in the region $r \leq R_1$. Then, on account of the functional limitation of the computer, the solution had to be extended to the outer region $r \geq R_1$ by means of the desk machine as usual. In the course of integration it was found that the TF potential for the inner region $\phi_0^{(1)}$ was rather insensitive to the boundary condition (20g), while $\phi_0^{(2)}$ and $\phi_0^{(3)}$ depended on it.

The numerical values of the TF potential $\phi_0(r)$ thus obtained are given in Table I, and the curve of corresponding $U_0(r)$ vs r is given in Fig. 1. It may be noticed that the potential curve reveals a minimum in the region $r \leq R_1$ as if an attractive force for electrons from the sphere passing through the ligands (ligands' sphere) does exist in spite of the fact that in the spherical approximation the nuclear charges of the ligands are smeared out so that the potential due to these charges becomes constant inside the sphere. This is due to the formation of sphere of neutral charge in the region $r < R_1$, the radius of which is just given by the position of potential minimum $R_n = 1.33 \text{ \AA}$ ($X_n = 8.5$). Outside this sphere, electrons at r are repelled towards ligands by the excess negative charges lying between r and R_n . Thus this is the cause

Table I. The numerical values of the T. F. potential $\phi_0(x)$.

Fig. 1. The curve of the potential $U_0(r)$

The density of valence-electrons is determined by subtracting K -shell, L -shell, $3s$ - and $3p$ -electrons of Co and K -shell electrons of six N 's as core-electrons from the density of total electrons. This can be done, after Coulson and March,¹⁰⁾ by seeking the energy E_l below which 30 core-electrons lie;

$$2\int_{-\infty}^{E_l} N(E)dE=30, \tag{23}$$

where the level density $N(E)$ is given by the formula

$$N(E)=\frac{16\pi^2(2m^3)^{1/2}}{h^3}\int_{E+eV>0} (E+eV)^{1/2}r^2 dr. \tag{24}$$

After the value of E_l is obtained (in our present case $E_l=-0.99$ a.u.), the radial charge distribution of valence-electrons $D_{val}(r)$ can be calculated by the formula

$$D_{val}(r)=\frac{4r^3}{3\pi} [\{2(E_0+V)\}^{3/2}-\{2(E_l+V)\}^{3/2}], \tag{25}$$

of the apparent attraction from the ligands' sphere. It will be interesting to compare R_n with Pauling's covalent radius $R_c=1.22\text{\AA}$.

The calculated radial charge densities of total, valence- and core-electrons are given in Fig. 2, Fig. 3 and Fig. 4 respectively.

where $E_0=-eV_0$ is the maximum energy and is found to be -0.34 a.u.

The discrimination between valence- and core-electrons adopted here is made from the difference of their orbital energies. Hartree's orbital energies of electrons in a free Co^{2+}

Fig. 2. The calculated radial charge density of total electrons. The approximate numbers of total electrons distributed in each region $0 \leq r < R_n$, $R_n \leq r < R_1$, $R_1 \leq r < R_2$ and $R_2 \leq r$ are also given.

Fig. 3. The calculated radial charge density of valence-electrons. The approximate numbers of valence-electrons distributed in each region $0 \leq r < R_n$, $R_n \leq r < R_1$, $R_1 \leq r < R_2$ and $R_2 \leq r$ are also given.

Fig. 4. The calculated radial charge density of core-electrons. The approximate numbers of core-electrons distributed in each region $0 \leq r < R_n$, $R_n \leq r < R_1$, and $R_1 \leq r < R_2$ are also given.

ion¹¹⁾ and the ionization energies of 2s- and 2p-electrons in an NH₃ molecule¹²⁾ are given in Table II for reference. Even if the orbital energy of 3p-electrons is somewhat lifted when Co becomes neutral, it will be still lower than 2s orbital energy of an NH₃ molecule.

Table II. Hartree's orbital energies of Co²⁺ and ionization potentials of an NH₃ molecule.

Co ²⁺		NH ₃	
1s	7711.2 ev	2s	27 ev
2s	916.6		
2p	810.6	2p _π	16
3s	119.7	(bonding)	
3p	85.0	2p _σ	11
3d	28.8	(non-bonding)	

Before we discuss the calculated charge distribution, an attention must be paid to such fault of the spherical approximation that core-electrons of the ligands drastically move into the region ($0 \leq r \leq R_n$) when this approximation is adopted, as March has pointed out in his treatment of CCl₄ molecule. In fact this fault also appears in our case; when the distribution of 22 electrons is examined excluding 8 3s-, 3p-electrons out of 30 core-electrons, we find only two or three electrons in the region of the ligands. This should be 12 for correct charge distribution, so that 10 electrons out of 12 have been missed from the region of the ligands.

In spite of the above fact, the resultant number of our core-electrons (30 electrons) distributed in the region ($R_n \leq r \leq R_2$), which is 9 as Fig. 4 shows, seems rather near 12 which can be expected in the real situation. This will be interpreted as follows: As the result of the movement of some core-electrons of the ligands into the central region, most of the 3s- and 3p-core-electrons of Co are overflowed outwards so that the missing core-electrons of the ligands are almost made up for by these overflowed. This overflowing will be due to the repulsive force of the negatively charged sphere in the central region and to the exclusion principle operating there. In Fig. 4 we can also partly see these circumstances in the fact that the core-electrons in the ligands' region are too scattered to be the K-shell electrons of N's.

On the other hand, the distribution of

valence-electrons obtained in this way should be nearer to the truth than that of total electrons, since core-electrons play a role in shielding the nuclear charges of ligands as well as in allowing the exclusion principle to be operated so that the wrong tendency of the spherical approximation, i.e., the movement of electrons towards the central region, is suppressed for valence-electrons. This fact was also pointed out by Banyard and March¹³⁾.

Further considerations show, however, that for valence-electrons there is another possibility that their distribution obtained becomes too diffuse rather than contracted. As already mentioned, the spherical approximation makes the distribution of electrons, especially that of deeply lying core-electrons, too compact in the central region and as the result of this the central nuclear charges are over-screened by these electrons, so that we can expect rather diffuse distribution of the valence-electrons which are mainly populated in the relatively shallow parts of the potential energy. The previously explained phenomenon of "overflowing" may be considered as the similar effect, though in this case it is the 3s- and 3p-core-electrons which spread out, but not the valence-electrons. Further, the more enhanced tail of curve 2 than that of curve 1 in Fig. 4 of Banyard and March's paper might be interpreted to show such effect clearly.

Keeping all these possible deviations in the calculated distribution from the real one in our mind, we now return to the discussion of our result for the density of valence-electrons (Fig. 3). It shows that in the region $R_1 \leq r \leq R_2$ 35 electrons are distributed. This should be compared with 36 electrons which is expected when a pair of electrons is used in each N-H bond of an NH₃ molecule. Although our result shows that in the region $r \leq R_n$, 6 valence-electrons are distributed and that in the region $R_1 \geq r \geq R_n$ 12 valence-electrons are distributed, it will be premature to conclude from this that Co is trebly ionized and 12 electrons form lone pair electrons of 6 NH₃ molecules in [Co(NH₃)₆]³⁺ complex ion. This is because, apart from the problems of the accuracy in our result and from the meaning of R_n , the orbital of 3d-electron is so spread that we can not determine the

ionicity of Co by the number of the valence electrons distributed in such limited region as $r \leq R_n$.

Considering from the fact that 35 electrons are found in the region $r > R_1$ we may expect there is little possibility for valence-electrons to be too diffuse in the present case. This is reasonable, since, compared with CCl_4 molecule treated by March et al, our object is of higher symmetry and has smaller value of $(N_1 + N_2)/Z$, which seems to give certain measure for the validity of the smoothing approximation.

Thus being encouraged to believe that our results for valence-electrons approximate well the real situation despite the crude approximation adopted here, we hope our results, especially the distribution of valence-electrons and the potential for them, will serve as a good starting point for the future.

Acknowledgements

The authors would like to express their sincere thanks to Professor Masao Kotani for his much instructive advices and continual encouragement during the course of this work. They further wish to express their gratitudes to Mr. S. Tatsuoka of the Fuji Film Co. for his kindness to operate "Fujic" to provide the table of the T.F. solution. They are also indebted to the Ministry of Education and to the members of Kotani laboratory for their financial aids. Finally, they would like to thank Mrs. H. Komuro and Miss. S. Kosugi for their valuable assistance in the numerical work.

Appendix

We shall consider here the case in which the trial function (21) is assumed. As it is more convenient to work in terms of the usual T.F. dimensionless quantities, we express (21) in the following form

$$U = \frac{Ze}{r} \phi_0(r) + C(\theta, \varphi) \frac{Ze}{r} \phi_4(r) \quad (\text{A1})$$

and set $r = bx$. Then, substituting (A1) into (5) and minimizing $-I$ with respect to ϕ_0 and ϕ_4 , we obtain the following simultaneous differential equations for ϕ_0 and ϕ_4 in the region T'

$$\begin{cases} \frac{d^2 \phi_0}{dx^2} = \frac{1}{\sqrt{x}} \int \frac{1}{4\pi} (\phi_0 + C(\theta, \varphi) \phi_4)^{3/2} d\Omega \\ \frac{d^2 \phi_4}{dx^2} - \frac{20}{x^2} \phi_4 \end{cases} \quad (\text{A2})$$

$$= \frac{1}{\sqrt{x}} \int C(\theta, \varphi) (\phi_0 + C(\theta, \varphi) \phi_4)^{3/2} d\Omega, \quad (\text{A3})$$

and for ϕ_0 and ϕ_4 outside the region T'

$$\begin{cases} \frac{d^2 \phi_0}{dx^2} = 0 \end{cases} \quad (\text{A4})$$

$$\begin{cases} \frac{d^2 \phi_0}{dx^2} - \frac{20}{x^2} \phi_4 = 0, \end{cases} \quad (\text{A5})$$

where $d\Omega$ is the solid angle, together with the boundary conditions

$$(a) \begin{cases} \phi_0^{(1)}(0) = 1 \\ \phi_4 \sim x^5 \text{ for small } x \end{cases}$$

$$(b) \begin{cases} \phi_0^{(1)}(X_1) = \phi_0^{(2)}(X_1) \\ \phi_4^{(1)}(X_1) = \phi_4^{(2)}(X_1) \end{cases}$$

$$(c) \begin{cases} \phi_0^{(2)}(X_2) = \phi_0^{(3)}(X_2) \\ \phi_4^{(2)}(X_2) = \phi_4^{(3)}(X_2) \end{cases}$$

$$(d) \begin{cases} \left(\frac{d\phi_0^{(1)}}{dx} \right)_{x_1} - \left(\frac{d\phi_0^{(2)}}{dx} \right)_{x_1} = \frac{N_1}{X_1 Z} \\ \left(\frac{d\phi_4^{(1)}}{dx} \right)_{x_1} - \left(\frac{d\phi_4^{(2)}}{dx} \right)_{x_1} = \sqrt{21\pi} \frac{N_1}{X_1 Z} \end{cases} \quad (\text{A6})$$

$$(e) \begin{cases} \left(\frac{d\phi_0^{(2)}}{dx} \right)_{x_2} - \left(\frac{d\phi_0^{(3)}}{dx} \right)_{x_2} = \frac{N_2}{X_2 Z} \\ \left(\frac{d\phi_4^{(2)}}{dx} \right)_{x_2} - \left(\frac{d\phi_4^{(3)}}{dx} \right)_{x_2} = \sqrt{21\pi} \frac{N_2}{X_2 Z} P_4(\cos \alpha) \end{cases}$$

$$(f) \phi_0(X_b) + C(\theta, \varphi) \phi_4(X_b) = 0$$

$$(g) \int d\Omega X_b(\theta, \varphi) \left(\frac{d}{dx} (\phi_0^{(3)} + C(\theta, \varphi) \phi_4^{(3)}) \right)_{x_b(\theta, \varphi)} - 20 \int d\Omega C(\theta, \varphi) \int_{x_2}^{x_b(\theta, \varphi)} \frac{1}{x} \phi_4^{(3)}(x) dx = -4\pi \frac{Z}{Z}$$

where α is $\angle \text{H-Co-N}$.

As is seen in (f), in this case the finite radius of the positive complex ion R_b depends on angular variables θ, φ . The condition (g) is easily derived from the condition

$$\frac{1}{4\pi} \int_{T'} \Delta V d\tau = Ne$$

using the equations (A2), (A3) and the other boundary conditions (a) ~ (f).

Though equations (A2) and (A3) were not solved numerically in this paper, we will remark the numerical procedure here. As a first approximation we assume for ϕ_0 the solution calculated in the present paper. Then, with this ϕ_0 we solve (A3) to obtain ϕ_1 . With these ϕ_0 and ϕ_1 , we can obtain X_0 as a function of θ , φ from the condition (f) and then examine whether they satisfy the condition (g) or not. If they do not satisfy (g), we then solve (A2) with ϕ_1 obtained now. Thus such a procedure is repeated until the condition (g) becomes to be satisfied.

Macroscopic Foundation of Plasma Dynamics

By Taro KIHARA

Department of Physics, Faculty of Science, University of Tokyo

(Received February 6, 1958)

A fluid which comprises several species of charged and neutral particles is treated macroscopically. Basic equations, energy and momentum theorems, and law of similarity are discussed. The condition under which current equation reduces to the usual form is considered; and one-dimensional transverse waves are treated as an example. Quasi-stationary phenomena are examined as a particular case; and it is pointed out that one of the usual basic equations of hydromagnetics, the Ohm's law $\mathbf{J} = \sigma(\mathbf{E} + \mathbf{v} \times \mathbf{B})$, should be replaced by $\text{rot}(\mathbf{E} + \mathbf{v} \times \mathbf{B} - \sigma^{-1}\mathbf{J}) = 0$, $\mathbf{v}$ being the velocity of the mean mass flow. An axially symmetric solution is obtained and applied to a self-pinch column, whose stability is explained in an elementary manner.

§ 1. Introduction

Both for cosmic problems and for thermonuclear fusion, study of ionized fluid, plasma, is needed. Theoretically, the plasma can be and must be investigated from two points of view, i.e. macroscopic and microscopic. The present article is a treatment from the former point of view.

The macroscopic or phenomenological theory of plasma has not well been developed in comparison with the theory of electromagnetic

field or classical fluid dynamics. The electromagnetic field is treated on the basis of the Maxwell equations; fluid flow is treated on the basis of the Euler equation and the equation of continuity. These basic equations are "exact" and there is no alternative or arbitrariness. As regards plasma, on the other hand, choice of basic equations is not fixed. Spitzer¹⁾ treated fully ionized gases composed of only electrons and one type of positive ion. He neglected all the quadratic terms in fluid

velocity and current density. His equation of the plasma flow is, therefore, not the usual Euler equation but a linear approximation. Alfven²⁾ and Cowling³⁾ treated quasi-stationary neutral plasma. They simply assumed Ohm's law in a magnetic field, which does not hold in general. Their system of equations, therefore, cannot be regarded as a basis of the plasma dynamics, although it is effective for discussing cosmic problems.

The aim of the present article is to consolidate, in an elementary way, the foundation for the plasma dynamics and hydromagnetics.

The electromagnetic field in a plasma is determined by four vectors, electric field $\mathbf{E}$, magnetic flux density $\mathbf{B}$, electric displacement $\mathbf{D}$, and magnetic field $\mathbf{H}$, which satisfy the Maxwell equations

$$\text{rot } \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = 0, \quad (1.1)$$

$$\text{div } \mathbf{B} = 0, \quad (1.2)$$

$$\text{rot } \mathbf{H} - \frac{\partial \mathbf{D}}{\partial t} = \mathbf{J}, \quad (1.3)$$

$$\text{div } \mathbf{D} = \rho^* \quad (1.4)$$

where $\mathbf{J}$ and ρ^* are current and charge densities. From (1.3) and (1.4) we have the equation of continuity for the flow of electric charge

$$\text{div } \mathbf{J} + \frac{\partial \rho^*}{\partial t} = 0. \quad (1.5)$$

Between $\mathbf{E}$ and $\mathbf{D}$ on one hand, and $\mathbf{B}$ and $\mathbf{H}$ on the other we assume the usual linear relations

$$\mathbf{D} = \varepsilon \mathbf{E} \quad \text{and} \quad \mathbf{B} = \mu \mathbf{H} \quad (1.6)$$

with two constants ε and μ . In this article the MKS rational system of units is used throughout.

§ 2. Basic Equations

We consider a plasma which comprises several species of charged and neutral particles (electrons, ions, atoms) in which neither ionization nor recombination occurs. Let us denote by m_j , n_j and $\mathbf{v}_j$ the particle mass, the number density and the mean velocity of the j th species, respectively. Then the equation of continuity for the j th species is simply

$$\text{div} (m_j n_j \mathbf{v}_j) + \frac{\partial m_j n_j}{\partial t} = 0. \quad (2.1)$$

For each species we assume the Euler equation of motion

tion of motion

$$\frac{\partial}{\partial t} (m_j n_j \mathbf{v}_j) = e_j n_j (\mathbf{E} + \mathbf{v}_j \times \mathbf{B}) - m_j n_j \text{grad } \phi + \mathbf{R}_j - \text{Div} (\mathbf{P}_j + m_j n_j \mathbf{v}_j \mathbf{v}_j) \quad (2.2)$$

($\text{Div}_x \mathbf{P} \equiv \partial P_{xx} / \partial x + \partial P_{yx} / \partial y + \partial P_{zx} / \partial z$, etc.) Here e_j and $\mathbf{P}_j$ are, respectively, the particle electric charge and the partial-pressure tensor of j th species; $\mathbf{R}_j$ is the resistance acting on the j th species per unit volume; and ϕ is the gravitational potential. As regards $\mathbf{R}_j$ we consider only friction with other species, hence

$$\Sigma \mathbf{R}_j = 0 \quad (\Sigma \equiv \Sigma_j). \quad (2.3)$$

Electric charge and current densities are given by

$$\rho^* = \Sigma e_j n_j \quad \text{and} \quad \mathbf{J} = \Sigma e_j n_j \mathbf{v}_j. \quad (2.4)$$

Let us introduce the mass density ρ and the mass-flow velocity $\mathbf{v}$ by the relation

$$\rho = \Sigma m_j n_j \quad \text{and} \quad \rho \mathbf{v} = \Sigma m_j n_j \mathbf{v}_j. \quad (2.5)$$

Then, adding all equations (2.1) together, we have

$$\text{div} (\rho \mathbf{v}) + \frac{\partial \rho}{\partial t} = 0, \quad (2.6)$$

which is the equation of continuity of the mass-flow.

From (2.2) we obtain similarly

$$\frac{\partial}{\partial t} (\rho \mathbf{v}) = \rho^* \mathbf{E} + \mathbf{J} \times \mathbf{B} - \rho \text{grad } \phi - \text{Div} (\mathbf{P} + \rho \mathbf{v} \mathbf{v}), \quad (2.7)$$

which is the equation of motion for the plasma as a whole. Here $\mathbf{P}$ is the total-pressure tensor which has connection with the partial pressure tensors as

$$\mathbf{P} + \rho \mathbf{v} \mathbf{v} = \Sigma (\mathbf{P}_j + m_j n_j \mathbf{v}_j \mathbf{v}_j). \quad (2.8)$$

For gaseous plasma pressure tensors are given by

$$\mathbf{P}_j = m_j n_j \langle (\mathbf{c}_j - \mathbf{v}_j)(\mathbf{c}_j - \mathbf{v}_j) \rangle$$

and

$$\mathbf{P} = \Sigma m_j n_j \langle (\mathbf{c}_j - \mathbf{v})(\mathbf{c}_j - \mathbf{v}) \rangle,$$

where $\mathbf{c}_j$ is particle velocity and $\langle \rangle$ means the average according to the velocity distribution (hence $\mathbf{v}_j = \langle \mathbf{c}_j \rangle$). Equation (2.8) can be derived by use of these relations, both sides being equal to $\Sigma m_j n_j \langle \mathbf{c}_j \mathbf{c}_j \rangle$. The equations (2.6) and (2.7) can be expressed in alternative forms

$$\left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \text{grad} \right) \rho + \rho \text{div } \mathbf{v} = 0, \quad (2.6a)$$

$$\rho \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \text{grad} \right) \mathbf{v} \\ = \rho^* \mathbf{E} + \mathbf{J} \times \mathbf{B} - \rho \text{grad} \phi - \text{Div} \mathbf{P}, \quad (2.7a)$$

in which $\partial/\partial t + \mathbf{v} \cdot \text{grad}$ is the so-called substantial derivative.

Multiplying (2.2) by e_j/m_j and taking summation over the subscript j we obtain a differential equation for the current density:

$$\frac{\partial \mathbf{J}}{\partial t} = \sum \frac{e_j^2 n_j}{m_j} (\mathbf{E} + \mathbf{v}_j \times \mathbf{B}) - \rho^* \text{grad} \phi + \sum \frac{e_j}{m_j} \mathbf{R}_j \\ - \text{Div} \sum \frac{e_j}{m_j} (\mathbf{P}_j + m_j n_j \mathbf{v}_j \mathbf{v}_j). \quad (2.9)$$

This equation will be reduced to a simpler form in § 4.

§ 3. Energy and Momentum Theorems, Law of Similarity

From (2.2) we have

$$\sum \mathbf{v}_j \cdot \frac{\partial}{\partial t} (m_j n_j \mathbf{v}_j) = \mathbf{J} \cdot \mathbf{E} - \rho \mathbf{v} \cdot \text{grad} \phi + \sum \mathbf{v}_j \cdot \mathbf{R}_j \\ - \sum \mathbf{v}_j \cdot \text{Div} (\mathbf{P}_j + m_j n_j \mathbf{v}_j \mathbf{v}_j),$$

which can be transformed into

$$\frac{\partial}{\partial t} \left(\sum \frac{1}{2} m_j n_j \mathbf{v}_j^2 + \phi \rho \right) = \mathbf{J} \cdot \mathbf{E} + \sum \mathbf{v}_j \cdot \mathbf{R}_j \\ - \sum \mathbf{v}_j \cdot \text{Div} \mathbf{P}_j - \text{div} \left(\sum \frac{1}{2} m_j n_j \mathbf{v}_j^2 \mathbf{v}_j + \phi \rho \mathbf{v} \right),$$

the left-hand side being the time rate of increase of the kinetic and potential energies per unit volume. From this equation and the energy theorem for electromagnetic field,

$$\frac{\partial}{\partial t} \left(\frac{1}{2} \mathbf{E} \cdot \mathbf{D} + \frac{1}{2} \mathbf{H} \cdot \mathbf{B} \right) = -\mathbf{J} \cdot \mathbf{E} - \text{div} (\mathbf{E} \times \mathbf{H}),$$

we obtain the energy theorem for the system composed of plasma and electromagnetic field:

$$\frac{\partial}{\partial t} \left(\sum \frac{1}{2} m_j n_j \mathbf{v}_j^2 + \phi \rho + \frac{1}{2} \mathbf{E} \cdot \mathbf{D} + \frac{1}{2} \mathbf{H} \cdot \mathbf{B} \right) \\ = \sum \mathbf{v}_j \cdot \mathbf{R}_j - \sum \mathbf{v}_j \cdot \text{Div} \mathbf{P}_j \\ - \text{div} \left(\sum \frac{1}{2} m_j n_j \mathbf{v}_j^2 \mathbf{v}_j + \phi \rho \mathbf{v} + \mathbf{E} \times \mathbf{H} \right). \quad (3.1)$$

First and second terms on the right-hand side are work done by the friction and by the partial pressure, respectively. It is to be noted that an equation for the heat flow must be considered if necessary.

The momentum theorem for the electromagnetic field is given by

$$\frac{\partial}{\partial t} (\varepsilon \mu \mathbf{E} \times \mathbf{H}) = -(\rho^* \mathbf{E} + \mathbf{J} \times \mathbf{B}) + \text{Div} \mathbf{T},$$

where $\mathbf{T}$ is Maxwell's stress tensor. From this equation and the equation of motion (2.7) we obtain the momentum theorem for the system composed of plasma and electromagnetic field:

$$\frac{\partial}{\partial t} (\rho \mathbf{v} + \varepsilon \mu \mathbf{E} \times \mathbf{H}) \\ = -\rho \text{grad} \phi - \text{Div} (\mathbf{P} + \rho \mathbf{v} \mathbf{v} - \mathbf{T}). \quad (3.2)$$

All the equations given in the foregoing are invariant with respect to the transformation

$$(\mathbf{r}, t) \rightarrow s^{-1}(\mathbf{r}, t), \\ \varepsilon, \mu, \phi, m_j, e_j, \mathbf{v}_j \text{ unaltered,} \\ (\mathbf{E}, \mathbf{B}, \mathbf{D}, \mathbf{H}) \rightarrow s(\mathbf{E}, \mathbf{B}, \mathbf{D}, \mathbf{H}), \\ (\mathbf{J}, \rho^*, \rho, n_j, \mathbf{P}_j, \mathbf{T}) \rightarrow s^2(\mathbf{J}, \rho^*, \rho, n_j, \mathbf{P}_j, \mathbf{T}), \\ \mathbf{R}_j \rightarrow s^3 \mathbf{R}_j,$$

s being any positive number. This is a form of the similarity law.

§ 4. Two-Component and Quasi-Two-Component Systems

Among our basic equations (2.6), (2.7) and (2.9), the equation of electric current is most complicated. This equation, however, can be reduced to a simpler form in some cases by virtue of the fact that the mass of an electron is much smaller than those of other constituent particles.

We first consider the case where the plasma is a fully ionized gas composed of only electrons and one type of positive ion. Let the particle mass, particle charge and number density of electrons be m , $-e$ and n , respectively, and assume $en \gg |\rho^*|$. The mean velocities of positive ions and electrons are approximately equal to $\mathbf{v}$ and $\mathbf{v} - (en)^{-1} \mathbf{J}$ respectively. In the equation (2.9), $\sum e_j^2 n_j / m_j$ can be replaced by $e^2 n / m$, and $\sum e_j^2 n_j \mathbf{v}_j / m_j$ by $e(en\mathbf{v} - \mathbf{J})/m$. The gravitation can usually be neglected. Let us assume that the friction $\mathbf{R}$ is proportional to the relative velocity between electron-fluid and ion-fluid; namely $\sum e_j \mathbf{R}_j / m_j$ is assumed to be proportional to the current density $\mathbf{J}$. Finally, $\sum (e_j / m_j) (\mathbf{P}_j + m_j n_j \mathbf{v}_j \mathbf{v}_j)$ has the meaning $\sum e_j n_j \langle \mathbf{c}_j \mathbf{c}_j \rangle$ in molecular terms. When the particle velocity $\mathbf{c}$ of electrons is much larger than the mean velocities and the velocity distribution of electrons is nearly isotropic, this quantity is reduced to a scalar $-eP_e/m$, P_e being the partial pressure of electrons. Thus in the two-component system under the above-mentioned

conditions we obtain the usual approximation

$$\frac{m}{e} \frac{\partial \mathbf{J}}{\partial t} = en \left(\mathbf{E} + \mathbf{v} \times \mathbf{B} - \frac{1}{\sigma} \mathbf{J} \right) - \mathbf{J} \times \mathbf{B} + \text{grad } P_e \quad (4.1)$$

to the equation of current. Here σ indicates the electric conductivity.

The approximation (4.1) holds not only for the two-component system but also for more general systems under the condition that all species of heavier constituents (ions and neutral atoms) have nearly equal mean velocities, which are therefore close to $\mathbf{v}$. This type of plasma may be called quasi-two-component. This condition is satisfied when the magnetic field is not very strong. Let us make an investigation for a slightly ionized gas.

We consider a slightly ionized gas at rest, which is uniform, steady and neutral as a whole. The gas is supposed to contain, besides neutral atoms, electrons and one type of monovalent positive ion. Let their number densities be both n , which is much smaller than the number density of neutral atoms. Then equations (2.2) for electrons and ions are

$$\begin{aligned} K_e(\mathbf{E} + \mathbf{v}_e \times \mathbf{B}) - \mathbf{v}_e &= 0, \\ K_i(\mathbf{E} + \mathbf{v}_i \times \mathbf{B}) - \mathbf{v}_i &= 0, \end{aligned}$$

respectively. Here $\mathbf{v}_e$ and $\mathbf{v}_i$ are mean velocities of electrons and ions, $K_e \equiv -|K_e|$ and K_i are mobilities of electrons and ions, respectively. From these equations we obtain

$$\mathbf{v}_e = (1 + K_e^2 B^2)^{-1} [K_e \mathbf{E} + K_e^2 (\mathbf{E} \times \mathbf{B}) + K_e^3 (\mathbf{E} \cdot \mathbf{B}) \mathbf{B}]$$

and

$$|\mathbf{v}_e|^2 = K_e^2 [E^2 + K_e^2 (\mathbf{E} \cdot \mathbf{B})^2] / (1 + K_e^2 B^2)$$

with similar expressions for the ion. Since $|K_e| \sim 10^3 K_i$ and

$$\frac{|\mathbf{v}_i|}{|\mathbf{v}_e|} \lesssim \frac{K_i}{|K_e|} (1 + K_e^2 B^2)^{1/2}$$

our condition is satisfied when $|K_e B| \ll 10^3$.

Eqs. (2.6), (2.7), (4.1), and the Maxwell equations compose a system of basic equations for the usual plasma dynamics. The similarity law is that these equations are invariant with respect to the transformation

$$\begin{aligned} (\mathbf{r}, t) &\rightarrow s^{-1}(\mathbf{r}, t), \\ \varepsilon, \mu, \phi, m/e, \mathbf{v} &\text{ unaltered,} \\ (\mathbf{E}, \mathbf{B}, \mathbf{D}, \mathbf{H}, \sigma) &\rightarrow s(\mathbf{E}, \mathbf{B}, \mathbf{D}, \mathbf{H}, \sigma), \\ (\mathbf{J}, \rho^*, en, \rho, \mathbf{P}, P_e) &\rightarrow s^2(\mathbf{J}, \rho^*, en, \rho, \mathbf{P}, P_e) \end{aligned}$$

with any positive number s .

§ 5. Transverse Plane Wave

As an example transverse plane wave will be treated in brief. Let us confine ourselves to the case of a neutral gravitation-free plasma in which the partial pressure of electrons is constant ($\rho^* = 0$, $\text{grad } \phi = 0$, $\text{grad } P_e = 0$). Taking the z -axis in the direction of propagation we denote the x, y, z components of the vectors by

$$\begin{aligned} \mathbf{B} &= (b_x(z, t), b_y(z, t), B_0), \\ \mathbf{J} &= (J_x(z, t), J_y(z, t), 0), \\ \mathbf{v} &= (v_x(z, t), v_y(z, t), 0), \\ \mathbf{E} &= (E_x(z, t), E_y(z, t), 0). \end{aligned}$$

Here $B_0 \equiv (0, 0, B_0)$ is a constant magnetic flux; and all other components are assumed to be so small that any product of them is negligible.

Using such notations as

$$b_x + i b_y = \tilde{b}, \quad J_x + i J_y = \tilde{J}, \quad \text{etc.}, \quad (i^2 = -1),$$

we have from (1.1)

$$i \frac{\partial \tilde{E}}{\partial z} + \frac{\partial \tilde{b}}{\partial t} = 0$$

and from (1.3)

$$i \frac{\partial \tilde{b}}{\partial z} - \varepsilon \mu \frac{\partial \tilde{E}}{\partial t} = \mu \tilde{J}.$$

Eliminating $\tilde{b}$ we obtain

$$\frac{\partial^2 \tilde{E}}{\partial z^2} - \varepsilon \mu \frac{\partial^2 \tilde{E}}{\partial t^2} = \mu \frac{\partial \tilde{J}}{\partial t}. \quad (5.1)$$

From the equation of motion (2.7), which reduces to

$$\rho \frac{\partial \mathbf{v}}{\partial t} = \mathbf{J} \times \mathbf{B}_0 - \text{Div } \mathbf{P}$$

in the present case, we have

$$\rho \frac{\partial \tilde{v}}{\partial t} = -i B_0 \tilde{J} + \eta \frac{\partial^2 \tilde{v}}{\partial z^2}, \quad (5.2)$$

where use has been made of the relation

$$P_{zx} = -\eta \frac{\partial v_y}{\partial z}, \quad P_{zy} = -\eta \frac{\partial v_x}{\partial z}$$

η being the coefficient of viscosity effective for the present phenomenon. Finally, from the current equation, which reduces to

$$\frac{m}{e} \frac{\partial \mathbf{J}}{\partial t} = en(\mathbf{E} + \mathbf{v} \times \mathbf{B}_0 - \sigma^{-1} \mathbf{J}) - \mathbf{J} \times \mathbf{B}_0,$$

we have

$$\frac{m}{e} \frac{\partial \tilde{J}}{\partial t} = en(\tilde{E} - i B_0 \tilde{v} - \sigma^{-1} \tilde{J}) + i B_0 \tilde{J}. \quad (5.3)$$

In order to get a dispersion relation we investigate the case in which (z, t) -dependence is such as $\exp(-i\omega t + ikz)$, thus

$$\tilde{E} = E_0 \exp(-i\omega t + ikz), \quad \text{etc.}$$

Then we have from (5.1)

$$(-k^2 + \omega^2 \varepsilon \mu) E_0 = -i\omega \mu J_0,$$

from (5.2)

$$(\omega \rho + ik^2 \eta) v_0 = B_0 J_0,$$

and from (5.3)

$$\left(\omega \frac{m}{e} + B_0 + i \frac{en}{\sigma} \right) J_0 = ien E_0 + en B_0 v_0.$$

Eliminating E_0 , J_0 , and v_0 we finally obtain the dispersion relation

$$\left(\omega \frac{m}{e} + B_0 + i \frac{en}{\sigma} - \frac{en B_0^2}{\omega \rho + ik^2 \eta} \right) (\omega^2 \varepsilon \mu - k^2) = en \mu \omega. \quad (5.4)$$

In the particular case where damping due to the resistivity σ^{-1} and the viscosity η can be ignored, the equation becomes

$$\left(\omega \frac{m}{e} + B_0 - \frac{en}{\omega \rho} B_0^2 \right) (\omega^2 \varepsilon \mu - k^2) = en \mu \omega. \quad (5.5)$$

Fig. 1, which shows this relation, clearly explains the well-known fact that the wave motion can exist in two separate regions of ω indicating the electric wave and the hydro-magnetic wave.

Fig. 1.

§ 6. Quasi-Stationary and Quasi-Static Phenomena in a Neutral Plasma

Let us consider the case where a neutral plasma satisfies the following three conditions: the displacement current in (1.3) is negligible, i.e.

$$\mathbf{J} = \text{rot } \mathbf{H}, \quad (6.1)$$

the electron inertia term in (4.1) is negligible; and $\text{grad } n$ is parallel to $\text{grad } P_e$. Under these conditions we have from (4.1)

$$\text{rot} [\mathbf{E} + \mathbf{v} \times \mathbf{B} - (en)^{-1} \mathbf{J} \times \mathbf{B} - \sigma^{-1} \mathbf{J}] = 0. \quad (6.2)$$

Substituting this relation into (1.1), we obtain

$$\frac{\partial \mathbf{B}}{\partial t} = \text{rot} (\mathbf{v} \times \mathbf{B}) - \text{rot} \left(\frac{\mathbf{J}}{en} \times \mathbf{B} \right) - \text{rot} \frac{\mathbf{J}}{\sigma}$$

from which follows, by virtue of (6.1),

$$\begin{aligned} \frac{\partial \mathbf{B}}{\partial t} = & \text{rot} (\mathbf{v} \times \mathbf{B}) - \text{rot} \left(\frac{\mathbf{J}}{en} \times \mathbf{B} \right) \\ & - \frac{1}{\mu} \text{rot} \left(\frac{1}{\sigma} \text{rot } \mathbf{B} \right) \end{aligned} \quad (6.3)$$

In many cases of importance the second term on the right-hand side vanishes or can be ignored. In quasi-static case, for example, where $\partial(\rho v)/\partial t$, $\mathbf{v} \mathbf{v}$, $\text{rot} (n^{-1} \text{Div } \mathbf{P})$, and $\text{rot} (n^{-1} \rho \text{grad } \phi)$ are all small, we have an approximation to (2.7),

$$\text{rot} (n^{-1} \mathbf{J} \times \mathbf{B}) = 0. \quad (6.4)$$

Another example will be seen in the next section. When (6.4) holds true, Eqs. (6.2) and (6.3) reduce to

$$\text{rot} (\mathbf{E} + \mathbf{v} \times \mathbf{B} - \sigma^{-1} \mathbf{J}) = 0, \quad (6.5)$$

and

$$\frac{\partial \mathbf{B}}{\partial t} = \text{rot} (\mathbf{v} \times \mathbf{B}) + \frac{1}{\mu \sigma} \nabla^2 \mathbf{B} \quad (6.6)$$

($\nabla^2 \equiv \text{grad div} - \text{rot rot}$), where the conductivity σ has been supposed to be uniform.

Eq. (6.6) is the so-called induction equation in hydromagnetics. In usual hydromagnetics Ohm's law in a magnetic field, $\mathbf{J} = \sigma(\mathbf{E} + \mathbf{v} \times \mathbf{B})$ is assumed as one of the basic equations, from which the induction equation is derived. The present assumption is not the Ohm's law itself but instead Eq. (6.5). The simple Ohm's law does not hold true in general and most results in hydromagnetics can be obtained by use of (6.5) instead of the simple ohm's law.

Within a perfectly conducting plasma Eq. (6.6) is reduced to

$$\frac{\partial \mathbf{B}}{\partial t} = \text{rot} (\mathbf{v} \times \mathbf{B}),$$

which, as pointed out by Alfvén²⁾, shows that the lines of magnetic flux are "frozen in" the material.

§ 7. An Axially Symmetric Solution

We consider quasi-stationary neutral plasma with axial symmetry assuming that no gravitational force is acting. By use of cylindrical

coordinates r, φ, z with respect to the axis, all the quantities are supposed to be independent of φ and z and furthermore of the form

$$\begin{aligned}(B_r, B_\varphi, B_z) &= (0, B_\varphi(r, t), B_z(r, t)), \\ (J_r, J_\varphi, J_z) &= (0, J_\varphi(r, t), J_z(r, t)), \\ (v_r, v_\varphi, v_z) &= (v_r(r, t), v_\varphi(r, t), v_z(r, t)).\end{aligned}\quad (7.1)$$

The equation of continuity for the electric current, (1.5), is satisfied identically since $\rho^* = 0$. The equation of continuity for the mass-flow, (2.6), becomes

$$\frac{1}{r} \frac{\partial}{\partial r} (r \rho v_r) + \frac{\partial \rho}{\partial t} = 0. \quad (7.2)$$

Denoting unit vectors in the direction of (r, φ, z) by $(\mathbf{u}_r, \mathbf{u}_\varphi, \mathbf{u}_z)$ we have in general

$$\begin{aligned}\text{Div } \mathbf{P} &= \frac{1}{r} \frac{\partial}{\partial r} (r \mathbf{u}_r \cdot \mathbf{P}) \\ &+ \frac{1}{r} \frac{\partial}{\partial \varphi} (\mathbf{u}_\varphi \cdot \mathbf{P}) + \frac{\partial}{\partial z} (\mathbf{u}_z \cdot \mathbf{P}).\end{aligned}$$

Since

$$\mathbf{u}_r \cdot \mathbf{P} = P_{rr} \mathbf{u}_r + P_{r\varphi} \mathbf{u}_\varphi + P_{rz} \mathbf{u}_z, \quad \text{etc.}$$

and

$$\partial \mathbf{u}_\varphi / \partial \varphi = -\mathbf{u}_r, \quad \partial \mathbf{u}_r / \partial \varphi = \mathbf{u}_\varphi,$$

and furthermore since all components of $\mathbf{P}$ in the present coordinate system are independent of φ and z , we obtain

$$\begin{aligned}\text{Div } \mathbf{P} &= \mathbf{u}_r \left[\frac{1}{r} \frac{\partial}{\partial r} (r P_{rr}) - \frac{1}{r} P_{\varphi\varphi} \right] \\ &+ \mathbf{u}_\varphi \left[\frac{1}{r} \frac{\partial}{\partial r} (r P_{r\varphi}) + \frac{1}{r} P_{\varphi r} \right] \\ &+ \mathbf{u}_z \frac{1}{r} \frac{\partial}{\partial r} (r P_{rz})\end{aligned}$$

or

$$\begin{aligned}\text{Div } \mathbf{P} &= \mathbf{u}_r \left[\frac{\partial}{\partial r} P_{rr} + \frac{1}{r} (P_{rr} - P_{\varphi\varphi}) \right] \\ &+ \mathbf{u}_\varphi \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 P_{r\varphi}) \\ &+ \mathbf{u}_z \frac{1}{r} \frac{\partial}{\partial r} (r P_{rz}),\end{aligned}$$

where the symmetry relation $P_{r\varphi} = P_{\varphi r}$ has been used. Similarly,

$$\begin{aligned}\text{Div } (\rho \mathbf{v} \mathbf{v}) &= \mathbf{u}_r \left[\frac{1}{r} \frac{\partial}{\partial r} (r \rho v_r^2) - \frac{\rho}{r} v_\varphi^2 \right] \\ &+ \mathbf{u}_\varphi \left[\frac{1}{r} \frac{\partial}{\partial r} (r \rho v_r v_\varphi) + \frac{\rho}{r} v_r v_\varphi \right] \\ &+ \mathbf{u}_z \frac{1}{r} \frac{\partial}{\partial r} (r \rho v_r v_z).\end{aligned}$$

By use of these expressions the equation of motion (2.7),

$$\frac{\partial}{\partial t} (\rho \mathbf{v}) - \mathbf{J} \times \mathbf{B} + \text{Div } (\mathbf{P} + \rho \mathbf{v} \mathbf{v}) = 0$$

can be evaluated. The r -component is

$$\begin{aligned}\rho \left(\frac{\partial}{\partial t} + v_r \frac{\partial}{\partial r} \right) v_r - \frac{\rho}{r} v_\varphi^2 + \frac{\partial}{\partial r} \left(\frac{B^2}{2\mu} + P_{rr} \right) \\ + \frac{B_\varphi^2}{\mu r} + \frac{1}{r} (P_{rr} - P_{\varphi\varphi}) = 0,\end{aligned}\quad (7.3)$$

where the relation $\mu \mathbf{J} = \text{rot } \mathbf{B}$ has been used and $B^2 = B_\varphi^2 + B_z^2$. The φ - and z -components are

$$\rho \left(\frac{\partial}{\partial t} + v_r \frac{\partial}{\partial r} \right) v_\varphi + \frac{\rho}{r} v_r v_\varphi + \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 P_{r\varphi}) = 0 \quad (7.4)$$

and

$$\rho \left(\frac{\partial}{\partial t} + v_r \frac{\partial}{\partial r} \right) v_z + \frac{1}{r} \frac{\partial}{\partial r} (r P_{rz}) = 0 \quad (7.5)$$

respectively.

In these equations $\partial/\partial t + v_r \cdot \partial/\partial r$ is the substantial derivative, $\rho v_\varphi^2/r$ is the centrifugal force, $-\rho v_r v_\varphi/r$ is (a part of) the Coriolis force. Eq. (7.3) simply explains the well-known fact that magnetic flux has a hydrostatic pressure of the amount $B^2/2\mu$ plus a longitudinal tension B^2/μ . It can be shown that Eqs. (7.3) and (7.5) agree with the Navier-Stokes equation if a constant isotropic viscosity η is introduced by

$$P_{rr} = P + \frac{2}{3} \eta \text{div } \mathbf{v} - 2\eta \frac{\partial v_r}{\partial r},$$

$$P_{\varphi\varphi} = P + \frac{2}{3} \eta \text{div } \mathbf{v} - 2\eta \frac{v_r}{r},$$

$$P_{r\varphi} = -\eta r \frac{\partial}{\partial r} \left(\frac{v_\varphi}{r} \right), \quad P_{rz} = -\eta \frac{\partial v_z}{\partial r}.$$

In reality, however, the plasma viscosity is not necessarily isotropic in a magnetic field.

Eq. (6.4) is identically satisfied in the present case and (6.5) holds. Hence we have the induction equation (6.6) which becomes

$$\frac{\partial B_\varphi}{\partial t} = -\frac{\partial}{\partial r} (v_r B_\varphi) + \frac{\partial}{\partial r} \left(\frac{1}{\mu\sigma} \frac{1}{r} \frac{\partial}{\partial r} (r B_\varphi) \right), \quad (7.6)$$

$$\frac{\partial B_z}{\partial t} = -\frac{1}{r} \frac{\partial}{\partial r} (r v_r B_z) + \frac{1}{r} \frac{\partial}{\partial r} \left(\frac{r}{\mu\sigma} \frac{\partial B_z}{\partial r} \right). \quad (7.7)$$

Within a perfectly conducting plasma we obtain, from these equations and the equation of continuity (7.2),

$$\left(\frac{\partial}{\partial t} + v_r \frac{\partial}{\partial r}\right) \frac{B_\varphi}{r\rho} = 0 \quad (7.8)$$

and

$$\left(\frac{\partial}{\partial t} + v_r \frac{\partial}{\partial r}\right) \frac{B_z}{\rho} = 0. \quad (7.9)$$

Thus B_z and B_φ/r are proportional to the mass density at a substantial point of the fluid flowing with the velocity $\mathbf{v}$. The ratio B_φ/rB_z is invariant at any substantial point:

$$\left(\frac{\partial}{\partial t} + v_r \frac{\partial}{\partial r}\right) \frac{B_\varphi}{rB_z} = 0. \quad (7.10)$$

As an important example let us consider a fully ionized plasma column with both longitudinal and circular currents. We assume that no current is flowing outside the plasma and that magnetic field in region distant from the column is weak. When the longitudinal current is increased the plasma column is compressed or "pinched" by the newly increased magnetic flux circling the current. As the pinch advances the longitudinal flux B_z within the plasma becomes dominant in comparison with the circular flux B_φ , because B_φ/rB_z is invariant at any substantial point. When the increase of current occurs rapidly, newly added current flows near the surface and the distribution of the flux may become such as shown in Fig. 2. As a result a self-

Fig. 2.

pinched plasma can be represented by an idealized model with sheet current

$$\begin{aligned} \sigma &= \begin{cases} \infty & \text{for } 0 \leq r < a \\ 0 & \text{for } r > a, \end{cases} \\ (B_r, B_\varphi, B_z) &= \begin{cases} (0, 0, P_0) & \text{for } 0 \leq r < a \\ (0, E_1 a/r, 0) & \text{for } r > a, \end{cases} \quad (7.11) \end{aligned}$$

where $a(t)$ is the radius of the column, B_0 and

B_1 are functions of t only. We also assume the density to be uniform in the plasma.

Let us confine ourselves to the case where $v_\varphi = v_z = 0$ and the inertia term in (7.3), $\rho(\partial/\partial t + v_r \cdot \partial/\partial r)v_r$, can be neglected. Then the distribution of particle velocities in the plasma may be isotropic within a plane perpendicular to the z -axis:

$$P_{rr} = P_{\varphi\varphi} (= P_{zz} \text{ in general}) \quad (7.12)$$

(compare Watson⁴¹). Hence P_{rr} is uniform for $r < a$. Since sum of material and magnetic pressures must be equal on both sides of the column boundary in equilibrium, we obtain

$$P_{rr} + (2\mu)^{-1} B_0^2 = (2\mu)^{-1} B_1^2 \quad (7.13)$$

assuming $P=0$ outside the column. The total flux Φ frozen in the column is $\pi a^2 B_0$ which is constant; the total longitudinal current I is given by $\mu I = 2\pi a B_1$. Inserting these into (7.13) we have

$$P_{rr} + \frac{1}{2\mu} \left(\frac{\Phi}{\pi a^2} \right)^2 = \frac{\mu}{2} \left(\frac{I}{2\pi a} \right)^2. \quad (7.14)$$

When P_{rr} is proportional to ρ^γ or $a^{-2\gamma}$ with $\gamma < 2$, the magnetic-pressure term on the left-hand side becomes predominant as the pinch progresses; and hence the radius of a highly pinched column is inversely proportional to the total longitudinal current. The ratio P_{rr}/ρ which is proportional to $\rho^{\gamma-1}$ or $a^{-2(\gamma-1)}$, is a measure of the plasma temperature. The temperature of a highly pinched column is therefore proportional to $I^{2(\gamma-1)}$. For $\gamma=2$, it is easy to see that both the density and the temperature are proportional to I^2 .

§ 8. Stability of a Self-pinched Plasma

A column of very large current is compressed or "pinched" by the magnetic flux circling the current. But this pinched column is unstable: any small constriction and any small kink will grow⁵⁾⁻⁷⁾. A known idea to stabilize (to some extent at least) the pinched column is to create not only a pinching magnetic field around the plasma but also a strong longitudinal magnetic field within the plasma column. Although Shrafranov⁸⁾ has discussed the problem mathematically, an elementary explanation will be helpful. We consider a column of perfectly conducting neutral plasma which has radius a in equilibrium. The pressure outside the column is assumed to be zero. The sheet current model (7.11) with the condi-

tion (7.13) in equilibrium will be treated.

If the column suffers quasi-statically a gently-sloping small constriction and the radius becomes $a(1-\delta)$ at one part, then $\mathbf{B}$ will become at this part

$$\begin{aligned} (0, 0, B_0(1-\delta)^{-2}) & \quad \text{for } 0 \leq r < a(1-\delta), \\ (0, B_1 a/r, 0) & \quad \text{for } r > a(1-\delta). \end{aligned}$$

The sum of material and magnetic pressures in the column is $P_{rr} + B_0^2(1-\delta)^{-4}/2\mu$ or $P_{rr} + B_0^2(1+4\delta)/2\mu$ for small δ ; the magnetic pressure just outside the boundary is $B_1^2(1-\delta)^{-2}/2\mu$ or $B_1^2(1+2\delta)/2\mu$ for small δ . Hence the condition for stability against gently-sloping constrictions is $2B_0^2 > B_1^2$.

For sharply-sloping constrictions the magnetic flux in the plasma is denser near the boundary surface than near the axis; hence the stability condition is less severe. In conclusion, therefore, the column (7.11) is stable against constrictions if $2B_0^2 > B_1^2 (> B_0^2)$ and unstable otherwise. The result agrees with that of Shrafranov's analytical treatment.

Although sufficiently strong longitudinal magnetic flux stabilizes a plasma column against constrictions, it does not stabilize the column against gently-curving kink, as shown by Shrafranov. The situation can be explained in an elementary way. When the column suffers a gently-curving kink with radius of curvature R , then the force due to the longitudinal flux is $\pi a^2 B_0^2/\mu R$ per unit length, which acts in the direction of stabilization. It will be shown that this quantity is smaller than the destabilizing force due to the pinching magnetic flux when a/R is sufficiently small.

Supposing that a kinked column of radius a forms a circle of radius $R (\gg a)$, we choose a quantity δ such as $a \ll \delta R \ll R$. Then the force acting on the part δR of the circle is directed outward, and it can be calculated by use of Biot-Savart's law. Let the total longitudinal current be I , then the force is equal to (compare Fig. 3a)

$$\begin{aligned} & \frac{\mu I^2}{4\pi} \int_0^\delta \int_{\delta-\xi}^{2\pi-\xi} \frac{\sin(\theta/2)}{[2R \sin(\theta/2)]^2} R^2 d\theta d\xi \\ &= \frac{\mu I^2}{4\pi} \int_0^\delta \int_{\delta-\xi}^{2\pi-\xi} \frac{d\theta}{4 \sin(\theta/2)} d\xi \\ &= -\frac{\mu I^2}{4\pi} \int_0^\delta \ln \tan \frac{\xi}{4} d\xi \\ &= -\frac{\mu I^2}{4\pi} \int_0^\delta \ln \frac{\xi}{4} d\xi \end{aligned}$$

$$= \frac{\mu I^2}{4\pi} \delta \left(\ln \frac{4}{\delta} + 1 \right).$$

Since $\mu I = 2\pi a B_1$ the destabilizing force is

$$\pi a^2 B_1^2 \mu^{-1} \delta [\ln(4/\delta) + 1],$$

which is greater than the stabilizing force acting on this part $\pi a^2 B_0^2 \mu^{-1} \delta$, which is directed inward. Hence the present plasma is unstable against gently-curving kinks.

This kink instability of a plasma column with longitudinal electric current and magnetic flux can not be avoided by an external magnetic flux parallel to the axis. When the column kinks gently in such a way as shown in Fig. 3b, point A moves toward this side and

Fig. 3.

B that side. Hence the column becomes helix-like, and, at a point C, the Lorentz force acts toward outside. For a helix with long spatial period, this outward force predominates, resulting in an instability of the plasma column. (For a helix with constant A and $\tan \theta$,

$$x = A \cos \tau, \quad y = A \sin \tau, \quad z = A \tau \tan \theta,$$

the curvature is given by $\cos^2 \theta/A$; and the sine of the angle between z -axis and a tangent to the helix is $\cos \theta$. If a column of plasma kinks into this helix under the condition $a/A \ll 1 \ll \tan \theta$, then the stabilizing force due to the magnetic tension, which is proportional to $\cos^2 \theta/A$, is less effective than the unstabilizing Lorentz force which is proportional to $\cos \theta$.)

When the plasma is constricted in a tube with a conducting wall and the radius of the tube is sufficiently small compared with that of the plasma column, then the column is expected to be stable against any mode of deformation. The condition of stability was recently calculated by Tayler⁹⁾ and independently by the present author. For the sheet-current model (7.11) in a tube of radius b and for the displacement which is proportional to $\exp(ikz + im\varphi)$ with $k > 0$ and an integer m as regards z and φ dependencies, the column is stable if and only if B_0^2/B_1^2 is greater than the value given by

$$\frac{B_0^2}{B_1^2} = \frac{I_m'(ka)}{ka I_m(ka)} [1 + m^2 F(ka, kb)], \quad (8.1)$$

$$F = \frac{K_m(ka) I_m'(kb) - I_m(ka) K_m'(kb)}{ka [K_m'(ka) I_m'(kb) - I_m'(ka) K_m'(kb)]}.$$

Here $I_m(x)$ and $K_m(x)$ are the modified Bessel functions and $I_m'(x) \equiv dI_m/dx$, etc. Curves are

Fig. 4.

shown in Fig. 4. (Modes of deformation with $m \geq 2$ are more stable.) Since B_0^2/B_1^2 must be smaller than 1, the column is unstable (against kink for which $m=1$) when $b > 5a$. For $b=4a$ the necessary and sufficient condition for stability is $B_0^2/B_1^2 > 0.82$; for $b=3a$ it is $B_0^2/B_1^2 > 0.60$.

Without making results greatly complicated, we can generalize the model (7.11) to

$$(B_r, B_\varphi, B_z) = \begin{cases} (0, B_0 \alpha r, B_0) & \text{for } 0 \leq r < a \\ (0, B_1 a/r, B_2) & \text{for } a < r < b. \end{cases} \quad (8.2)$$

Here B_0 , B_1 and B_2 are constants and αa is assumed to be so small that its square may be neglected (compare Fig. 2 for $B_2=0$). Then the pressure in the plasma is uniform as in the foregoing and the equilibrium condition is

$$P_{rr} + (2\mu)^{-1} B_0^2 = (2\mu)^{-1} (B_1^2 + B_2^2). \quad (8.3)$$

A relation giving the critical value of B_0^2/B_1^2 for stability is the following:

$$\frac{B_0^2}{B_1^2} \left(1 + \frac{2m\alpha}{k} \right) = \frac{1}{(ka)^2} \left[\frac{ka I_m'(ka)}{I_m(ka)} + \frac{2m\alpha}{k} \right] \times \left[1 + \left(m + ka \frac{B_2}{B_1} \right)^2 F(ka, kb) \right], \quad (8.4)$$

which is a generalization of (8.1).

The author wishes to thank Prof. I. Imai, Prof. G. Miyamoto, and Mr. Y. Midzuno for useful discussions.

Externally Pinched Plasma

By Tihiro OHKAWA and Taro KIHARA

Department of Physics, Faculty of Science, University of Tokyo

(Received February 6, 1958)

A new process of pinching a plasma column is treated theoretically. A column of plasma with no longitudinal current can be pinched by an external magnetic field parallel to the column; and the plasma thus pinched will not show any instability. The process depends on the effective value of γ , the ratio of specific heats. For $\gamma=2$ in particular, the temperature of a perfectly conducting plasma with no heat loss will rise in proportion to the external magnetic field.

The self-pinched plasma column with longitudinal current has been well investigated both theoretically and experimentally as a possible method of achieving thermonuclear reaction. A known method of making the plasma stable is to create a longitudinal magnetic flux within the plasma, and surround the column with a tube with a conducting wall. The condition for the stability is that the radius of the tube must be smaller than five times the radius of the plasma column in an ideal case.^{1,2)} Because of this severe condition, another method is needed.

A preferable approach is to use a plasma column with no longitudinal current and pinch the column with external magnetic field parallel to the column.

The field may be produced by a solenoid energized by a discharge of a condenser bank or an impulse generator. Closed current will be induced in the plasma and the plasma will be compressed radially by the Lorentz force $\mathbf{J} \times \mathbf{B}$. The system has a larger inductance than the usual self-pinched plasma and hence requires a larger stored energy in the power supply.

In the following, this type of pinch effect is discussed. We consider a neutral plasma in which both the displacement current and the inertia term of the electron mass motion can be neglected (quasi-stationary neutral plasma).²⁾

The equation of continuity and the equation of motion for the plasma flow are

$$\text{div}(\rho \mathbf{v}) + \partial \rho / \partial t = 0, \quad (1)$$

and

$$\rho[\partial \mathbf{v} / \partial t + (\mathbf{v} \cdot \text{grad}) \mathbf{v}] = \mathbf{J} \times \mathbf{B} - \text{Div} \mathbf{P}, \quad (2)$$

respectively [Eqs. (2.6) and (2.7a) of reference 2]. Here ρ is the density of the fluid; $\mathbf{v}$ is

the flow velocity; $\mathbf{J} \times \mathbf{B}$ is the Lorentz force density on the neutral plasma; $-\text{Div} \mathbf{P}$ is the mechanical force density. In addition to these comes the equation

$$\frac{\partial \mathbf{B}}{\partial t} = \text{rot}(\mathbf{v} \times \mathbf{B}) + \frac{1}{\mu \sigma} \nabla^2 \mathbf{B} - \text{rot}[(en)^{-1} \mathbf{J} \times \mathbf{B}] \quad (3)$$

($\nabla^2 \equiv \text{grad div} - \text{rot rot}$) [Eq. (6.3) of reference 2]. Here $-e$ is the electron charge, n the number density of electrons, and σ the electrical conductivity assumed to be uniform.

By use of a cylindrical coordinate system (r, φ, z) we investigate the case in which all the quantities are independent of φ and z , $\mathbf{B}$ has only the z -component $B(r, t)$, and $\mathbf{v}$ has only the r -component $v(r, t)$. Then the current density $\mathbf{J}$ has only the φ -component $J(r, t)$. As the domain of the independent variables we choose $0 \leq r < R$ and $t > 0$. In this case the last term of (3) vanishes and we have

$$\frac{\partial B}{\partial t} = -\frac{1}{r} \frac{\partial}{\partial r}(rvB) + \frac{1}{\mu \sigma} \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial B}{\partial r}\right). \quad (3a)$$

Eq. (1) becomes

$$\frac{1}{r} \frac{\partial}{\partial r}(rv\rho) + \frac{\partial \rho}{\partial t} = 0. \quad (1a)$$

If the isotropy of the pressure tensor in (r, φ) -plane, is assumed, $P_{rr} = P_{\varphi\varphi}$, and the r -component of Eq. (2) becomes,

$$\rho\left(\frac{\partial v}{\partial t} + v \frac{\partial v}{\partial r}\right) + \frac{\partial}{\partial r}\left(P_{rr} + \frac{B^2}{2\mu}\right) = 0, \quad (2a)$$

$B^2/2\mu$ being the so-called magnetic pressure. [Compare Eq. (7.3) of reference 2].

As an idealized model let us consider a perfectly conducting fully ionized cylindrical plasma of radius $a(<R)$, a being a function of the time t , which is "pinched" by the external magnetic pressure. We namely assume the conductivity to be

$$\sigma = \begin{cases} \infty & \text{for } 0 \leq r < a \\ 0 & \text{for } a < r < R; \end{cases}$$

the magnetic flux density B and the pressure P are assumed to be continuous

$$B = \begin{cases} B(r, t) & P_{rr} = \begin{cases} P_{rr}(r, t) & \text{for } 0 \leq r < a \\ P_{rr}(a, t) \equiv 0 & \text{for } a < r < R. \end{cases} \end{cases}$$

Inside the plasma we then have, from (3a) and (1a),

$$\left(\frac{\partial}{\partial t} + v \frac{\partial}{\partial r} \right) B + \frac{B}{r} \frac{\partial}{\partial r} (rv) = 0, \quad (3b)$$

$$\left(\frac{\partial}{\partial t} + v \frac{\partial}{\partial r} \right) \rho + \frac{\rho}{r} \frac{\partial}{\partial r} (rv) = 0, \quad (1b)$$

from which we obtain

$$\left(\frac{\partial}{\partial t} + v \frac{\partial}{\partial r} \right) \frac{B}{\rho} = 0, \quad (4)$$

[Eq. (7.9) of reference 2]. The magnetic flux density is proportional to the fluid density at any substantial point of the fluid flowing with the radial velocity v . Eq. (2a) is reduced, at such high pressures as the inertia term may be neglected, to

$$P_{rr}(r, t) + (2\mu)^{-1} B(r, t)^2 = (2\mu)^{-1} B(a, t)^2. \quad (5)$$

Now we will suppose the adiabatic condition to be satisfied. When the pressure is isotropic, it is proportional to ρ^γ (hence to B^γ) at any substantial point of the fluid, r being the ratio of the specific heats, $5/3$. The plasma temperature is determined by P/ρ ; it is proportional to $\rho^{\gamma-1}$ (hence to $B^{\gamma-1}$) at any substantial point. A relation between B at a substantial point and the external $B(a, t)$ can be found from (5). In the part of the domain where the magnetic pressure is much smaller than the fluid pressure the flux density B at a substantial point is proportional to $B(a, t)^{2/\gamma}$, and hence the temperature to $B(a, t)^{2-2/\gamma}$. Under very high magnetic pressures, on the other hand, the B at a substantial point is close to the external $B(a, t)$, and hence the plasma temperature is proportional to $B(a, t)^{\gamma-1}$.

Our assumption of perfect conductivity may be close to the reality when the plasma is pinched suddenly. For a sudden radial compression, however, the pressure is not isotropic; P_{rr} and $P_{\varphi\varphi}$ are larger than P_{zz} . In this case P_{rr} is nearly proportional to ρ^γ with γ somewhat larger than $5/3$.

For $\gamma=2$ in particular there exists a simple solution of our equations. If we namely assume the "similar compression"

$$v = \frac{r}{a} \frac{da}{dt}, \quad (6)$$

we obtain from (3b) and (1b)

$$\left(\frac{\partial}{\partial t} + v \frac{\partial}{\partial r} \right) (a^2 B) = 0, \quad (7)$$

and

$$\left(\frac{\partial}{\partial t} + v \frac{\partial}{\partial r} \right) (a^2 \rho) = 0, \quad (8)$$

which indicate that both $a^2 B$ and $a^2 \rho$ at a substantial point are constant. In particular, $a^2 B(a, t)$ is independent of the time (see Fig. 1). Taking Eq. (5) into account we know that

Fig. 1.

P_{rr} at a substantial point is proportional to a^{-4} or ρ^2 . Hence the assumption (6) corresponds to $\gamma=2$. In this case the temperature at any substantial point rises simply in proportion to the external magnetic field. It is to be noted that the general solution of (7) is

$$a^2 B = f(r/a),$$

f being any differential function, and then

$$P_{rr} = \frac{1}{2\mu} B(a, t)^2 \left[1 - \frac{f(r/a)^2}{f(1)^2} \right].$$

The authors wish to thank Prof. G. Miyamoto and Dr. G. Iwata for useful discussions.

The Arc Spectrum of Iodine and the Quadrupole Moment of I^{127}

By Kiyoshi MURAKAWA

*Institute of Science and Technology, University of Tokyo,
Komaba-machi, Meguro-ku, Tokyo*

(Received January 20, 1958)

The analysis of the arc spectrum of iodine has been continued, and the identification of the term sequence $(^3P_2)nf$ has been fairly well completed, and some other levels newly detected. From the hyperfine structure of $(^3P_2)7p^4D_{7/2}$ the quadrupole moment without shielding correction was found to be $Q'(I^{127}) = -0.63$ barn, whereas the value that was deduced from $(^3P)6s^4P_{5/2}$ previously was $Q'(I^{127}) = -0.71$ barn. The mean of these two values is $Q'(I^{127}) = -0.67 \pm 0.04$ barn. This is in agreement with the value $Q'(I^{127}) = -0.66$ barn that is deduced from the hfs of the ground term $5p^5\ ^2P_{3/2}$ whose measurement is given in the literature. Assuming the shielding correction $\Delta = -0.07$, the true quadrupole moment $Q(I^{127}) = -0.62$ barn has been obtained.

§ 1. Introduction

About twenty years ago the author analysed the spark spectrum of iodine (I II) and published a preliminary description of I I¹⁾ (referred to as Part I in the following: all the previous literatures are quoted there). Suwa and the author (to be referred to as Part II) improved the light source and extended the analysis of I I²⁾.

Schmidt³⁾ (to be referred to as S) analysed the hyperfine structure (hfs) of I I for the first time and calculated the quadrupole moment (Q) of I^{127} , while the author calculated $Q(I^{127})$ from the hfs of I II⁴⁾. Eshbash and Fisher⁵⁾ (to be referred to as EF) studied the far infra-red spectrum of I I; their result will be quoted later.

The purpose of the present paper is to extend the analysis of I I published in Parts I and II, to review critically the wave functions used in Part II in order to calculate Q , and to obtain Q from the hfs of $(^3P_2)7p^4D_{7/2}$ whose wave function can be regarded as simple.

§ 2. Experimental Procedure

The light source used was an electrodeless discharge tube described in Part II, the technique of the high frequency being similar to that of Lacroute⁶⁾. The red part of the spectrum was photographed with a plane grating equipped with a large concave mirror. The dispersion was 8Å/mm in the first order and 4Å/mm in the second. This grating gives strong intensity only in the red and

green region. In order to obtain wave length standard a small amount of neon was sometimes mixed with iodine. In the region shorter than 4600 the spectrum was photographed with a two-prism spectrograph having a camera-lens with one-meter focal length.

The infra-red plates that are available (since 1945) in this country are sensitive only to the region 7900–6700 and the sensitivity falls off rapidly from 8100 towards longer wave length, although that of the pre-war plates reached 10000. In the region 7544–5000 in which the neon lines are abundant the wave length was measured directly against neon standards. In the region longer than 7544 in which neon lines are scarce, data that were obtained with plates taken with the same plane grating equipped with a lens of shorter focal length were utilized.

In order to resolve the hfs a Fabry-Pérot etalon was used, which was crossed with the prism spectrograph. In the infra-red region lines are crowded in a space of low dispersion, so the hfs had to be measured using thin spacers, except in a very few strong and isolated lines.

Fig. 1. Enlargement of the interference pattern of II 4862, taken with a 8mm etalon. Two copies of a same plate are shown. One was printed with medium strength; the other was printed somewhat strongly.

An example of the interference pattern of the spectrum of iodine is shown in Fig. 1.

§ 3. Analysis of the Arc Spectrum of Iodine

In order to test whether the wave function of $(^3P)7p^4D_{7/2}$ is perturbed or not the level $(^1D)6p^2F_{7/2}$ must be detected. For this purpose

the hfs of the levels $(^1D)6p^2F_{7/2}$ and $(^3P)5d^4D_{5/2}$ were approximately calculated assuming that they are not perturbed, and then the hfs of the transition $(^3P)5d^4D_{5/2}-(^1D)6p^2F_{7/2}$ was constructed. Then a line having the desired hfs was searched, and it was at once found that only $\lambda 7700$ satisfies this condition (see Fig. 2). The hfs of the lines having $(^3P)5d^4D_{5/2}$ as the final level was studied and it was found that the hfs splittings of $(^3P)5d^4D_{5/2}$ are identical with those of the level with $J=5/2$ contained in $\lambda 7700$ within the accuracy of 0.02 cm^{-1} . It was therefore concluded that $\lambda 7700$ corresponds to the above-mentioned transition. In a similar way other lines were classified. In Figs. 3-7 hfs of some lines which served as key to the classification are shown. Most of them are situated either close to strong lines or close to each other, so the hfs given in Figs. 2-7 serve merely to prove the classification, and do not claim any great accuracy.

Fig. 2. Hfs of the line $\lambda 7700$.

Fig. 3. Hfs of the lines of the transitions $5d^4D_{7/2} - 5f^4F_{7/2}$, $5d^4D_{5/2} - 5f^4F_{5/2}$, $5d^4D_{3/2} - 5f^4F_{3/2}$.

Fig. 4. Hfs of the line $\lambda 7491$.

EF: wave length according to Eshbach and Fisher; the intensity given by EF is shown in parentheses.

* classification according to EF.

** classification of EF somewhat modified.

*** hfs narrow.

**** hfs similar to $\lambda 7402$.

P: wave length measured with prisms only.

Fig. 6. Hfs of the lines $\lambda\lambda 4701$ and 4691 .Fig. 7. Hfs of the line $\lambda 4408$. The upper level has two levels in the neighborhood, so it should be perturbed. The accuracy of the measurement was not sufficient for detecting this perturbation, however.

Fig. 8. Hfs of four unclassified lines.

All the classified lines of I I in the region $\lambda 14460$ – 4690 are listed in Table I. Unclassified lines with intensity larger than 5 are also listed, with the indication of their hfs either in footnote or in Fig. 8. It will be seen that the hfs of these unclassified lines are of poor value for the classification, but it may be concluded that none of them contains any level with $J=1/2$. All the lines of I I in the region shorter than $\lambda 4500$ with intensity larger than 2 were contained in Table I of Part II,

so they will not be repeated here. Some supplement is given in Table II in which all the unclassified lines in this region with intensity larger than 0.5 (they are only four in number) are also listed.

All the terms of I I that have been hitherto detected are given in Table III. The first column lists the labels of terms adopted in the present work (and also in Parts II and I). They were named so that analogy with the

Table II. Supplement to the list of the Spectrum of I I in the violet region ($\lambda 4500$ – 3600)

Int.	$\lambda(\text{air})$	$\nu(\text{vac})$	Term combination

spectrum of F I is good, although none of the terms of I I is of LS-coupling. In case where the label of Part II is changed, the old one is given in square brackets. The second column lists the values of levels measured from the ground level of I II, while in the third column distances from the ground level of I I ($5p^{62}P_{3/2}$) are given.

Most of the J -values of the levels ($^3P_2$) $5f$ could not be determined by the hfs data alone except in $5fW_{1/2}$ and $5f r_{9/2}$ where the hfs

* according to EF.

** according to EF. EF call this level $6p\ 4P_{5/2}$, but the J -value $5/2$ is not consistent with the hfs of $\lambda 7193$ and $\lambda 7192$ (see Fig. 5).

data allow us to determine J uniquely and in $5f\ x_{3/2}$ where the combination relations seem to justify the J -determination. It was tried to determine the J -values by comparison with the theory of Condon and Shortley⁷⁾, but, since some indications of existence of small perturbations were apparent, this was abandoned. The J -values that seem to fit the hfs data qualitatively but are not altogether unique are given in parentheses.

§ 4. Quadrupole Moment of I^{27}

In order to confirm the hfs of $6s^4P_{5/2}$, hfs of further lines were measured. Since the hfs of the level $6s^4P_{3/2}$ was accurately determined in Part II, $\lambda 6294$ and $\lambda 5894$ having the same final level were measured (see Fig. 9) and the hfs of the initial levels determined.

Then the hfs of the lines ending on $6s^4P_{5/2}$ and starting with the same levels were measured (see Fig. 10), and the hfs of $6s^4P_{5/2}$ given

Fig. 9. Hfs of the lines $\lambda 6294$ and 5894 .

Fig. 10. Hfs of the lines $\lambda 5764$ and 5427 .

Fig. 11. Hfs of the line $\lambda 4917$.

in Part II or by Schmidt was confirmed. Also the complicated hfs of $\lambda 4917$ can be interpreted using the same hfs of $6s^4P_{5/2}$ (see Fig. 11).

The hfs of $\lambda 4862$ and $\lambda 4129$ are given in Fig. 12. Both of them are qualitatively identical. The initial level of $\lambda 4862$ namely $(^3P_2)7p\ ^4D_{7/2}$ is close to $(^3P_2)7p\ ^4D_{5/2}$, which is characteristic of jj-coupling. The hfs of the latter level is obtained from $\lambda 5235$ (see Fig. 13) in which the components are so close together that the accuracy of measurement is not great. The amount of perturbation in $7p\ ^4D_{7/2}$ can be calculated, using the theory of Casimir⁸⁾. The hfs levels of $7p\ ^4D_{7/2}$ $F=5, 4, 3, 2$ and 1 are pushed upwards by the amount $0.003, 0.004, 0.003, 0.002$ and 0.001 cm^{-1} respectively

Fig. 12. Hfs of the lines $\lambda\lambda 4862$ and 4129 . The accuracy of measurement of $\lambda 4129$ is somewhat inferior to that of $\lambda 4862$, so that no attempt was made to calculate Q from the hfs of the level $8p^4D_{7/2}$.
Correction: The splitting of $8p^4D_{7/2}$, $F=4-3$ should read .084 instead of .072.

Fig. 13. Hfs of the line $\lambda 5235$. The components h , j and e were recognized to form a broad band, but they were not resolved.

owing to the perturbation by $7p^4D_{5/2}$. The unperturbed hfs of $(^3P_2)7p^4D_{7/2}$ is given by $A=0.01909$ and $B=-0.057\times 10^{-3}\text{cm}^{-1}$.

The level $(^3P_2)7p^4D_{7/2}$ is so highly excited that we can assume the wave function to be a product of $^3P_2$ and $7p_{3/2}$. Using the values $\zeta_{5p}=5760\text{cm}^{-1}$ given by Robinson and Shortley⁹⁾, Schmidt calculated the wave function:

$$\begin{aligned}\psi(^3P_2^2) &= c_1[\phi_{3/2}^{3/2}\phi_{1/2}^{1/2}]^2 + c_2[\phi_{3/2}^{3/2}\phi_{3/2}^{1/2}]^2, \\ c_1 &= 0.300, \quad c_2 = 0.955.\end{aligned}$$

We get therefore $(\omega=3\cos^2\theta-1)$

$$\begin{aligned}({}^4D_{7/2}|\omega|{}^3\phi({}^4D_{7/2})) &= \frac{2}{5}(c_1^2R_1' - 2\sqrt{2}c_1c_2S_1)\langle r_{5p}^{-3} \rangle \\ &\quad - \frac{2}{5}R_1'\langle r_{7p}^{-3} \rangle.\end{aligned}$$

ζ_{7p} is so small compared with ζ_{5p} that the second term can be neglected. Thus, putting $R_1'=1.11$ and $S_1=1.19$ in this expression, we get

$$({}^4D_{7/2}|\omega|{}^4D_{7/2}) = -0.3458.$$

Putting this and $\zeta_{5p}=5760\text{cm}^{-1}$, $H_1=1.06$, $Z_{5p}^*=53-4=49$, $I=5/2$, and $J=7/2$ in the usual formula (see Part II), we obtain

$$Q' = -0.63 \text{ barn} \quad \text{from } ({}^3P_2)7p^4D_{7/2}$$

where Q' means that the shielding correction has not been included.

In Part II, the energy matrix for $5p^46s$ was solved and $\zeta(5p)=5284$, $F_2=1454$, $G_1=681\text{cm}^{-1}$ were obtained. The solutions are listed in Table IV. According to the calculation 6s

Table IV. Calculated and observed term values of the $5p^46s$ -configuration

	Calculated	Observed	Δ
$({}^3P)6s^4P_{5/2}$	54631	54630	+ 1
$({}^3P)6s^4P_{3/2}$	56087	56089	- 2
$({}^3P)6s^4P_{1/2}$	60870	60893	- 23
$({}^3P)6s^2P_{3/2}$	61412	61816	-404
$({}^3P)6s^2P_{1/2}$	62879	63187	-308
$({}^1D)6s^2D_{5/2}$	68805	68800	+ 5
$({}^1D)6s^2D_{3/2}$	68958	68545	+413

$^3D_{3/2}$ should lie higher than $6s\ ^2D_{5/2}$. This situation does not change even if we alter the parameter values in reasonable range. This is not in agreement with the observation, so we have to assume that $6s\ ^2D_{3/2}$ and $6s\ ^2D_{5/2}$ are perturbed by higher lying $5p^4\ 5d$ levels containing large percent of LS-coupling $5d\ ^2D_{3/2}$ and $5d\ ^2D_{5/2}$ wave functions respectively. The fact that $6s\ ^2D_{3/2}$ lies deeper than $6s\ ^2D_{5/2}$ shows that $6s\ ^2D_{3/2}$ is perturbed more strongly than $6s\ ^2D_{5/2}$. From this it can be assumed that $6s\ ^2P_{3/2}$ is also somewhat perturbed and $6s\ ^4P_{3/2}$ slightly perturbed. This explains why somewhat discrepant values of Q' were obtained in Part II:

$$Q' = -0.71 \text{ barn} \quad \text{from } 6s\ ^4P_{5/2},$$

$$Q' = -0.75 \text{ barn} \quad \text{from } 6s\ ^4P_{3/2},$$

$$Q' = -0.51 \text{ barn} \quad \text{from } 6s\ ^2P_{3/2}.$$

We shall therefore adopt $Q' = -0.71$ barn as the best value from $5p^4\ 6s$. When this is combined with the above-mentioned Q' obtained from $7p\ ^4D_{7/2}$, we get

$$Q' = -0.67 \pm 0.04 \text{ barn}.$$

Some time ago Jaccarino et al.¹⁰⁾ measured the hfs of $5p^5\ ^2P_{3/2}$ by the atomic beam resonance method and obtained $A = 0.0275755\text{ cm}^{-1}$, $B = 0.47765 \times 10^{-3}\text{ cm}^{-1}$, $C = 0.00454 \times 10^{-6}\text{ cm}^{-1}$. From this B , the present author deduced¹¹⁾

$$Q' = -0.66_4 \text{ barn} \quad \text{from } 5p^5\ ^2P_{3/2}.$$

The above-mentioned spectroscopic value of Q' is in agreement with this.

In order to obtain the true quadrupole moment $Q = (1 + \Delta)Q'$, we have to get Δ . The value of Δ was calculated by Sternheimer¹²⁾ only for $3p^5$ of Cl I, so we shall extrapolate Δ for I I, as shown by the dotted curve in Fig. 14. and consider $\Delta = -0.07$ the best value available at present. Under this assumption, we get

$$Q(I^{127}) = -0.62 \text{ barn}.$$

Naturally the values of Δ for $5p^5$, $5p^4\ 6s$ and $5p^4\ 7p$ would be different in a strict sense. It is possible that the above-mentioned slight differences between $Q'(5p^5\ ^2P_{3/2})$, $Q'(5p^4\ 6s\ ^4P_{5/2})$ and $Q'(5p^4\ 7p)$ are real and are partly explained by the differences of Δ 's. But at present we have no means of confirming or disproving such an assumption.

Measurement of all of the plates was finished in December, 1956. Since then much effort has been made toward calculating the shielding correction for iodine theoretically, but

Fig. 14. The shielding corrections (Δ) for various states plotted versus the charge number Z . All of the values were calculated by Sternheimer. Two kinds of wave functions (a and b) for alkali atoms were used by him. The graph shows that the result of calculation is sensitive to the wave functions chosen. The value for iodine was obtained by extrapolation (dotted curve) from chlorine.

this has been found to be a hard task for the author and has therefore been abandoned. The extrapolation from chlorine is not altogether free from objection, so the value of $Q(I^{127})$ presented here would perhaps require a small correction in the end, but it is not likely that this would be materially altered.

§ 5. Correction to Part I and Part II

Everywhere read $4f$ and $5f$ in place of $5f$ and $6f$ respectively.

Viscous Flow at Low Reynolds Numbers past an Infinite Row of Equal Circular Cylinders

By Tosio MIYAGI

Junior College of Engineering, University of Osaka Prefecture

(Received January 31, 1958)

Steady viscous flow at low Reynolds numbers passing through an infinite row of parallel circular cylinders of the same radius is investigated on the basis of the Stokes equations of motion. Tamada and Fujikawa's expansion formula for the drag coefficient has been extended up to the 14th power of the diameter-distance ratio of the row. An alternative simple formula is presented for the case where the said ratio approaches unity so that the above-mentioned expansion formula becomes divergent. Numerical discussion is made on the drag coefficient *versus* the diameter-distance ratio of the row.

§ 1. Introduction

In a recent paper¹⁾, Tamada and Fujikawa have treated, according to Oseen's approximation, the steady viscous flow at low Reynolds numbers passing through an infinite row of equal circular cylinders. They have thus found among others that at sufficiently low Reynolds numbers the drag D experienced by any one of the cylinders is of Stokes's type, namely it becomes directly proportional to the product of the viscosity coefficient μ and the undisturbed flow speed U . This result seems to suggest that an appropriate solution may also be found when the problem is considered on the basis of the Stokes equations of motion. (In this connexion one may remember the well-known so-called Stokes's paradox that there exists no solution of the Stokes equations for the case of flow past a single cylinder.) It is the object of the present paper to report such an analysis. As will be seen later, the computation required is far simpler than in Tamada and Fujikawa's case. The expansion formula for $D/\mu U$ as a power series in the diameter-distance ratio of the row has been extended up to the 14th power. (Tamada and Fujikawa's result includes only the 10th power.) Also an alternative simple formula has been deduced for the case where the diameter-distance ratio approaches unity so that the above-mentioned expansion formula becomes useless. Numerical discussion is made on the drag coefficient *versus* the diameter-distance ratio of the row, especially for the values of the ratio close to unity.

§ 2. Stokes Equations of Motion and their Solution

Let us consider the steady two-dimensional flow of a viscous fluid passing through an infinite row of equal circular cylinders of radius a , spaced regularly at a distance $2h$ between the centres and lying in a plane perpendicular to the uniform stream of velocity U . We take the rectangular coordinates (x, y) in the plane of fluid motion in such a way that the origin coincides with the centre of any cylinder of the row and the x -axis is along the direction of the uniform stream.

Let u and v be the x - and y -components of the fluid velocity at any point in the field of flow, μ the viscosity coefficient, and p the pressure. Then the Stokes equations of motion and the equation of continuity are given by

$$\left. \begin{aligned} \partial p / \partial x &= \mu \Delta u, & \partial p / \partial y &= \mu \Delta v, \\ \partial u / \partial x + \partial v / \partial y &= 0, \end{aligned} \right\} \quad (1)$$

where Δ stands for $\partial^2 / \partial x^2 + \partial^2 / \partial y^2$.

Elimination of p yields

$$\Delta \omega = 0, \text{ or } \partial^2 \omega / \partial z \partial \bar{z} = 0, \quad (2)$$

where ω is the vorticity defined as

$$\omega = \partial v / \partial x - \partial u / \partial y = 2i \partial \omega / \partial \bar{z},$$

and

$$z = x + iy, \quad \bar{z} = x - iy, \quad w = u - iv. \quad (3)$$

Since ω should be real, the general solution of (2) is given in the form:

$$\omega = \Omega(z) + \overline{\Omega}(\bar{z}), \quad (4)$$

where $\Omega(z)$ is an arbitrary analytic function of z and $\overline{\Omega}(\bar{z})$ is its conjugate complex function. Further, ω must be one-valued through-

out the field of flow and should vanish at infinity. Therefore, taking, in addition, the periodicity of the field into account, we may put the function $\Omega(z)$ in the form:

$$\Omega(z) = \frac{\pi U}{ih} \sum_{n=0}^{\infty} a_{2n} \frac{d^{2n}}{d\zeta^{2n}} \coth \zeta, \quad \zeta = \frac{\pi z}{2h}.$$

(5)

Here arbitrary constants a_{2n} 's turn out to be real owing to the symmetry of the field under consideration.

Inserting (4) and (5) into (3), and integrating with respect to $\bar{z}$, we obtain

$$\frac{w}{U} = a_0 [\log(2 \sinh \bar{\zeta}) - \bar{\zeta} \coth \zeta] + \sum_{n=1}^{\infty} a_{2n} \left[\frac{d^{2n-1}}{d\bar{\zeta}^{2n-1}} \coth \bar{\zeta} - \bar{\zeta} \frac{d^{2n}}{d\zeta^{2n}} \coth \zeta \right] + f(\zeta).$$

The boundary condition at infinity (i.e., $w \rightarrow U$ when $|\zeta| \rightarrow \infty$) together with the periodicity of the w -field restricts the form of the arbitrary function $f(\zeta)$ and we obtain

$$\begin{aligned} \frac{w}{U} = & a_0 [\log(2 \sinh \bar{\zeta}) + \log(2 \sinh \zeta) - (\zeta + \bar{\zeta}) \coth \zeta] \\ & + \sum_{n=1}^{\infty} a_{2n} \left[\frac{d^{2n-1}}{d\bar{\zeta}^{2n-1}} \coth \bar{\zeta} - (\zeta + \bar{\zeta}) \frac{d^{2n}}{d\zeta^{2n}} \coth \zeta \right] \\ & + \sum_{n=1}^{\infty} b_{2n} \frac{d^{2n-1}}{d\zeta^{2n-1}} \coth \zeta. \end{aligned} \quad (6)$$

§ 3. Boundary Condition on the Cylinders

We next proceed to the fulfilment of the boundary condition on the surface of each cylinder. In virtue of the periodicity of (6), it is obviously sufficient to apply the condition on any one of the cylinders. Thus,

$$\begin{aligned} w/U = -1, \quad \text{at } |z| = a \quad \text{or } \bar{\zeta} = t^2/\zeta, \\ t = \pi a/2h. \end{aligned} \quad (7)$$

Substituting $\bar{\zeta} = t^2/\zeta$ into (6), expanding the right-hand side into Laurent series in ζ and equating the resulting expression to -1 , we get an infinite set of algebraic equations for determining the constants a_{2n} 's and b_{2n} 's.

Thus, after tedious but straightforward calculation we arrive at the following result:

$$a_0 [1 - 2 \log(2t) + k_1 t^2] - \sum_{n=1}^{\infty} (2n-1)! k_n a_{2n} + \sum_{n=1}^{\infty} (2n+1)! k_{n+1} t^2 a_{2n} - \sum_{n=1}^{\infty} (2n-1)! k_n b_{2n} = 1, \quad (8)$$

$$\begin{aligned} a_0 \left[\frac{2s-1}{2s} k_s + k_{s+1} t^2 \right] + (2s-1)! t^{-4s} a_{2s} + \sum_{n=1}^{\infty} \frac{(2n+2s-1)!}{(2s-1)!} k_{n+s} a_{2n} \\ + \sum_{n=1}^{\infty} \frac{(2n+2s+1)!}{(2s+1)!} k_{n+s+1} t^2 a_{2n} - \sum_{n=1}^{\infty} \frac{(2n+2s-1)!}{(2s)!} k_{n+s} b_{2n} = 0, \end{aligned} \quad (9)$$

$$a_0 \left[\frac{k_s}{2s} t^{4s} \right] + \sum_{n=1}^{\infty} \frac{(2n+2s-1)!}{(2s)!} k_{n+s} t^{4s} a_{2n} - (2s)! a_{2s} - (2s-2)! t^2 a_{2s-2} - (2s-1)! b_{2s} = 0, \quad (10)$$

where

$$k_s = (-1)^{s-1} 2^{2s} B_s / (2s)! \quad (s=1, 2, 3, \dots), \quad (11)$$

and B_s 's are Bernoulli numbers.

Further, we can eliminate b_{2n} 's from these equations and we obtain

$$\begin{aligned} a_0 \left[1 - 2 \log(2t) + 2k_1 t^2 - \sum_{n=1}^{\infty} \frac{k_n^2 t^{4n}}{2n} \right] + \sum_{n=1}^{\infty} a_{2n} \left[(2n-1)(2n-1)! k_n + 2(n+1)(2n)! k_{n+1} t^2 \right. \\ \left. - \sum_{s=1}^{\infty} \frac{(2n+2s-1)!}{(2s)!} k_s k_{n+s} t^{4s} \right] = 1, \end{aligned} \quad (12)$$

$$\begin{aligned} a_0 \left[\frac{2s-1}{2s} k_s + 2(s+1) k_{s+1} t^2 - \sum_{n=1}^{\infty} \frac{(2n+2s-1)!}{(2s)!(2n)!} k_n k_{n+s} t^{4n} \right] + (2s-1)! t^{-4s} a_{2s} \\ + \sum_{n=1}^{\infty} a_{2n} \left[\frac{(2n+2s)!}{(2s)!} k_{n+s} + \frac{(2n+2s+2)!}{(2n+1)(2s+1)!} k_{n+s+1} t^2 - \sum_{j=1}^{\infty} \frac{(2j+2s-1)!(2j+2n-1)!}{(2s)!(2j-1)!(2j)!} k_{j+s} k_{n+j} t^{4j} \right] = 0, \end{aligned} \quad (s \geq 1). \quad (13)$$

Close examination of these equations shows that a_{2n} is $O(t^{4n})$ and first n equations determine the expansion of a_0 up to the $(4n-2)$ th power of t . In the following lines we content ourselves with taking only four equations. These can be solved successively and we obtain

$$\begin{aligned} \frac{1}{a_0} &= 1 - 2 \log(2t) + \frac{2}{3}t^2 - \frac{1}{9}t^4 + \frac{8}{135}t^6 - \frac{53}{1350}t^8 + \frac{1112}{42525}t^{10} - \frac{241643}{13395375}t^{12} + \frac{18776}{1488375}t^{14} - \dots, \\ \frac{a_2}{a_0} &= -\frac{t^4}{6} \left[1 - \frac{8}{15}t^2 + \frac{1}{3}t^4 - \frac{1072}{4725}t^6 + \frac{2153}{14175}t^8 - \frac{5816}{55125}t^{10} + \dots \right], \\ \frac{a_4}{a_0} &= \frac{t^8}{360} \left[1 - \frac{16}{21}t^2 + \frac{20}{27}t^4 - \frac{544}{945}t^6 + \dots \right], \\ \frac{a_6}{a_0} &= -\frac{t^{12}}{68040} \left[1 - \frac{24}{25}t^2 + \dots \right]. \end{aligned} \tag{14}$$

Further we find from (10)

$$\begin{aligned} \frac{b_2}{a_0} &= -t^2 \left[1 - \frac{1}{2}t^2 + \frac{8}{45}t^4 - \frac{11}{90}t^6 + \frac{1156}{14175}t^8 - \frac{4651}{85050}t^{10} + \frac{18832}{496125}t^{12} - \dots \right], \\ \frac{b_4}{a_0} &= \frac{t^6}{18} \left[1 - \frac{3}{4}t^2 + \frac{17}{35}t^4 - \frac{599}{1575}t^6 + \frac{17}{63}t^8 - \dots \right], \\ \frac{b_6}{a_0} &= -\frac{t^{10}}{1800} \left[1 - \frac{25}{27}t^2 + \frac{844}{945}t^4 - \dots \right], \\ \frac{b_8}{a_0} &= \frac{t^{14}}{476280} \left[1 - \dots \right]. \end{aligned} \tag{15}$$

§ 4. Drag Formula and Numerical Discussion

By summing up the stress acting on a cylinder one can verify a general formula

$$D + iL = \oint (ip + \mu\omega) dz, \tag{16}$$

where D and L are the x - and y -components of the force experienced by the cylinder and the integration is carried along the surface of the cylinder. Moreover, it can be seen without difficulty that to Stokes approximation

$$ip + \mu\omega = 2\mu\Omega(z). \tag{17}$$

Therefore, inserting this together with (5) into (16), we obtain a very simple result:

$$D + iL = 8\pi\mu U a_0,$$

or

$$D/\mu U = 8\pi a_0, \quad L = 0. \tag{18}$$

Inserting the expression for a_0 in (14), it will

Table I. Values of $D/\mu U$ against a/h .

a/h	$D/\mu U$
0.01	3.17
0.04	4.88
0.1	7.54
0.2	12.60
0.4	31.74
0.5	52.82
0.55	70.15
0.6	98.60
$2/\pi \approx 0.64$	119.69
0.7	170.64

readily be seen that our expansion formula for the drag is in perfect agreement with Tamada and Fujikawa's formula up to the 10th power of t .

In Table I are shown the values of $D/\mu U$ against a/h as calculated by the formula (18). Also, the values of $(D/\mu U)^{-1}$ are plotted against a/h in Fig. 1. It will be seen that the value of $D/\mu U$ increases rapidly as the ratio a/h approaches unity. At the same time, the convergency of the series for a_0 in (14)

Fig. 1.

becomes worse so that our expansion formula seems to be hardly applicable beyond the value 0.7 of a/h . However, as will be seen from Fig. 1, a formula of the form

$$D/\mu U = \text{const.} \{1 - (a/h)\}^{-2} \quad (19)$$

seems to hold in this range of difficulty. In fact, this form is verified for the case of flow past a flat screen²⁾. Analytical deduction of the exact value of the constant in (19) seems to be hopeless for the present problem. However, approximate evaluation of it can be achieved by numerical matching with the results in Table I. Thus, using the values of $D/\mu U$ for $a/h=0.6, 2/\pi, 0.7$, we find that

$$\text{const.} = 15.8. \quad (20)$$

With this value, the formula (19) gives, for example, the values 176, 395, 1580 of $D/\mu U$ when a/h is 0.7, 0.8 and 0.9 respectively.

The writer wishes to express his cordial thanks to Professor S. Tomotika for his interest and encouragement. The writer's thanks are also due to Professor K. Tamada for his suggestion of the present problem and to Professor H. Fujikawa for his valuable discussions.

The Wall-effect upon the Forces experienced by an Elliptic Cylinder in a Viscous Liquid.

By Yorisaburo TAKAISI

Department of Physics, Faculty of Education, Ehime University, Matuyama

(Received January 31, 1958)

The steady slow motion of an elliptic cylinder with an arbitrary angle of attack in a viscous liquid bounded either by a plane wall or by two parallel plane walls is discussed on the basis of Oseen's linearized equations of motion. The analytical expressions for the lift and drag coefficients are obtained to a first approximation, and numerical calculations are carried out for the thickness ratio $t=0, 0.1, 0.5$ and 1. It is found that the wall-effect upon the lift is in either case much greater than that on the drag.

§ 1. Introduction

Since Harrison's study¹⁾ in 1924, the steady flow of an unbounded viscous liquid past an elliptic cylinder at small Reynolds numbers was studied by several authors on the basis of Oseen's linearized equations of motion, and approximate expansion formulae for the forces experienced by the cylinder were obtained. As far as the present writer is aware, however, there have been few works concerning the wall-effect upon the forces experienced by an elliptic cylinder moving in a viscous liquid.

Recently, the present writer has made investigations²⁾³⁾ on the wall-effect upon the forces experienced by a circular cylinder moving in a viscous liquid bounded either by

a plane wall or by parallel plane walls on the basis of Oseen's linearized equations of motion, by developing a similar analysis to that of Faxén⁴⁾ in his treatment of the wall-effect upon the forces experienced by a sphere moving in a viscous liquid.

In this paper, we study similar problems relating to an elliptic cylinder moving with low speeds at an arbitrary angle of attack in a viscous liquid.

§ 2. Fundamental Equation and its Solutions

Let us assume that a cylindrical obstacle is placed in a uniform flow of velocity U streaming parallel to the x -axis. Then Oseen's linearized equations of motion for the two-

dimensional steady motion of a viscous liquid can be written in the form

$$\psi=\psi_1+\psi_2\,,\tag{2.1}$$

$$\Delta\psi_1=0\,,\tag{2.2}$$

$$(\Delta-k^2)(e^{-kx}\psi_2)=0\,,\tag{2.3}$$

where ψ is the stream function for the perturbation and is connected with the components of the perturbation velocity as:

$$u=\partial\psi/\partial y\,,\quad v=-\partial\psi/\partial x\,,\tag{2.4}$$

and $k=U/2\nu$, ν is the kinematic viscosity of the liquid and Δ stands for $\partial^2/\partial x^2+\partial^2/\partial y^2$.

According to L. N. G. Filon⁵⁾, the appropriate solutions of (2.2) and (2.3) which satisfy the boundary conditions at infinity are given respectively by

$$\psi_1=A_0\ln r+B_0\theta+\sum_{n=1}^{\infty}r^{-n}(A_n\cos n\theta+B_n\sin n\theta)\,,\tag{2.5}$$

$$\begin{aligned}\psi_2&=a_0e^{kx}K_0(kr)\\&+b_0\int_0^\theta kr\{K_1(kr)+K_0(kr)\cos\theta\}e^{kr\cos\theta}d\theta\\&+e^{kx}\sum_{n=1}^{\infty}K_n(kr)(a_n\cos n\theta+b_n\sin n\theta)\,,\end{aligned}\tag{2.6}$$

where $x=r\cos\theta$, $y=r\sin\theta$, and

$$b_0=-B_0\,.\tag{2.7}$$

$K_n(x)$ is the modified Bessel function of the second kind. The condition (2.7) ensures that the stream function $\Psi=Uy+\psi$ is one-valued and continuous throughout the whole field of flow.

If we confine ourselves to the first order approximation, it suffices to take only the first two terms in (2.5) and (2.6) respectively. Then, as shown in our previous paper²⁾, the conjugate complex velocity $w=u-iv$ ($i=\sqrt{-1}$) can be expressed in integral forms as

$$\begin{aligned}w&=\frac{1}{2}k\int_{-\infty}^{\infty}\left(\frac{y}{|y|}+\frac{\beta}{|\beta|}\right)(A_0-iB_0)e^{k(i\beta x-|\beta||y|)}d\beta\\&-\frac{1}{2}k\int_{-\infty}^{\infty}\left\{\left(\frac{y}{|y|}+\frac{\beta}{\lambda}\right)a_0+i\left(\frac{y}{|y|}+\frac{\lambda}{\beta}\right)b_0\right\}\\&\times e^{k(i\beta x-\lambda|y|)}d\beta\,,\end{aligned}\tag{2.3}$$

where $\lambda=\sqrt{\beta^2+2i\beta}$

We introduce elliptic coordinates ξ , η , related with x , y by the equation

$$x+iy=ce^{-i\vartheta}\cosh(\xi+i\eta)\,.\tag{2.9}$$

Then the surface of the elliptic cylinder is given by $\xi=\xi_0$, and the angle between the uniform flow and the major-axis of the ellipse is ϑ .

If we take

$$\sigma=\exp(-\xi_0)\,,\quad c=2\sigma\,,\tag{2.10}$$

the half-length of the major- and minor-axes are given respectively by

$$a=c\cosh\xi_0=1+\sigma^2\,,\quad b=c\sinh\xi_0=1-\sigma^2\,.\tag{2.11}$$

We insert (2.9) into (2.8) and expand the integrands with respect to $e^{i\eta}$, retaining only constant terms as well as terms involving $e^{-i\eta}$. Then, after some calculations, we obtain

$$\begin{aligned}(w/k)_{\xi=\xi_0}&=1/2\cdot ia_0(2S-1-\sigma^2e^{2i\vartheta})+1/2\cdot b_0(2S+1+\sigma^2e^{2i\vartheta})\\&+e^{-i\eta}k^{-1}\{i(A_0-a_0)e^{i\vartheta}+(B_0+b_0)e^{i\vartheta}\}+O(ka)\,,\end{aligned}\tag{2.12}$$

with

$$S=-\ln(1/2\cdot k)-\gamma\,,\tag{2.13}$$

where $\gamma=0.57721\cdots$ is Euler's constant.

§ 3. Elliptic Cylinder in a Semi-infinite Viscous Liquid

Suppose that an elliptic cylinder is moving, with constant slow velocity U , from right to left in a semi-infinite viscous liquid otherwise at rest parallel to its bounding plane wall (Fig. 1). Referring to rectangular coordinates

Fig. 1.

with its origin at the centre of the cylinder, the fluid at infinity flows, with constant velocity U , past the cylinder at rest in the positive direction of the x -axis. In this case the bounding plane wall should also move, with the same velocity U , from left to right in its own plane, so as to satisfy the boundary conditions.

As in our previous paper²⁾, in order to satisfy the boundary conditions on the bounding plane wall, we now superpose an image flow which is defined as

$$w^* = u^* - iv^*$$

$$= -\frac{1}{2} k^2 \int_{-\infty}^{\infty} (\beta + |\beta|) f_1^{(1)}(\beta) e^{k[\epsilon \beta x - |\beta|(y+2d)]} d\beta$$

$$-\frac{1}{2} k^2 \int_{-\infty}^{\infty} (\lambda + \beta) f_2^{(1)}(\beta) e^{k[\epsilon \beta x - \lambda(y+2d)]} d\beta, \quad (3.1)$$

where $f_1^{(1)}(\beta)$ and $f_2^{(1)}(\beta)$ are determined by the boundary condition on the bounding plane wall ($w + w^*$)_{y=-d} = 0, and are expressed in terms of the unknown constants A_0, B_0, a_0 and b_0 as:

$$\left. \begin{aligned} f_1^{(1)}(\beta) &= \frac{1}{2k} \left\{ -i \frac{(\lambda + |\beta|)^2}{\beta |\beta|} A_0 + \frac{(\lambda + |\beta|)^2}{\beta^2} B_0 \right\} + \frac{1}{k} \left\{ i \frac{\lambda + |\beta|}{\beta} a_0 + \frac{\lambda(\lambda + |\beta|)}{\beta^2} b_0 \right\} e^{-l(\lambda - |\beta|)}, \\ f_2^{(1)}(\beta) &= \frac{1}{k} \left\{ i \frac{\lambda + |\beta|}{\beta} A_0 - \frac{\lambda + |\beta|}{|\beta|} B_0 \right\} e^{l(\lambda - |\beta|)} + \frac{1}{2k} \left\{ -i \frac{(\lambda + |\beta|)^2}{\lambda \beta} a_0 - \frac{(\lambda + |\beta|)^2}{\beta^2} b_0 \right\}, \end{aligned} \right\} \quad (3.2)$$

where $l = kd$.

If we insert (2.9) and (3.2) into (3.1) and expand the integrands with respect to $e^{i\eta}$, retaining only constant terms as well as terms involving $e^{-i\eta}$, we obtain, after some lengthy calculations,

$$\begin{aligned} (w^*/k)_{\xi=\xi_0} &= A_0(G_1 + iG_2) + B_0(G_6 + iG_7) + a_0(G_{11} + iG_{12}) + b_0(G_{16} + iG_{17}) \\ &\quad + ke^{-i\eta} [A_0\{iG_3e^{i\theta} + \sigma^2(G_4 + iG_5)e^{-i\theta}\} + B_0\{iG_8e^{i\theta} + \sigma^2(G_9 + iG_{10})e^{-i\theta}\} \\ &\quad + a_0\{iG_{13}e^{i\theta} + \sigma^2(G_{14} + iG_{15})e^{-i\theta}\} + b_0\{iG_{18}e^{i\theta} + \sigma^2(G_{19} + iG_{20})e^{-i\theta}\}], \end{aligned} \quad (3.3)$$

where, for the sake of simplicity, we have put

$$\left. \begin{aligned} G_1 &= 1/2 \cdot l^{-1} + 1/4 \cdot \pi \{ J_0(2l) + J_2(2l) \} \cos 2l + 1/4 \cdot \pi \{ Y_0(2l) + Y_2(2l) \} \sin 2l - g_2(l), \\ G_2 &= -1/4 \cdot l^{-2} + 1/4 \cdot \pi \{ J_0(2l) + J_2(2l) \} \sin 2l - 1/4 \cdot \pi \{ Y_0(2l) + Y_2(2l) \} \cos 2l - 1/2 \cdot h_1(l) + h_2(l), \\ G_3 &= -1/2 \cdot l^{-2} - 1/2 \cdot h_1(l) + h_2(l), \\ G_4 &= 1/4 \cdot l^{-3} + 1/2 \cdot l^{-1} + 1/8 \cdot \pi \{ 2J_0(2l) + Y_1(2l) + 2J_2(2l) + Y_3(2l) \} \cos 2l \\ &\quad + 1/8 \cdot \pi \{ 2Y_0(2l) - J_1(2l) + 2Y_2(2l) - J_3(2l) \} \sin 2l - 1/4 \cdot g_1(l) - 5/4 \cdot g_2(l) + g_3(l), \\ G_5 &= 1/8 \cdot \pi \{ 2J_0(2l) + Y_1(2l) + 2J_2(2l) + Y_3(2l) \} \sin 2l \\ &\quad - 1/8 \cdot \pi \{ 2Y_0(2l) - J_1(2l) + 2Y_2(2l) - J_3(2l) \} \cos 2l + 3/4 \cdot h_2(l) - h_3(l), \\ G_6 &= 1/4 \cdot l^{-2} + 1/4 \cdot \pi \{ Y_0(2l) + Y_2(2l) \} \cos 2l - 1/4 \cdot \pi \{ J_0(2l) + J_2(2l) \} \sin 2l + 1/2 \cdot h_1(l) + h_2(l), \\ G_7 &= -1/2 \cdot l^{-1} + 1/4 \cdot \pi \{ J_0(2l) + J_2(2l) \} \cos 2l + 1/4 \cdot \pi \{ Y_0(2l) + Y_2(2l) \} \sin 2l - g_1(l) + g_2(l), \\ G_8 &= -g_1(l) + g_2(l), \\ G_9 &= 1/8 \cdot \pi \{ 2Y_0(2l) - J_1(2l) + 2Y_2(2l) - J_3(2l) \} \cos 2l \\ &\quad - 1/8 \cdot \pi \{ 2J_0(2l) + Y_1(2l) + 2J_2(2l) + Y_3(2l) \} \sin 2l + 1/2 \cdot h_1(l) + 3/4 \cdot h_2(l) - h_3(l), \\ G_{10} &= 1/4 \cdot l^{-3} + 1/8 \cdot \pi \{ 2J_0(2l) + Y_1(2l) + 2J_2(2l) + Y_3(2l) \} \cos 2l \\ &\quad + 1/8 \cdot \pi \{ 2Y_0(2l) - J_1(2l) + 2Y_2(2l) - J_3(2l) \} \sin 2l - 1/4 \cdot g_1(l) + 5/4 \cdot g_2(l) - g_3(l), \\ G_{11} &= -1/3 \cdot l + 1/4 \pi \{ I_0(2l) + I_2(2l) - L_0(2l) - L_2(2l) \} - g_1(l) + g_2(l), \\ G_{12} &= -1/4 \cdot l^{-2} - 1 - 1/2 \cdot K_0(2l) + 1/2 \cdot K_2(2l) + 1/2 \cdot \pi \{ I_1(2l) - L_1(2l) \} - 1/2 \cdot h_1(l) + h_2(l), \\ G_{13} &= 1/4 \cdot l^{-2} - 1 - 1/2 \cdot K_0(2l) + 1/2 \cdot K_2(2l) + 1/2 \cdot \pi \{ I_1(2l) - L_1(2l) \}, \\ G_{14} &= 1/4 \cdot l^{-3} - 1/3 \cdot l + 1/4 \cdot K_1(2l) - 1/4 \cdot K_3(2l) + 1/4 \cdot \pi \{ I_0(2l) + I_2(2l) - L_0(2l) - L_2(2l) \} \\ &\quad - 5/4 \cdot g_1(l) + 9/4 \cdot g_2(l) - g_3(l), \\ G_{15} &= -1/3 + 1/15 \cdot l^2 - 1/2 \cdot K_0(2l) + 1/2 \cdot K_2(2l) + 1/8 \cdot \pi \{ I_1(2l) - I_3(2l) - L_1(2l) + L_3(2l) \} \\ &\quad - 1/2 \cdot h_1(l) + 7/4 \cdot h_2(l) - h_3(l), \\ G_{16} &= -1/4 \cdot l^{-2} + 1 - 1/2 \cdot K_0(2l) + 1/2 \cdot K_2(2l) - 1/2 \cdot \pi \{ I_1(2l) - L_1(2l) \} - 1/2 \cdot h_1(l) - h_2(l), \\ G_{17} &= -l^{-1} + 1/3 \cdot l - 1/4 \cdot \pi \{ I_0(2l) + I_2(2l) - L_0(2l) - L_2(2l) \} + g_2(l), \\ G_{18} &= 1/3 \cdot l - 1/4 \cdot \pi \{ I_0(2l) + I_2(2l) - L_0(2l) - L_2(2l) \}, \\ G_{19} &= 1/4 \cdot l^{-2} + 2/3 + 1/15 \cdot l^2 - 1/8 \cdot \pi \{ 3I_1(2l) + I_3(2l) - 3L_1(2l) - L_3(2l) \} \\ &\quad - 1/2 \cdot h_1(l) - 3/4 \cdot h_2(l) + h_3(l), \\ G_{20} &= -1/4 \cdot l^{-3} - 1/2 \cdot l^{-1} - 1/4 \cdot K_1(2l) + 1/4 \cdot K_3(2l) + 1/4 \cdot g_1(l) + 5/4 \cdot g_2(l) - g_3(l), \end{aligned} \right\} \quad (3.4)$$

where $J_n(x)$ is the Bessel function of the first kind, $Y_n(x)$ is Neumann's Bessel function of the second kind, $I_n(x)$ is the modified Bessel function of the first kind and $\mathbf{L}_n(x)$ is Struve's function⁶⁾ of imaginary argument defined as:

$$\mathbf{L}_n(x) = \sum_{m=0}^{\infty} \frac{(1/2 \cdot x)^{n+2m+1}}{\Gamma(m+3/2)\Gamma(n+m+3/2)} . \quad (3.5)$$

also, the functions $g_n(x) = \int_0^{\infty} (u^2+1)^{-n} e^{-xu} du$ and $h_n(x) = \int_0^{\infty} u(u^2+1)^{-n} e^{-xu} du$ ($n=1, 2, 3$) are given by

$$\left. \begin{aligned} g_1(x) &= \text{Ci}(x) \sin x - \text{Si}(x) \cos x + 1/2 \cdot \pi \cos x , \\ g_2(x) &= 1/2 \{ \text{Ci}(x) \sin x - \text{Si}(x) \cos x + 1/2 \cdot \pi \cos x \} \\ &\quad - 1/2 \cdot x \{ \text{Ci}(x) \cos x + \text{Si}(x) \sin x - 1/2 \cdot \pi \sin x \} , \\ g_3(x) &= 1/8 \cdot x + 3/8 \{ \text{Ci}(x) \sin x - \text{Si}(x) \cos x + 1/2 \cdot \pi \cos x \} \\ &\quad - 3/8 \cdot x \{ \text{Ci}(x) \cos x + \text{Si}(x) \sin x - 1/2 \cdot \pi \sin x \} \\ &\quad - 1/8 \cdot x^2 \{ \text{Ci}(x) \sin x - \text{Si}(x) \cos x + 1/2 \cdot \pi \cos x \} , \end{aligned} \right\} \quad (3.6)$$

$$\left. \begin{aligned} h_1(x) &= -\text{Ci}(x) \cos x - \text{Si}(x) \sin x + 1/2 \cdot \pi \sin x , \\ h_2(x) &= 1/2 - 1/2 \cdot x \{ \text{Ci}(x) \sin x - \text{Si}(x) \cos x + 1/2 \cdot \pi \cos x \} , \\ h_3(x) &= 1/4 - 1/8 \cdot x \{ \text{Ci}(x) \sin x - \text{Si}(x) \cos x + 1/2 \cdot \pi \cos x \} \\ &\quad + 1/8 \cdot x^2 \{ \text{Ci}(x) \cos x + \text{Si}(x) \sin x - 1/2 \cdot \pi \sin x \} , \end{aligned} \right\} \quad (3.7)$$

with

$$\text{Si}(x) = \int_0^x \frac{\sin u}{u} du , \quad \text{Ci}(x) = - \int_x^{\infty} \frac{\cos u}{u} du . \quad (3.8)$$

Since the boundary conditions at infinity as well as on the bounding plane wall are already satisfied by w and w^* as given respectively by (2.8) and (3.1), we have only to consider the boundary condition at the surface of the elliptic cylinder. It is

$$(w + w^*)_{\xi=\xi_0} = -U . \quad (3.9)$$

Inserting (2.12) and (3.3) into (3.9), we have, on neglecting terms of $O(ka)$,

$$a_0 = A_0 , \quad (3.10)$$

$$b_0 = -B_0 , \quad (3.11)$$

$$A_0 = \frac{U}{k} \frac{F_1(kd) - 1/2 \cdot \sigma^2 \sin 2\vartheta}{\{1/2(1 + \sigma^2 \cos 2\vartheta) - F_3(kd)\}^2 - \{F_1(kd)\}^2 - \{-S + F_2(kd)\}^2 + 1/4 \cdot \sigma^4 \sinh^2 2\vartheta} , \quad (3.12)$$

$$B_0 = \frac{U}{k} \frac{1/2(1 + \sigma^2 \cos 2\vartheta) - F_3(kd) + \{-S + F_2(kd)\}}{\{1/2(1 + \sigma^2 \cos 2\vartheta) - F_3(kd)\}^2 - \{F_1(kd)\}^2 - \{-S + F_2(kd)\}^2 + 1/4 \cdot \sigma^4 \sin^2 2\vartheta} , \quad (3.13)$$

where, for the sake of convenience, we have used the same notations as in our previous paper²⁾, namely:

$$\left. \begin{aligned} F_1(l) &= G_1 + G_{11} = G_7 - G_{17} \\ &= 1/2 \cdot l^{-1} - 1/3 \cdot l + 1/4 \cdot \pi \{ J_0(2l) + J_2(2l) \} \cos 2l + 1/4 \cdot \pi \{ Y_0(2l) + Y_2(2l) \} \sin 2l \\ &\quad + 1/4 \cdot \pi \{ I_0(2l) + I_2(2l) - \mathbf{L}_0(2l) - \mathbf{L}_2(2l) \} - g_1(l) , \\ F_2(l) &= 1/2 \cdot (-G_2 + G_6 - G_{12} - G_{16}) \\ &= 1/2 \cdot l^{-2} + 1/2 \cdot K_0(2l) - 1/2 \cdot K_2(2l) - 1/4 \cdot \pi \{ J_0(2l) + J_2(2l) \} \sin 2l \\ &\quad + 1/4 \cdot \pi \{ Y_0(2l) + Y_2(2l) \} \cos 2l + h_1(l) , \\ F_3(l) &= 1/2 \cdot (G_2 + G_6 + G_{12} - G_{16}) = -1 + 1/2 \cdot \pi \{ I_1(2l) - \mathbf{L}_1(2l) \} + 2h_2(l) . \end{aligned} \right\} \quad (3.14)$$

The relation (3.11) has been obtained again independently of (2.7).

As in the case of a circular cylinder in a viscous liquid bounded either by a plane wall or by parallel plane walls, the lift L and the drag D experienced by the elliptic cylinder under discussion per unit length can be expressed as:

$$L = 2\pi\rho UA_0, \quad (3.15)$$

$$D = 2\pi\rho UB_0, \quad (3.16)$$

where ρ is the density of the liquid concerned.

Hence, if use is made of (3.12) and (3.13), we obtain for the lift and drag coefficients $C_L^{(1)}$ and $C_D^{(1)}$

$$\begin{aligned} C_L^{(1)} &= L/(1/2 \cdot \rho U^2 \cdot 2a) \\ &= \frac{8\pi}{R} \frac{F_1(kd) - 1/2 \cdot \sigma^2 \sin 2\vartheta}{\{1/2 \cdot (1 + \sigma^2 \cos 2\vartheta) - F_3(kd)\}^2 - \{F_1(kd)\}^2 - \{-S + F_2(kd)\}^2 + 1/4 \cdot \sigma^4 \sin^2 2\vartheta} \end{aligned} \quad (3.17)$$

$$\begin{aligned} C_D^{(1)} &= D/(1/2 \cdot \rho U^2 \cdot 2a) \\ &= \frac{8\pi}{R} \frac{1/2 \cdot (1 + \sigma^2 \cos 2\vartheta) - F_3(kd) + \{-S + F_2(kd)\}}{\{1/2 \cdot (1 + \sigma^2 \cos 2\vartheta) - F_3(kd)\}^2 - \{F_1(kd)\}^2 - \{-S + F_2(kd)\}^2 + 1/4 \cdot \sigma^4 \sin^2 2\vartheta}, \end{aligned} \quad (3.18)$$

where $R = 4ka$.

For a circular cylinder, we have only to put $\sigma = 0$ in (3.17) and (3.18), thus

$$\left. \begin{aligned} C_L^{(1)} &= \frac{8\pi}{R} \frac{F_1(kd)}{\{1/2 - F_3(kd)\}^2 - \{F_1(kd)\}^2 - \{-S + F_2(kd)\}^2}, \\ C_D^{(1)} &= \frac{8\pi}{R} \frac{1/2 - F_3(kd) + \{-S + F_2(kd)\}}{\{1/2 - F_3(kd)\}^2 - \{F_1(kd)\}^2 - \{-S + F_2(kd)\}^2}, \end{aligned} \right\} \quad (3.19)$$

which are in perfect agreement with the formulae obtained recently by the present writer.

When the bounding plane wall recedes far away to infinity from the centre of the cylinder, the value of kd tends to infinity and our case is reduced to the case of an elliptic cylinder in an unbounded stream of viscous liquid. The value of ka is, however, kept to be small.

Making use of the well-known asymptotic expressions for the Bessel functions $J_n(x)$, $Y_n(x)$ and $K_n(x)$, and also for $\text{Si}(x)$ and $\text{Ci}(x)$, together with

$$I_n(x) - \mathbf{I}_n(x) = \frac{1}{\pi} \sum_{m=0}^{p-1} (-1)^m \frac{\Gamma(m+1/2)}{\Gamma(n+1/2-m)(1/2 \cdot x)^{2m-n+1}} + O(x^{n-2p-1}), \quad (3.20)$$

we easily find that

$$\lim_{kd \rightarrow \infty} F_n(kd) \rightarrow 0 \quad (n=1, 2, 3)$$

Thus, we have ultimately

$$C_{L\infty} = \lim_{kd \rightarrow \infty} C_L^{(1)} \rightarrow \frac{16\pi}{R} \frac{\sigma^2 \sin 2\vartheta}{4S^2 - (1 + 2\sigma^2 \cos 2\vartheta + \sigma^4)}, \quad (3.21)$$

$$C_{D\infty} = \lim_{kd \rightarrow \infty} C_D^{(1)} \rightarrow \frac{16\pi}{R} \frac{2S - (1 + \sigma^2 \cos 2\vartheta)}{4S^2 - (1 + 2\sigma^2 \cos 2\vartheta + \sigma^4)}. \quad (3.22)$$

As should be expected, (3.21) and (3.22) are in perfect agreement with the first approximation obtained previously by H. Hasimoto⁷⁾, I. Imai⁸⁾ and others for the case of an elliptic cylinder in an unbounded viscous liquid.

On the other hand, in case when the value of kd becomes small subject to the restriction $d > a$ so that all terms higher than $(kd)^2$ can be neglected, we can make use of the well-known expansion formulae for the various functions used in $F_n(kd)$'s. Thus, we get ultimately approximate formulae for $C_L^{(1)}$ and $C_D^{(1)}$, which are valid for sufficiently small ka and kd , in the forms:

$$C_L^{(1)} = \frac{16\pi}{R} \frac{\sigma^2 \sin 2\vartheta + kd}{4\omega_1^2 - (1 + 2\sigma^2 \cos 2\vartheta + \sigma^4)}, \quad (3.23a)$$

$$\approx \frac{16\pi}{R} \frac{\sigma^2 \sin 2\vartheta}{4\omega_1^2 - (1 + 2\sigma^2 \cos 2\vartheta + \sigma^4)}, \quad (3.23b)$$

$$C_D^{(1)} = \frac{16\pi}{R} \frac{2\omega_1 - (1 + \sigma^2 \cos 2\vartheta)}{4\omega_1^2 - (1 + 2\sigma^2 \cos 2\vartheta + \sigma^4)}, \quad (3.24)$$

where

$$\omega_1 = \ln(2d) - 1/2. \quad (3.25)$$

§ 4. Elliptic Cylinder in a Viscous Liquid bounded by Two Parallel Plane Walls

In the special case when an elliptic cylinder is moving midway between two bounding plane walls, we superpose flows due to images, which are defined as:

$$\begin{aligned} w^* &= -\frac{1}{2}k^2 \int_{-\infty}^{\infty} (|\beta| + \beta) f_1^{(2)}(\beta) e^{k(i\beta x - |\beta|y)} d\beta \\ &\quad - \frac{1}{2}k^2 \int_{-\infty}^{\infty} (\lambda + \beta) f_2^{(2)}(\beta) e^{k(i\beta x - \lambda y)} d\beta, \end{aligned} \quad (4.1)$$

$$\begin{aligned} w^{**} &= \frac{1}{2}k^2 \int_{-\infty}^{\infty} (|\beta| - \beta) f_3^{(2)}(\beta) e^{k(i\beta x + |\beta|y)} d\beta \\ &\quad + \frac{1}{2}k^2 \int_{-\infty}^{\infty} (\lambda - \beta) f_4^{(2)}(\beta) e^{k(i\beta x + \lambda y)} d\beta, \end{aligned} \quad (4.2)$$

where $f_n^{(2)}(\beta)$'s are unknown functions to be determined by the boundary conditions on the bounding plane walls.

Remembering the relations (3.10) and (3.11), it is natural to put $a_0 = A_0$ and $b_0 = -B_0$. Thus, we have

$$\left. \begin{aligned} \frac{f_1^{(2)}}{f_3^{(2)}}(\beta) &= [(\lambda + |\beta|)e^{i(\lambda - |\beta|)} - (\lambda - |\beta|)e^{-i(\lambda + |\beta|)} - 2|\beta|]A_0/k|\beta|M_1(\beta) \\ &\quad \pm [(\lambda + |\beta|)e^{i(\lambda - |\beta|)} + (\lambda - |\beta|)e^{-i(\lambda + |\beta|)} - 2\lambda]B_0/ik\beta M_2(\beta), \\ \frac{f_2^{(2)}}{f_4^{(2)}}(\beta) &= [(\lambda + |\beta|)e^{-i(\lambda - |\beta|)} + (\lambda - |\beta|)e^{-i(\lambda + |\beta|)} - 2\lambda]A_0/k\lambda M_1(\beta) \\ &\quad \pm [(\lambda + |\beta|)e^{-i(\lambda - |\beta|)} - (\lambda - |\beta|)e^{-i(\lambda + |\beta|)} - 2|\beta|]B_0/ik\beta M_2(\beta), \end{aligned} \right\} \quad (4.3)$$

where we have put for brevity

$$\begin{aligned} \frac{M_1}{M_2}(\beta) &= (\lambda + |\beta|)\{e^{i(\lambda - |\beta|)} - e^{-i(\lambda - |\beta|)}\} \\ &\quad \pm (\lambda - |\beta|)\{e^{i(\lambda + |\beta|)} - e^{-i(\lambda + |\beta|)}\}. \end{aligned} \quad (4.4a)$$

We insert (2.9), (4.3) and (4.4a) into (4.1) and (4.2) and expand the integrands with respect to $e^{i\eta}$, retaining only constant terms as well as terms involving $e^{-i\eta}$. Then we obtain

$$\begin{aligned} (w^*/k + w^{**}/k)_{\xi \rightarrow \xi_0} &= -A_0 \left\{ \int_0^{\infty} [(\lambda + \beta)e^{i(\lambda + \beta)} - (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\beta] d\beta / M_1'(\beta) \right. \\ &\quad \left. + \int_0^{\infty} \beta [(\lambda + \beta)e^{-i(\lambda - \beta)} + (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\lambda] d\beta / \lambda M_1'(\beta) - C.C. \right\} \end{aligned}$$

Fig. 2.

$$\begin{aligned}
& + iB_0 \left\{ \int_0^\infty [(\lambda + \beta)e^{i(\lambda - \beta)} + (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\lambda] d\beta / M_2'(\beta) \right. \\
& \quad \left. + \int_0^\infty \lambda [(\lambda + \beta)e^{-i(\lambda - \beta)} - (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\beta] d\beta / \beta M_2'(\beta) - \text{C.C.} \right\} \\
& + i e^{-i\eta} \left[k e^{i\vartheta} A_0 \left\{ \int_0^\infty (\lambda^2 - \beta^2) [(\lambda + \beta)e^{-i(\lambda - \beta)} + (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\lambda] d\beta / 2\lambda M_1'(\beta) + \text{C.C.} \right\} \right. \\
& \quad \left. - k \sigma^2 e^{-i\vartheta} A_0 \left\{ \int_0^\infty \beta [(\lambda + \beta)e^{i(\lambda - \beta)} - (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\beta] / M_1'(\beta) \right. \right. \\
& \quad \left. \left. + \int_0^\infty (\lambda^2 + \beta^2) [(\lambda + \beta)e^{-i(\lambda - \beta)} + (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\lambda] d\beta / 2\lambda M_1'(\beta) + \text{C.C.} \right\} \right. \\
& \quad \left. + i k \sigma^2 e^{-i\vartheta} B_0 \left\{ \int_0^\infty \beta [(\lambda + \beta)e^{i(\lambda - \beta)} + (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\lambda] d\beta / M_2'(\beta) \right. \right. \\
& \quad \left. \left. + \int_0^\infty \lambda [(\lambda + \beta)e^{-i(\lambda - \beta)} - (\lambda - \beta)e^{-i(\lambda + \beta)} - 2\beta] d\beta / M_2'(\beta) + \text{C.C.} \right\} \right] , \quad (4.5)
\end{aligned}$$

where

$$\frac{M_1'}{M_2'}(\beta) = (\lambda + \beta) \{ e^{i(\lambda - \beta)} - e^{-i(\lambda - \beta)} \} \pm (\lambda - \beta) \{ e^{i(\lambda + \beta)} - e^{-i(\lambda + \beta)} \} . \quad (4.4b)$$

In (4.5) the notation C.C. stands for "the conjugate complex of the foregoing integrals".

Since it seems very difficult to evaluate exactly the integrals in (4.5), we confine ourselves to the evaluation of the integrals for sufficiently small values of kd such that all terms higher than $(kd)^{1/2}$ can be neglected. After straightforward calculations similar to those in our previous paper³⁾, we have finally

$$(w^*/k + w^{**}/k)_{\xi=\xi_0} = iA_0 \{ \ln(1/2 \cdot kd) + 0.4569 \} - B_0 \{ \ln(1/2 \cdot kd) - 0.8384 \} . \quad (4.6)$$

Making use of the relations $a_0 = A_0$ and $b_0 = -B_0$ we have from (2.12)

$$\begin{aligned}
(w/k)_{\xi=\xi_0} = & 1/2 \cdot A_0 \sigma^2 \sin 2\vartheta - 1/2 \cdot B_0 \{ 2S + (1 + \sigma^2 \cos 2\vartheta) \} \\
& + i[1/2 \cdot A_0 \{ 2S - (1 + \sigma^2 \cos 2\vartheta) \} - 1/2 \cdot B_0 \sigma^2 \sin 2\vartheta] . \quad (4.7)
\end{aligned}$$

The boundary condition at the surface of the elliptic cylinder is

$$(w + w^* + w^{**})_{\xi=\xi_0} = -U . \quad (4.8)$$

Inserting (4.6) and (4.7) into (4.8), we obtain

$$\left. \begin{aligned} A_0 &= \frac{U}{k} \frac{2\sigma^2 \sin 2\vartheta}{4\omega_2^2 - (0.0872 - 0.5906\sigma^2 \cos 2\vartheta + \sigma^4)} , \\ B_0 &= \frac{U}{k} \frac{2\{2\omega_2 - (-0.2953 + \sigma^2 \cos 2\vartheta)\}}{4\omega_2^2 - (0.0872 - 0.5906\sigma^2 \cos 2\vartheta + \sigma^4)} , \end{aligned} \right\} \quad (4.9)$$

where

$$\omega_2 = \ln d - \gamma - 0.1908 . \quad (4.10)$$

The lift L and the drag D experienced by the elliptic cylinder can also be calculated by (3.15) and (3.16) respectively. Thus we have for the lift and drag coefficients $C_L^{(2)}$ and $C_D^{(2)}$

$$C_L^{(2)} = L/(1/2 \cdot \rho U^2 \cdot 2a) = \frac{16\pi}{R} \frac{\sigma^2 \sin 2\vartheta}{4\omega_2^2 - (0.0872 - 0.5906\sigma^2 \cos 2\vartheta + \sigma^4)} , \quad (4.11)$$

$$C_D^{(2)} = D/(1/2 \cdot \rho U^2 \cdot 2a) = \frac{16\pi}{R} \frac{2\omega_2 - (-0.2953 + \sigma^2 \cos 2\vartheta)}{4\omega_2^2 - (0.0872 - 0.5906\sigma^2 \cos 2\vartheta + \sigma^4)} . \quad (4.12)$$

We may put $\sigma=0$ for a circular cylinder, and then (4.11) and (4.12) reduce simply to

$$\left. \begin{aligned} C_L^{(2)} &= 0 \\ C_D^{(2)} &= \frac{8\pi}{R \ln d - 0.9156} \end{aligned} \right\} \quad (4.13)$$

which are in perfect agreement with the formulae obtained previously by the present writer for a circular cylinder.

§ 5. Numerical Discussions

Numerical calculations were made for the cases $t=0$ (flat plate), 0.1, 0.5 and 1 (circular cylinder), where $t=b/a$ is the thickness ratio of the cylinder.

Fig. 3. Values of $C_D^{(1)}/(16\pi/R)$ plotted against Reynolds number R . Values of thickness ratio are indicated on the curves.

Fig. 4. Values of $C_L/(16\pi/R)$ at very low speeds ($R \approx 0$) plotted against angle of attack ϑ , for $d/a=10$. Values of thickness ratio are indicated on the curves.

—, single wall, calculated by (3.23b);
 ---, double walls, calculated by (4.11).

The values of $C_D^{(1)}/(16\pi/R)$ have been calculated by using the formulae (3.18) and (3.22) for various values ranging from 0.002 to 0.4 of the Reynolds number R . They are plotted in Fig. 3.

Table I and Fig. 4 give the values of $C_L/(16\pi/R)$ for sufficiently small Reynolds numbers R and $R^*(=Ud/\nu)$, calculated by using the formulae (3.23b) and (4.11), for various values of ϑ ranging from 0 to 90 deg., where the value of the ratio $d/a=10$.

Fig. 5. Values of $C_D/(16\pi/R)$ at very low speeds ($R \approx 0$) plotted against angle of attack ϑ , for $d/a=10$. Values of thickness ratio are indicated on the curves.

—, single wall, calculated by (3.24);
 ---, double walls, calculated by (4.12).

Fig. 6. Values of $C_L/(16\pi/R)$ at very low speeds ($R \approx 0$) plotted against d/a , for $\vartheta=45$ deg. Values of thickness ratio are indicated on the curves.

—, single wall, calculated by (3.23b);
 ---, double walls, calculated by (4.11).

Table II and Fig. 5 give the values of $C_D/(16\pi/R)$ for sufficiently small Reynolds numbers R and R^* , calculated by using the formulae (3.24) and (4.12), for various values of ϑ ranging from 0 to 90 deg., where the value of the ratio $d/a=10$.

It is worth noticing that the values of $C_L/(16\pi/R)$ and $C_D/(16\pi/R)$ for sufficiently small Reynolds numbers R and R^* are independent of them.

Table III and Fig. 6 give the values of $C_L/(16\pi/R)$, calculated by using the formulae (3.23b) and (4.11), for various values of the ratio d/a ranging from 10 to 100, where $\vartheta=45$ deg.

Table IV and Fig. 7 give the values of $C_D/(16\pi/R)$, calculated by using the formulae (3.24) and (4.12), for various values of the ratio d/a ranging from 10 to 100, where $\vartheta=45$ deg.

Table V and Fig. 8 give the values of $C_L/C_{L\infty}$, calculated by using the formulae (3.23b), (4.11) and (3.21), for various values

Fig. 7. Values of $C_D/(16\pi/R)$ at very low speeds ($R\approx 0$) plotted against d/a , for $\vartheta=45$ deg. Values of thickness ratio are indicated on the curves. —, single wall, calculated by (3.24); ---, double walls, calculated by (4.12).

The Forces Experienced by Two Elliptic Cylinders in a Uniform Flow at Small Reynolds Numbers

By Shinji KUWABARA

Department of Physics, Faculty of Science, University of Tokyo
(Received February 4, 1958)

Using Imai's general method of solving two-dimensional Oseen's equations, the drag and lift coefficients for one of two parallel elliptic cylinders in a uniform flow at small Reynolds numbers are calculated. When the thickness ratios of both elliptic cylinders are taken to be unity, the general expressions for these coefficients reduce to those for the case of two circular cylinders which have been obtained in the author's previous paper. The expressions for the case of two flat plates are also included as a special case.

§ 1. Introduction and Summary

In a previous paper¹⁾, the author studied the forces experienced by two circular cylinders in a uniform flow at small Reynolds

numbers. H. Fujikawa also studied the same problem^{2),3)} and further obtained the expressions for the drag and lift in power series in $1/d$ up to $O(1/d^4)$, where d is the distance

between the two circular cylinders⁴⁾. His expressions are considered to be valid even when the two cylinders are close to each other. In the present paper, studies on the flow past two elliptic cylinders at small Reynolds numbers will be carried out by Oseen's approximation.

As in the previous paper, we make use of Imai's general method of solving two-dimensional Oseen's equations⁵⁾. On the basis of his method, Imai himself investigated the uniform flow past an elliptic cylinder at an arbitrary angle of incidence and obtained the expressions for the velocity distribution near the elliptic cylinder as well as for the drag and lift up to a third approximation. In §2 we give the outline of Imai's method, and in §3 we apply it to the case of two elliptic cylinders in a modified form.

The effects of the elliptic cross-sections and the angles of incidence of both elliptic cylinders make the expressions for the drag and lift much more complicated than in the case of two circular cylinders. These effects are characterized by the following parameters: σ_1 , σ_2 , β_1 and β_2 , where $1+\sigma_1^2$, $1-\sigma_1^2$ and β_1 are respectively the semi-major axis, the semi-minor axis and the angle of incidence of the first elliptic cylinder and $a(1+\sigma_2^2)$, $a(1-\sigma_2^2)$ and β_2 are those of the second elliptic cylinder. The parameters which characterize the flow past two elliptic cylinders are σ_1 , σ_2 , β_1 , β_2 , a , d , α and R . a , d , α and R appeared already in the previous investigation, but R , the Reynolds number, is here based on the major axis of the first elliptic cylinder, so that $R=2U(1+\sigma_1^2)/\nu$ instead of $R=2U/\nu$.

In particular, if we put σ_1 and σ_2 equal to unity, then we have the formulae for the two flat plates, while if we make σ_1 and σ_2 vanish, the formulae reduce to those for the two circular cylinders which were obtained in the previous paper.

Numerical calculations were carried out in the following cases: (i) $a=1$; $h=10$; $t_1=t_2=0, 0.1, 0.5$; $\alpha=90^\circ$; $\beta_1=-\beta_2=0^\circ\sim 90^\circ$; $R=0.04\sim 1.0$; (ii) $a=1$; $h=10$; $t_1=t_2=0, 0.1, 0.5$; $\alpha=0^\circ, 180^\circ$; $\beta_1=0^\circ, 90^\circ$; $\beta_2=0^\circ, 90^\circ$; $R=0.04\sim 1.0$, where $t_1=(1-\sigma_1^2)/(1+\sigma_1^2)$, $t_2=(1-\sigma_2^2)/(1+\sigma_2^2)$ are the thickness ratios of the two cylinders respectively and $h=d/(1+\sigma_1^2)$.

§ 2. Imai's Method of Solving Oseen's Equations

In the previous paper¹⁾, we have given the general expression for the complex velocity to the Oseen approximation. But it is inconvenient for the application to the elliptic cylinder. Therefore, we need the expression for the complex velocity which can be applied to arbitrary profiles. We derive this, following Imai's deduction⁵⁾.

We introduce the complex variables

$$z=x+iy=re^{i\theta}, \quad \bar{z}=x-iy=re^{-i\theta}, \quad (2.1)$$

and

$$W=u-iv, \quad (2.2)$$

where (x, y) are the Cartesian coordinates, (u, v) the velocity components and (r, θ) the polar coordinates. In the previous paper, we obtained the complex velocity to Oseen's approximation as

$$W = \frac{i}{2k} e^{kz} \left\{ A_1 K_0(kr) + \sum_{n=1}^{\infty} (A_{n+1} e^{n i \theta} - \bar{A}_n e^{-n i \theta}) K_n(kr) \right\} + \frac{df}{dz}, \quad (2.3)$$

and

$$f(z) = Uz + \frac{m+i\Gamma}{2\pi} \ln z + O\left(\frac{1}{z}\right), \quad (2.4)$$

which satisfies the boundary conditions at infinity. Here $2k=U/\nu$ (U is the velocity of the uniform flow in the direction of the x -axis and ν the kinematic viscosity), A_n 's are complex coefficients, m and Γ are real constants and K_n is the modified Bessel function of the second kind.

If we consider only the state near the cylinder, the argument kr of the Bessel function is expected to be $O(R)$, R being the Reynolds number which is assumed small. Hence, we can expand Bessel functions in the power series of kr , then we have

$$W = \frac{df}{dz} - \frac{i}{2k} e^{kz} \left[\frac{8}{k^3} g''(z) + \frac{4}{k^2} \bar{g}'(\bar{z}) + \frac{2}{k} \bar{z} g'(z) + z \bar{g}(\bar{z}) - \frac{k^3}{32} \bar{A}_1 z \bar{z}^2 \left(\ln \bar{z} - 2S - \frac{3}{2} \right) - \frac{k}{4} A_2 z (\ln z - 2S - 1) \right], \quad (2.5)$$

where

$$S = \ln(2/k) - \gamma, \quad (2.6)$$

$$g(z) = \frac{1}{32} k^3 A_1 \left\{ z^2 \ln z - \frac{1}{2} z^2 - (2S+1)z^2 \right\}$$

$$+\frac{1}{8}k^2\bar{A}_1z(\ln z-1)-\frac{1}{4}k\bar{A}_2\ln z$$

$$+\frac{1}{4}k\sum_{n=3}^{\infty}(n-3)!\bar{A}_n\left(\frac{1}{2}kz\right)^{2-n}. \quad (2.7)$$

If we assume the following forms, in view of the form of W ,

$$\bar{A}_1=k(a_0+ka_1+k^2a_2+\dots), \quad (2.8a)$$

$$\bar{A}_2=k^2(b_0+kb_1+k^2b_2+\dots), \quad (2.8b)$$

$$g(z)=k^3\{g_0(z)+kg_1(z)+k^2g_2(z)+\dots\}, \quad (2.8c)$$

$$f(z)=k^{-1}\{f_0(z)+kf_1(z)+k^2f_2(z)+\dots\}, \quad (2.8d)$$

we have from (2.7) and (2.8)

$$g_0''(z)=\frac{1}{8}\frac{a_0}{z}+\frac{1}{4}\frac{b_0}{z^2}+\dots, \quad (2.9a)$$

$$g_m''(z)=\frac{1}{16}\bar{a}_{m-1}(\ln z-2S)+\frac{1}{8}\frac{a_m}{z}+\frac{1}{4}\frac{b_m}{z^2}+\dots$$

$$(m=1, 2, \dots) \quad (2.9b)$$

The condition $W=0$ at the surface of the cylinder, or the modified condition:

$$e^{-kz}W=0 \quad (2.10)$$

is sufficient to determine the analytic functions $f(z)$ and $g(z)$. Equating to zero the coefficients of each power of k of the left-hand side of (2.10), we have a series of equations:

$$f_0'(z)=4ig_0''(z), \quad (2.11a)$$

$$f_1'(z)=\frac{1}{2}(z+\bar{z})f_0'(z)+4ig_1''(z)+2i\bar{g}_0'(\bar{z}), \quad (2.11b)$$

$$f_2'(z)=\frac{1}{2}(z+\bar{z})f_1'(z)-\frac{1}{2}(z+\bar{z})^2f_0'(z)$$

$$+i\{4g_2''(z)+2\bar{g}_1'(\bar{z})+\bar{z}g_0'(\bar{z})\}, \quad (2.11c)$$

on the profile. Then, we rearrange (2.5) and obtain the complex velocity near the cylinder as

$$W=e^{kz}\sum_{n=0}^{\infty}k^n\{F_{n+1}(z)-G_n(z, \bar{z})\}, \quad (2.12)$$

where

$$F_n(z)=f_n'(z)-4ig_n''(z) \quad (2.13)$$

and

$$G_0(z, \bar{z})=\frac{1}{2}(z+\bar{z})f_0'(z)+2i\bar{g}_0'(\bar{z}), \quad (2.14)$$

$$G_1(z, \bar{z})=\frac{1}{2}(z+\bar{z})f_1'(z)-\frac{1}{2}(z+\bar{z})^2f_0'(z)$$

$$+i\{2\bar{g}_1'(\bar{z})+\bar{z}g_0'(\bar{z})\}, \quad (2.15)$$

and so on. The terms of $O(k^{-1})$ in (2.12) have been omitted on account of the boundary condition (2.11a) which holds throughout the field of flow.

The boundary conditions on the profile are

$$F_{n+1}(z)=G_n(z, \bar{z}). \quad (2.16)$$

To a first approximation, we have

$$F_1(z)=G_0(z, \bar{z}), \quad (2.17)$$

with

$$F_1(z)=f_1'(z)-4ig_1''(z), \quad (2.18)$$

$$G_0(z, \bar{z})=\frac{1}{2}(z+\bar{z})f_0'(z)+2i\bar{g}_0'(\bar{z}). \quad (2.19)$$

We assume that the region outside the profile can be mapped onto the region outside a unit circle in the Z -plane by the transformation function

$$z=\omega(Z). \quad (2.20)$$

Then (2.17) becomes

$$F_1[\omega(\zeta)]=G_0[\omega(\zeta), \bar{\omega}(\bar{\zeta})] \quad \text{for } \zeta=e^{i\theta}. \quad (2.21)$$

Substituting from (2.4), (2.9) and (2.20) into (2.18), we have

$$F_1[\omega(\zeta)]=U-\frac{1}{2}i\bar{a}_0\{\ln \omega(\zeta)-2S\}+P(Z^{-1}), \quad (2.22)$$

where $P(Z)=\sum_{n=1}^{\infty}C_nZ^n$. (2.21) and (2.22) lead to an integro-differential equation for the function $g_0'(z)$ of the form:

$$\oint_C \frac{G_0[\omega(\zeta), \bar{\omega}(\bar{\zeta})]+\frac{1}{2}i\bar{a}_0\ln \omega(\zeta)}{\zeta-Z}d\zeta$$

$$=2\pi i(U+\frac{1}{2}i\bar{a}_0S), \quad (2.23)$$

where C is the unit circle. Thus, the first approximation has been completed. The successive approximations can be carried out in the same way.

§ 3. Application of Imai's Method to the Case of Two Elliptic Cylinders

In the general cases of two elliptic cylinders submerged in a uniform flow at small Reynolds numbers, we assume the following form for the complex velocity

$$W(z_1, z_2)=W_1(z_1)+W_2(z_2)+U, \quad (3.1)$$

with

$$W_1(z_1)=e^{kx_1}\sum_{n=1}^{\infty}k^n\{F_{n+1}^{(1)}(z_1)-G_n^{(1)}(z_1, \bar{z}_1)\}, \quad (3.2)$$

$$W_2(z_2)=\frac{i}{2k}e^{kx_2}\left\{A_1^{(2)}K_0(kr_2)+\sum_{n=1}^{\infty}(A_{n+1}^{(2)}e^{n i\theta_2}\right.$$

$$\left.-\bar{A}_n^{(2)}e^{-n i\theta_2})K_n(kr_2)\right\}+\frac{df^{(2)}}{dz_2}, \quad (3.3)$$

near the first elliptic cylinder E_1 and with

$$W_1(z_1)=\frac{i}{2k}e^{kx_1}\left\{A_1^{(1)}K_0(kr_1)+\sum_{n=1}^{\infty}(A_{n+1}^{(1)}e^{n i\theta_1}\right.$$

$$\left.-\bar{A}_n^{(1)}e^{-n i\theta_1})K_n(kr_1)\right\}+\frac{df^{(1)}}{dz_1}, \quad (3.4)$$

$$W_2(z_2)=e^{kx_2}\sum_{n=1}^{\infty}k^n\{F_{n+1}^{(2)}(z_2)-G_n^{(2)}(z_2, \bar{z}_2)\}, \quad (3.5)$$

near the second elliptic cylinder E_2 alternatively. Here $F_{n+1}^{(1)}(z_1)$, $F_{n+1}^{(2)}(z_2)$, $G_n^{(1)}(z_1, \bar{z}_1)$,

$G_n^{(2)}(z_2, \bar{z}_2)$, $f^{(1)}(z_1)$, $f^{(2)}(z_2)$ and so on have forms similar to those obtained in § 2 except that they are devoid of the terms corresponding to the uniform flow. Also z_1 and z_2 are the vectors drawn from the centres of the elliptic cylinders E_1 and E_2 to the point in

Fig. 1. The general configuration of two elliptic cylinders.

question and $de^{i\alpha}$ is the vector connecting the centres of E_1 and E_2 (cf. Fig. 1.).

By the transformation function

$$z_1 = C_1 \left(Z_1 + \frac{\sigma_1^2}{Z_1} \right), \quad (0 \leq \sigma_1 \leq 1, C_1 = e^{-i\beta_1}) \quad (3.6)$$

the unit circle $Z_1 = e^{i\theta}$ in the Z_1 -plane is mapped onto the first ellipse which is inclined at an angle β_1 with respect to the x_1 -axis and whose semi-major and semi-minor axes are respectively

$$a_1 = 1 + \sigma_1^2, \quad b_1 = 1 - \sigma_1^2. \quad (3.7)$$

The expressions corresponding to (3.6) and (3.7) for the second ellipse E_2 are

$$z_2 = C_2 \left(Z_2 + \frac{\sigma_2^2}{Z_2} \right), \quad (0 \leq \sigma_2 \leq 1, C_2 = ae^{-i\beta_2}), \quad (3.8)$$

$$a_2 = a(1 + \sigma_2^2), \quad b_2 = a(1 - \sigma_2^2). \quad (3.9)$$

In this paper we shall confine ourselves to the first approximation. Thus we take only the terms of $O(k^0)$ in the complex velocity. Then, (3.2) and (3.5) reduce to

$$W_p(z_p) = F_1^{(p)}(z_p) - G_0^{(p)}(z_p, \bar{z}_p) \quad \text{near } E_p. \quad (3.10)$$

Here as well as in what follows, $p=1$ and 2 correspond to the first and the second ellipse respectively. From (2.4), (2.9), (2.11a), (3.6) and (3.8), we have

$$f_1^{(p)'}(z_p) = P(Z_p^{-1}), \quad (3.11)$$

$$g_1^{(p)'}(z_p) = \frac{1}{16} \bar{a}_0^{(p)} (\ln C_p Z_p - 2S) + P(Z_p^{-1}), \quad (3.12)$$

$$\bar{g}_0^{(p)'}(\bar{z}_p) = \frac{1}{8} \bar{a}_0^{(p)} \ln \bar{C}_p \bar{Z}_p + P(\bar{Z}_p^{-1}), \quad (3.13)$$

$$f_0^{(p)'}(z_p) = 4i g_0^{(p)'}(z_p) = \frac{1}{2} i a_0^{(p)} C_p^{-1} Z_p^{-1} \{1 + P(Z_p^{-1})\}. \quad (3.14)$$

Hence, by (2.13) and (2.14) we have

$$F_1^{(p)}(z_p) = -\frac{1}{4} i \bar{a}_0^{(p)} (\ln C_p Z_p - 2S) + P(Z_p^{-1}), \quad (3.15)$$

$$G_0^{(p)}(z_p, \bar{z}_p) = \frac{1}{4} i a_0^{(p)} (1 + \sigma_p^2 \bar{D}_p^2) - \frac{1}{4} i \bar{a}_0^{(p)} \ln C_p Z_p + 2i \{ \bar{g}_0^{(p)'}(\bar{z}_p) - \frac{1}{8} \bar{a}_0^{(p)} \ln \bar{C}_p \bar{Z}_p \} + P(Z_p^{-1}), \quad (3.16)$$

where $D_p = e^{-i\beta_p}$ ($=C_1$ or C_2/a according as $p=1$ or 2). By use of (3.15) and (3.16), we can rewrite (3.10) explicitly as

$$W_p(z_p) = -\frac{1}{4} i a_0^{(p)} (1 + \sigma_p^2 \bar{D}_p^2) + \frac{1}{4} i \bar{a}_0^{(p)} S_p + 2i \{ \bar{g}_0^{(p)'}(\bar{z}_p) - \frac{1}{8} \bar{a}_0^{(p)} \ln \bar{C}_p \bar{Z}_p \} + P(Z_p^{-1}) \quad \text{near } E_p, \quad (3.17)$$

where

$$S_1 = \ln(2/k) - \gamma, \quad S_2 = \ln(2/ka) - \gamma. \quad (3.18)$$

We now assume that $kd \geq O(1)$ so that $K_n(kd) = O(1)^*$. Taking the terms of $O(k^0)$ in (3.3) and (3.4), we obtain

$$W_q(z_q) = \frac{i}{2k} e^{kd \cos(\alpha + p\pi)} (A_1^{(q)} K_0 - \bar{A}_1^{(q)} e^{-i(\alpha + p\pi)} K_1) + \frac{1}{k} \frac{df_0^{(q)}}{dz_q} + P(Z_p) \quad \text{near } E_p,$$

where $q \approx p$, that is, $q=3-p$ and we have put $K_n(kd) = K_n$ for brevity. By use of (2.8) and (3.14), which hold throughout the field of flow, we rewrite the above expressions as follows.

$$W_q(z_q) = \frac{i}{2} (K_1 e^{kd \cos(\alpha + p\pi)} - 1/kd) e^{-i(\alpha + p\pi)} a_0^{(q)} + \frac{i}{2} K_0 e^{kd \cos(\alpha + p\pi)} \bar{a}_0^{(q)} + P(Z_p). \quad (3.19)$$

The boundary conditions are

$$W(z_1, z_2) = W_1(z_1) + W_2(z_2) + U = 0, \quad (3.20)$$

on the surfaces of E_1 and E_2 . Substituting from (3.17) and (3.19) into (3.20), we obtain

$$g_0^{(p)'}(z_p) - \frac{1}{8} a_0^{(p)} \ln C_p Z_p + P(Z_p^{-1}) = \frac{1}{8} \{ 4iU + 2a_0^{(p)} S_p - \bar{a}_0^{(p)} (1 + \sigma_p^2 \bar{D}_p^2) + 2K_0 e^{kd \cos(\alpha + p\pi)} a_0^{(q)} \}$$

* If $kd \rightarrow \infty$, then $K_n(kd) \rightarrow 0$. The following argument is also valid for such a case.

$$+2(K_1 e^{kd \cos(\alpha + p\pi)} - 1/kd) e^{i\alpha} \bar{a}_0^{(q)} \} + P(Z_p) \quad (3.21)$$

on the profile $Z_p = e^{i\theta}$. From (2.9), we find that the left-hand side of (3.21) is $P(Z^{-1})$, while the right-hand side is $P(Z)$. Hence both sides must be separately equal to zero. Thus we have

$$g_0^{(p)'}(z_p) = \frac{1}{2} a_0^{(p)} \ln C_p Z_p, \quad (3.22)$$

$$\begin{aligned} 4iU &= -2a_0^{(p)} S_p + \bar{a}_0^{(p)} (1 + \sigma_p^2 D_p^2) \\ &\quad - 2K_0 e^{kd \cos(\alpha + p\pi)} a_0^{(q)} \\ &\quad - 2(K_1 e^{kd \cos(\alpha + p\pi)} - 1/kd) e^{i\alpha} \bar{a}_0^{(q)}. \end{aligned} \quad (3.23)$$

From (3.23) and its complex conjugate, we can determine $a_0^{(1)}$ and $a_0^{(2)}$.

Substituting (3.22) into (2.11a) and using (3.6), we obtain

$$\begin{aligned} f_0^{(1)'} &= 4i \frac{dg_0^{(1)'}(z_1)}{dZ_1} \bigg/ \frac{dz_1}{dZ_1} = \frac{ia_0^{(1)}}{2C_1} \frac{Z_1}{Z_1^2 - \sigma_1^2} \\ &\quad + P(Z_1^{-2}). \end{aligned} \quad (3.24)$$

Now the drag coefficient $C_D^{(p)}$ and the lift coefficient $C_L^{(p)}$ for the elliptic cylinder E_p are respectively defined as

$$C_D^{(p)} = -\frac{X_p}{\frac{1}{2}\rho U^2 a_p}, \quad C_L^{(p)} = \frac{Y_p}{\frac{1}{2}\rho U^2 a_p}, \quad (3.25)$$

where X_p and Y_p are the drag and lift of the elliptic cylinder E_p ($p=1, 2$).

It is known⁽⁶⁾ that the drag X and the lift Y of a cylinder are given by

$$X = \rho U m, \quad Y = \rho U \Gamma, \quad (3.26)$$

where $(m + i\Gamma)/2\pi$ is the coefficient of $1/z$ in the asymptotic expansion of df/dz , as given by (2.4). Hence it may be supposed that we can put

$$X_p = \rho U m_p, \quad Y_p = \rho U \Gamma_p, \quad (3.27)$$

where $(m_p + i\Gamma_p)/2\pi$ is the coefficient of $1/z_p$ in the asymptotic expansion of $df^{(p)}/dz_p$.

$$a_0^{(1)} = -2iU$$

$$\times \frac{(S - \frac{1}{2} - \frac{1}{2}\sigma^2 \cos 2\beta - K_0) + i(K_1 - 4/Rh + \frac{1}{2}\sigma^2 \sin 2\beta)}{(S + \frac{1}{2} + \frac{1}{2}\sigma^2 \cos 2\beta + K_0)(S - \frac{1}{2} - \frac{1}{2}\sigma^2 \cos 2\beta - K_0) + (K_1 - 4/Rh + \frac{1}{2}\sigma^2 \sin 2\beta)(K_1 - 4/Rh - \frac{1}{2}\sigma^2 \sin 2\beta)}, \quad (4.3)$$

where $h = d/(1 + \sigma^2)$ is the ratio of the distance between the two cylinders to the semi-major axis of the elliptic cylinder.

Substituting from (4.3) into (3.29) and taking the real and imaginary parts, we obtain

$$C_D^{(1)} = \frac{8\pi}{R}$$

$$\times \frac{S - \frac{1}{2} - \frac{1}{2}\sigma^2 \cos 2\beta - K_0}{(S + \frac{1}{2} + \frac{1}{2}\sigma^2 \cos 2\beta + K_0)(S - \frac{1}{2} - \frac{1}{2}\sigma^2 \cos 2\beta - K_0) + (K_1 - 4/Rh + \frac{1}{2}\sigma^2 \sin 2\beta)(K_1 - 4/Rh - \frac{1}{2}\sigma^2 \sin 2\beta)}, \quad (4.4)$$

It is obviously sufficient to consider the lift and drag coefficients of the first cylinder E_1 only. Now, we have from (2.8d)

$$\frac{df^{(1)}}{dz_1} = \frac{1}{k} \{f_0^{(1)'} + k f_1^{(1)'} + \dots\}.$$

Hence, we obtain from (3.24), in the first approximation,

$$\frac{m_1 + i\Gamma_1}{2\pi} = \frac{ia_0^{(1)}}{2k}. \quad (3.28)$$

Substituting from (3.27) and (3.28) into (3.25), we have

$$C_D^{(1)} + iC_L^{(1)} = \frac{4\pi ia_0^{(1)}}{UR}, \quad (3.29)$$

where $R = 4(1 + \sigma_1^2)k$ is the Reynolds number based on the major axis of the first elliptic cylinder.

§ 4. The Case of the Symmetrical Configurations with the Central Line Perpendicular to the Uniform Flow

In this section, we apply the method given in the last section to the flow past two equal elliptic cylinders placed symmetrically with the central line perpendicular to the oncoming uniform flow, that is, $a=1$, $\sigma_1 = \sigma_2 = \sigma$, $\beta_1 = -\beta_2 = \beta$ and $\alpha = \pi/2$ so that $S_1 = S_2 = S$, $C_1 = \bar{C}_2 = C = e^{-i\beta}$ (cf. Fig. 2 (a)). In this case, in view of symmetry, we find

$$W_1(z) = \bar{W}_2(z),$$

so that

$$a_0^{(1)} = -\bar{a}_0^{(2)}, \quad (4.1)$$

and consequently (3.23) can be written as

$$\begin{aligned} 4iU &= -2\{S - i(K_1 - 1/kd)\}a_0^{(1)} \\ &\quad + (1 + \sigma_1^2 C_1^2 + 2K_0)\bar{a}_0^{(1)}. \end{aligned} \quad (4.2)$$

From (4.2) and its complex conjugate, we have

Fig. 2. (a)-(d)

Fig. 2. The symmetrical configurations with the central line perpendicular to the uniform flow. The drag and lift coefficients of the hatched cylinders and the thick flat plates are considered.

$$C_L^{(1)} = \frac{8\pi}{R} \times \frac{K_1 - 4/Rh \frac{1}{2} + \sigma^2 \sin 2\beta}{(S + \frac{1}{2} + \frac{1}{2}\sigma^2 \cos 2\beta + K_0)(S - \frac{1}{2} - \frac{1}{2}\sigma^2 \cos 2\beta - K_0) + (K_1 - 4/Rh + \frac{1}{2}\sigma^2 \sin 2\beta)(K_1 - 4/Rh - \frac{1}{2}\sigma^2 \sin 2\beta)}, \quad (4.5)$$

$$\text{where} \quad R = 2(1 + \sigma^2)U/\nu, \quad (4.6)$$

$$S = \ln [8(1 + \sigma^2)/R] - \gamma, \quad (4.7)$$

$$K_0 = K_0(Rh/4), \quad K_1 = K_1(Rh/4), \quad (4.8)$$

$$\text{and} \quad h = d/(1 + \sigma^2). \quad (4.9)$$

Next, we consider some special cases of interest.

(A) Case when the elliptic two cylinders are both parallel or perpendicular to the flow direction.

Putting $\beta = 0$ in (4.4) and (4.5), we have

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S - \frac{1}{2} - \frac{1}{2}\sigma^2 - K_0}{(S + \frac{1}{2} + \frac{1}{2}\sigma^2 + K_0)(S - \frac{1}{2} - \frac{1}{2}\sigma^2 - K_0) + (K_1 - 4/Rh)^2}, \quad (4.10)$$

$$C_L^{(1)} = \frac{8\pi}{R} \frac{K_1 - 4/Rh}{(S + \frac{1}{2} + \frac{1}{2}\sigma^2 + K_0)(S - \frac{1}{2} - \frac{1}{2}\sigma^2 - K_0) + (K_1 - 4/Rh)^2}, \quad (4.11)$$

for the first of the two elliptic cylinders both with their major axes parallel to the flow direction (cf. Fig. 2 (b)). Also, putting $\beta = \pi/2$, we have

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S - \frac{1}{2} + \frac{1}{2}\sigma^2 - K_0}{(S + \frac{1}{2} - \frac{1}{2}\sigma^2 + K_0)(S - \frac{1}{2} + \frac{1}{2}\sigma^2 - K_0) + (K_1 - 4/Rh)^2}, \quad (4.12)$$

$$C_L^{(1)} = \frac{8\pi}{R} \frac{K_1 - 4/Rh}{(S + \frac{1}{2} - \frac{1}{2}\sigma^2 + K_0)(S - \frac{1}{2} + \frac{1}{2}\sigma^2 - K_0) + (K_1 - 4/Rh)^2}, \quad (4.13)$$

for the first of the two elliptic cylinders with their major axes perpendicular to the flow direction (*cf.* Fig. 2 (c)).

(B) Case of two circular cylinders.

In this case, we put $\sigma=0$ in (4.4) and (4.5). Thus we have

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S - \frac{1}{2} - K_0}{(S + \frac{1}{2} + K_0)(S - \frac{1}{2} - K_0) + (K_1 - 4/Rd)^2}, \quad (4.14)$$

$$C_L^{(1)} = \frac{8\pi}{R} \frac{K_1 - 4/Rd}{(S + \frac{1}{2} + K_0)(S - \frac{1}{2} - K_0) + (K_1 - 4/Rd)^2}. \quad (4.15)$$

They agree with the expressions (3.41) and (3.42) given in the previous paper¹⁾ (*cf.* Fig. 2(d)).

(C) Case of two flat plates.

For two flat plates, we put $\sigma=1$ in (4.4) and (4.5). Thus, we have

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S - \frac{1}{2} - \frac{1}{2} \cos 2\beta - K_0}{(S + \frac{1}{2} + \frac{1}{2} \cos 2\beta + K_0)(S - \frac{1}{2} - \frac{1}{2} \cos 2\beta - K_0) + (K_1 - 4/Rh + \frac{1}{2} \sin 2\beta)(K_1 - 4/Rh - \frac{1}{2} \sin 2\beta)}, \quad (4.16)$$

$$C_L^{(1)} = \frac{8\pi}{R} \frac{K_1 - 4/Rh + \frac{1}{2} \sin 2\beta}{(S + \frac{1}{2} + \frac{1}{2} \cos 2\beta + K_0)(S - \frac{1}{2} - \frac{1}{2} \cos 2\beta - K_0) + (K_1 - 4/Rh + \frac{1}{2} \sin 2\beta)(K_1 - 4/Rh - \frac{1}{2} \sin 2\beta)}, \quad (4.17)$$

for the first of the two flat plates symmetrically placed with respect to the uniform flow at arbitrary angles of incidence (*cf.* Fig. 2 (e)). In particular, putting $\beta=0$, we have

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S - 1 - K_0}{(S + 1 + K_0)(S - 1 - K_0) + (K_1 - 4/Rh)^2}, \quad (4.18)$$

$$C_L^{(1)} = \frac{8\pi}{R} \frac{K_1 - 4/Rh}{(S + 1 + K_0)(S - 1 - K_0) + (K_1 - 4/Rh)^2}, \quad (4.19)$$

for the first of the two flat plates both parallel to the uniform flow (*cf.* Fig. 2 (f)). Also, putting $\beta=\pi/2$, we have

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S - K_0}{(S + K_0)(S - K_0) + (K_1 - 4/Rh)^2}, \quad (4.20)$$

$$C_L^{(1)} = \frac{8\pi}{R} \frac{K_1 - 4/Rh}{(S + K_0)(S - K_0) + (K_1 - 4/Rh)^2}, \quad (4.21)$$

for the first of the two flat plates perpendicular to the uniform flow (*cf.* Fig. 2 (g)).

§ 5. The Case of Symmetrical Configurations with the Central Line Parallel to the Uniform Flow

In the case when the two elliptic cylinders are placed symmetrically with the central line parallel to the uniform flow (*cf.* Fig. 3), that is, $\beta_1=0$ or $\pi/2$, $\beta_2=0$ or $\pi/2$ and $\alpha=0$ or π , we find in view of symmetry that the lifts of both cylinders vanish, so that we can suppose that $a_0^{(1)}$ and $a_0^{(2)}$ are purely imaginary. Thus

$$a_0^{(1)} = -\bar{a}_0^{(1)}, \quad a_0^{(2)} = -\bar{a}_0^{(2)}. \quad (5.1)$$

We can solve (3.23) for $a_0^{(1)}$, and then substituting it into (3.29), we obtain

$$C_D^{(1)} = \frac{8\pi}{R} \times \frac{S_2 + \frac{1}{2} + \frac{1}{2}\sigma_2^2 \cos 2\beta_2 - (K_0 - K_1 \cos \alpha)e^{-Rh \cos \alpha/4} - 4 \cos \alpha/Rh}{(S_1 + \frac{1}{2} + \frac{1}{2}\sigma_1^2 \cos 2\beta_1)(S_2 + \frac{1}{2} + \sigma_2^2 \cos 2\beta_2) - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}, \quad (5.2)$$

where

$$R = 2(1 + \sigma_1^2)U/\nu, \quad (5.3)$$

$$S_1 = \ln [8(1 + \sigma_1^2)/R] - \gamma, \quad S_2 = \ln [8(1 + \sigma_1^2)/Ra] - \gamma, \quad (5.4)$$

$$K_0 = K_0(Rh/4), \quad K_1 = K_1(Rh/4). \quad (5.5)$$

They include many configurations according to the parameters α , β_1 , β_2 , σ_1 and σ_2 , as sketched in Fig. 3. Next, we consider some special cases of interest.

(A) Case of two equal elliptic cylinders.

In this case, $a=1$. Hence we put $S_1=S_2=S$ and $\sigma_1=\sigma_2=\sigma$ in (5.2). Then, we have

(i) $\beta_1=\beta_2=0$; $\alpha=0$ or π (cf. Fig. 3 (a) and (b)):

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S + \frac{1}{2}(1 + \sigma^2) - (K_0 \mp K_1)e^{\mp Rh/4} \mp 4/Rh}{\{S + \frac{1}{2}(1 + \sigma^2)\}^2 - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}, \quad (5.6)$$

where as well as in what follows the upper and lower signs correspond to $\alpha=0$ and $\alpha=\pi$ respectively.

Fig. 3. (a)-(f)

Fig. 3. (g)-(l).

(ii) $\beta_1=0$, $\beta_2=\pi/2$; $\alpha=0$ or π (cf. Fig. 3 (c) and (d)):

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S + \frac{1}{2}(1-\sigma^2) - (K_0 \mp K_1)e^{\mp Rh/4} \mp 4/Rh}{\{S + \frac{1}{2}(1+\sigma^2)\}\{S + \frac{1}{2}(1-\sigma^2)\}^2 - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}, \quad (5.7)$$

(iii) $\beta_1=\pi/2$, $\beta_2=0$; $\alpha=0$ or π (cf. Fig. 3 (e) and (f)):

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S + \frac{1}{2}(1+\sigma^2) - (K_0 \mp K_1)e^{\mp Rh/4} \mp 4/Rh}{\{S + \frac{1}{2}(1+\sigma^2)\}\{S + \frac{1}{2}(1-\sigma^2)\} - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}. \quad (5.8)$$

(iv) $\beta_1=\beta_2=\pi/2$; $\alpha=0$ or π (cf. Fig. 3 (g) and (h)):

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S + \frac{1}{2}(1-\sigma^2) - (K_0 \mp K_1)e^{\mp Rh/4} \mp 4/Rh}{\{S + \frac{1}{2}(1-\sigma^2)\}^2 - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}, \quad (5.9)$$

where

$$R = 2(1+\sigma^2)U/\nu, \quad (5.10)$$

$$S = \ln [8(1+\sigma^2)/R] - \gamma. \quad (5.11)$$

(B) Case of two circular cylinders (cf. Fig. 3 (i) and (j)).

In this case, we put $\sigma_1=\sigma_2=0$ and then (5.2) becomes

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S_2 + \frac{1}{2} - (K_0 \mp K_1)e^{\mp Ra/4} \mp 4/Rd}{(S_1 + \frac{1}{2})(S_2 + \frac{1}{2}) - \{(K_0 + K_1)e^{Ra/4} - 4/Rd\}\{(K_0 - K_1)e^{-Ra/4} - 4/Rd\}}, \quad (5.12)$$

where

$$R = 2U/\nu, \quad (5.13)$$

$$S_1 = \ln (8/R) - \gamma, \quad S_2 = \ln (8/Ra) - \gamma, \quad (5.14)$$

$$K_0 = K_0(Rd/4), \quad K_1 = K_1(Rd/4). \quad (5.15)$$

The formula (5.12) agrees with (3.43) and (3.44) given in the previous paper¹⁾.

(C) Case of two equal flat plates.

In this case, we put $S_1=S_2=S$, $\sigma_1=\sigma_2=1$ and $a=1$. Then, we have

(i) $\beta_1=\beta_2=0$; $\alpha=0$ or π (cf. Fig. 3 (k) and (l)):

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S + 1 - (K_0 \mp K_1)e^{\mp Rh/4} \mp 4/Rh}{(S+1)^2 - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}, \quad (5.16)$$

(ii) $\beta_1=0$; $\beta_2=\pi/2$; $\alpha=0$ or π (cf. Fig. 3 (m) and (n)):

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S - (K_0 \mp K_1)e^{\mp Rh/4} \mp 4/Rh}{S(S+1) - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}, \quad (5.17)$$

(iii) $\beta_1=\pi/2$; $\beta_2=0$; $\alpha=0$ or π (cf. Fig. 3 (o) and (p)):

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S + 1 - (K_0 \mp K_1)e^{\mp Rh/4} \mp 4/Rh}{S(S+1) - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}, \quad (5.18)$$

(iv) $\beta_1=\beta_2=0$; $\alpha=0$ or π (cf. Fig. 3 (q) and (r)):

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S - (K_0 \mp K_1)e^{\mp Rh/4} \mp 4/Rh}{S^2 - \{(K_0 + K_1)e^{Rh/4} - 4/Rh\}\{(K_0 - K_1)e^{-Rh/4} + 4/Rh\}}, \quad (5.19)$$

Fig. 3. The symmetrical configurations with the central line parallel to the uniform flow. The drag coefficients of the hatched cylinders and the thick flat plates are considered.

where

$$R = 4U/\nu, \quad (5.20)$$

$$S = \ln(16/R) - \gamma, \quad (5.21)$$

$$K_0 = K_0(Rh/4) = K_0(Rd/8),$$

$$K_1 = K_1(Rh/4) = K_1(Rd/8). \quad (5.22)$$

§ 6. The General Case

The general case can be dealt with in quite a similar manner to § 4 and § 5. Thus, we have

$$C_D^{(1)} = \frac{8\pi}{R} \frac{\Delta_X^{(1)}}{J}, \quad (6.1)$$

$$C_L^{(1)} = \frac{8\pi}{R} \frac{\Delta_Y^{(1)}}{J}, \quad (6.2)$$

with

$$\begin{aligned} J = & (o_1 o_2 - n_1^2)(o_3 o_4 - n_2^2) + (p_1 p_2 - q_1^2)(p_3 p_4 - q_2^2) \\ & - (o_1 p_2 + q_1 n_1)(o_3 p_3 - q_2 n_2) \\ & - (o_2 p_1 + q_1 n_1)(o_4 p_4 - q_2 n_2) \\ & + (o_1 q_1 + p_1 n_1)(o_4 q_2 - p_3 n_2) \\ & + (o_2 q_1 + p_1 n_1)(o_3 q_2 - p_4 n_2), \end{aligned} \quad (6.3)$$

$$\begin{aligned} \Delta_X^{(1)} = & o_2(o_3 o_4 - n_2^2) + p_2(p_3 p_4 - q_2^2) \\ & - p_2(o_3 p_3 - q_2 n_2) - o_2(o_4 p_4 - q_2 n_2) \\ & + (q_1 + n_1)(o_4 q_2 - p_3 n_2), \end{aligned} \quad (6.4)$$

$$\begin{aligned} \Delta_Y^{(1)} = & n_1(o_3 o_4 - n_2^2) - q_1(p_3 p_4 - q_2^2) \\ & + q_1(o_3 p_3 - q_2 n_2) - n_1(o_4 p_4 - q_2 n_2) \\ & + (o_1 - p_1)(o_4 q_2 - p_3 n_2), \end{aligned} \quad (6.5)$$

where

$$o_1, o_2 = S_1 \pm \frac{1}{2}(1 + \sigma_1^2 \cos 2\beta_1), \quad (6.6)$$

$$o_3, o_4 = S_2 \pm \frac{1}{2}(1 + \sigma_2^2 \cos 2\beta_2), \quad (6.7)$$

$$p_1, p_2 = K_0 e^{Rh \cos \alpha/4} \pm (K_1 e^{Rh \cos \alpha/4} - 4/Rh) \cos \alpha, \quad (6.8)$$

$$p_3, p_4 = K_0 e^{-Rh \cos \alpha/4} \pm (K_1 e^{-Rh \cos \alpha/4} - 4/Rh) \cos \alpha, \quad (6.9)$$

$$q_1, q_2 = (K_1 e^{\pm Rh \cos \alpha/4} - 4/Rh) \sin \alpha, \quad (6.10)$$

$$n_p = \frac{1}{2} \sigma_p^2 \sin 2\beta_p, \quad (p=1, 2) \quad (6.11)$$

and

$$R = 2(1 + \sigma_1^2)U/\nu, \quad (6.12)$$

$$S_1 = \ln[8(1 + \sigma_1^2)/R] - \gamma,$$

$$S_2 = \ln[8(1 + \sigma_1^2)/Ra] - \gamma, \quad (6.13)$$

$$K_0 = K_0(Rh/4), \quad K_1 = K_1(Rh/4). \quad (6.14)$$

If we put $\sigma_1 = \sigma_2 = 0$, then $n_1 = n_2 = 0$ and (6.1)–(6.11) agree with (3.25)–(3.39) in the previous paper for two circular cylinders in the general configurations.

Making use of the asymptotic form of $K_n(kd)$, we have the limiting forms of (6.1) and (6.2) for $kd \rightarrow \infty$ as

$$C_D^{(1)} = \frac{8\pi}{R} \frac{S_1 - \frac{1}{2}(1 + \sigma_1^2 \cos 2\beta_1)}{S_1^2 - \frac{1}{4}(1 + \sigma_1^4 + 2\sigma_1^2 \cos 2\beta_1)}, \quad (6.15)$$

$$C_L^{(1)} = \frac{8\pi}{R} \frac{\frac{1}{2} \sigma_1^2 \sin 2\beta_1}{S_1^2 - \frac{1}{4}(1 + \sigma_1^4 + 2\sigma_1^2 \cos 2\beta_1)}, \quad (6.16)$$

which coincide with the first approximate expressions for the case of a single elliptic cylinder obtained by Imai⁵⁾, Tomotika and Yosinobu⁶⁾ and Hasimoto⁷⁾.

It can be proved that the general expressions (6.1)–(6.11) reduce to the previous results in § 4 and § 5 by taking $\alpha = \pi/2, 0, \pi$.

§ 7. Numerical Discussions

The parameters to characterize the flow past the two elliptic cylinders are $\sigma_1, \sigma_2, \beta_1, \beta_2, a, h, \alpha$ and R . The effects of a, h and α may be expected to be qualitatively similar to those for the case of two circular cylinders. Therefore we shall here confine ourselves to the investigation of the effects of the new parameters $\sigma_1, \sigma_2, \beta_1$ and β_2 . Further, we fix

$h=d/(1+\sigma_1^2)=10$ and consider only the cases of symmetrical configurations of two equal cylinders.

Numerical calculations have been carried out for the cases:

- (i) $a=1$; $h=10$; $t_1=t_2=0, 0.1, 0.5$; $\alpha=90^\circ$; $\beta_1=-\beta_2=0^\circ-90^\circ$; $R=0.04-1.0$ by using (4.4) and (4.5) and their simplified forms (4.10)–(4.21),
- (ii) $a=1$; $h=10$; $t_1=t_2=0, 0.1, 0.5$; $\alpha=0^\circ, 180^\circ$; $\beta_1=0^\circ, 90^\circ$; $\beta_2=0^\circ, 90^\circ$; $R=0.04-1.0$ by using (5.6)–(5.25). They are shown in Figs. 4 and 5 and tabulated in Tables I and II.

In the case (i) with the perpendicular central line, the curves of the drag coefficients $C_D^{(1)}$ vs. $\beta=\beta_1=-\beta_2$ is symmetrical about $\beta=\pi/2$, so that the reversal of the flow direction does not change the values of the drag, in the first approximation. In the case (ii) with the parallel central line, comparison of the four configurations: I. $\alpha=0^\circ, \beta_2=0^\circ$ (Fig. 3 (a)), II. $\alpha=180^\circ, \beta_2=0^\circ$ (Fig. 3 (b)), III. $\alpha=0^\circ, \beta_2=90^\circ$ (Fig. 3 (c)) and IV. $\alpha=180^\circ, \beta_2=90^\circ$ (Fig. 3 (d)) shows that, irrespectively of β_1 ($=0^\circ$ or 90°), the drag is the largest for case I and

Fig. 4. $C_D^{(1)}$ and $C_L^{(1)}$ vs. $\beta=\beta_1=-\beta_2$ in the symmetrical configurations with the central line perpendicular to the uniform flow when $a=1$ and $h=10$. (a) $R=0.4$; (b) $R=0.8$.

- equal circular cylinders,

Experimental Studies on the Initiation of Electric Arcs

By Tasaburô YAMAGUTI

Physical Institute, College of Arts and Sciences, Chiba University

(Received January 8, 1958)

Concerning the initiation of stable arcs under atmospheric pressure it is pointed out that the customary theories have some difficulties in their explanations. Considering that the boiling point of the electrode and the work function of the cathode may take part in the initiation, arcs between electrodes with remarkably different boiling points are experimentally investigated. The results are qualitatively explained by two stability conditions: (a) an arc spot of one of the electrodes at least must be in boiling state, and (b) the ionization potential of the evaporated metal vapour must be larger than double the work function of the cathode material.

§ 1. Introduction

In preliminary experimental studies on the initiation of stable arcs between electrodes connected to an *ac* power source by excitation of high frequency oscillations, it is observed that the arcs kindle in both positive and negative half cycles of the power source between a carbon rod and an iron plate, whereas between an iron rod and an iron plate arc starts predominantly in the half cycles of positive rod. Interpretations of these experiments with the customary theories for arc formation, however, meet with some difficulties. In these experiments it is also observed that the arc spot on the plate reaches the temperature of boiling point when the plate is faced to a carbon rod electrode, whereas the spot facing an iron rod may be below the boiling point.

The effect of boiling of the arc spot on the initiation of arc was studied by Nottingham¹⁾ and Suits.²⁾ The former shows that the arc potential increases gradually with the boiling point of the electrode material, while the latter shows that no such regular relation can be obtained from more accurate data. As any certain relation between the boiling point and the arc formation is not yet known, it will be worth-while to experimentally investigate the conditions of the initiation with electrodes of different materials, which have boiling points distributed in a wide range of temperature.

In the present experiment, the initiation and stability of the arc are studied by connecting the electrodes to an alternating source (50 c/s) and superposing high frequency oscil-

lations in every other half cycle of the *ac*. The stability of the arc is examined by measurement of the arc current or by observation of its oscillogram, which numbers of the igniting half cycles are responsible to. Thus, it can be said that the present experiment offers a convenient method of observation which is equivalent to a large number of experiments on *dc* arc initiation.

§ 2. Experimental Methods

Electrical connection of the experimental apparatus is shown in Fig. 1, which is similar to that of the previous paper³⁾ in the point

Fig. 1. Schematic diagram of the experimental apparatus.

that the low voltage arc is initiated between electrodes separated by a small gap by means of the superposition of high frequency oscillations. By the action of a kenotron K , arcs can first ignite only in every other half cycle in which the rod electrode A has one and the same polarity, and its sign can be interchanged by exchange of connections of the primary terminals of the neon transformer N of 6000 volts. When the kenotron is in short circuit, the oscillations are superposed in every half cycle. The high frequency oscillations are started in circuit (1), where C is 2000 pF and the spark gap S is 1 mm.

To determine certainty of the initiation and stability of the arc, it is investigated whether the arc can kindle or not between electrodes in the following cases: when the high frequency oscillation is superposed in both half cycles of the ac , when the oscillation is superposed only in the half cycles when the rod is positive, and when the rod negative. It is also observed whether the arc still continues to kindle when the superposition is ceased.

The initiation and stability of the arc can be seen from the readings of an ac ammeter M and of a dc ammeter M' or from wave forms of the arc current observed on an oscillograph O . In cases when the self-rectifying action of the arc is remarkable, M' indicates about 5.5 A and M 11 A. Whereas, in arcs kindled on carbon electrodes M' indicates nearly zero A and M about 17 A.

Materials of the rod electrode are iron (4 mm in diameter), tungsten (3 mm) and carbon (5 mm), and those of the plate electrode iron, zinc, cadmium and tungsten. To diminish oxidation of the electrodes, arcs are kindled always in methane gas flames. When the plate electrode materials have low melting points (Cd and Zn) they are pre-heated by methane gas flame in crucibles of 25 cc capacity as shown in the figure to nearly 600°C with an expectation that the temperature will be raised to the boiling point by the arc, and their melted surfaces are used as plate electrodes.

§ 3. Experimental Results

Experimental results on the initiation of arc are shown in Table I. The first vertical column represents chemical symbols of the plate materials and the first horizontal row

those of the rod electrodes. Symbols $+$ and $-$ of the second row represent the half cycles, during which the rod polarity is positive or negative respectively. Symbol s in the third row denotes the superposition of high frequency oscillations during the corresponding half cycles, and symbols c of the same row represent that the superposition is ceased after the arc has started steadily and the electrodes have attained high temperature by the heating action of the arc. Circles $\bigcirc$ given in co-ordinate points mean that the arc initiates with certainty between the given two electrodes, and black circles $\bullet$ with less certainty in the half cycles of superposed oscillations. With regard to every other half cycle with no superposed oscillations $\odot$ is given for easy starting of arc, triangle $\triangle$ for an uncertain initiation, and cross $\times$ for no initiation. When the arc still kindles on even after the stop of the superposed oscillation (columns with symbol c), they are marked too with double circles, and no initiation with crosses. In the following some details how the arcs kindle between rods and plates are given for some electrode materials.

(a) Iron rod electrode

As will be seen from Table I, arcs surely start by the superposition in the half cycles of positive rod. However, for the negative rod, after the plate temperature reached the melting points arcs do not start in cases of iron and zinc plates even when the oscillation is applied. Only for cadmium plate steady arcs are initiated and kindle even after the cease of the superposition.

Deformations of the electrodes caused by the arc, which are most typical in the case of iron electrodes, give suggestions for the working mechanism of the electric discharge machining:⁴⁾ the melted material of the anode is stretched toward the cathode and forms a needle-like shape. Contrary to this, softened and melted part of the cathode forms a rather flat convex surface as if it is pressed by fast flow of positive ions, and especially for a rod-shaped cathode its top becomes flat having area more than two times the cross section of the rod. In open air, however, both electrodes are covered by thick layers of oxides and are deformed less remarkably.

(b) Tungsten rod electrode

By application of the high frequency oscil-

Table I. Stability of arcs formed between materials, which have boiling and melting points distributed in a wide range.

W					⊙ ○	○ △	⊙ ⊙	⊙ ⊙	○ △	○ △	⊙ ⊙	⊙ ⊙						

lations the arc starts when the rod is positive, whereas in negative half cycles the initiation is uncertain for iron and zinc plates. On the contrary, once the alternating current arc starts between the rod and a zinc or cadmium plate by high frequency excitation, the arc continues to kindle even after the high frequency oscillations are stopped. In case of a tungsten rod and a tungsten plate, the arc started by the excitation shows such an oscillogram of arc current as shown in Fig. 2a:

Fig. 2. Schematic diagram of arc current oscillogram, a: a-type arc formed on boiling electrode, b: b-type arc due to thermal emission.

the current begins to flow at certain potential of the *ac* source. However, after the electrodes glew in brilliant white the oscillogram changes from type *a* to type *b* of the figure. The arc current is larger than the former and the phase angle of current start is remarkably decreased in the latter. Thus it will be natural to consider that the arc of type *b* is due to thermal emission of electrons and that of type *a* as due to field emission. Once an arc of type *b* starts between the electrodes, the arc continues in each half cycle even though the excitation is ceased, although it fades away in a short time by heat loss at the arc spots due to thermal conduction through the electrodes.

(c) Carbon rod electrode

Between a carbon rod and all metal plates examined arcs are formed always by the excitation irrespective of the rod polarity, and

moreover the arcs start even with no excitation after the electrode became white heated. When the carbon rod is heated in brilliant white, oscillogram of arc current is the *b* type in half cycle of negative carbon rod.

§ 4. Explanation of the Experimental Results

According to the usual theories arcs are classified to a thermionic emission type and a field emission type. Some arcs in the present experiment are also to be attributed to thermionic emission type when the electrodes are not in boiling state and hence can not supply considerable amount of vapours as in the case of tungsten-tungsten arc. However, stability of arcs kindled on electrodes evaporating violently can hardly be explained by a simple field or spray discharge theory as will be shown in the following. In this work, therefore, a criterion that *the ionization potential of vapour of an electrode material must be larger than double the work function of a cathode* is introduced to explain the stability of arc. Its physical meaning is that each positive ion draws out two electrons from the cathode taking one for neutralization of itself and another for maintainance of the arc. Since the above criterion concerns with vapour ions evaporated from an electrode the arc stability depends on the boiling temperature of electrodes, more stable for electrodes of lower boiling point. It must be noted here, however, that the temperature of an electrode depends on the property of the opposite electrode. Namely, it is probable that there are cases in which an arc spot on an electrode may reach its boiling point or not according to the mode of partition for two electrodes of the input power supplied to the discharge gap. In other words, the temperature of the

spot on a plate seems to depend on materials of rod electrode. For instance, when the arcs are formed between a carbon rod and an iron plate, flames accompanied by thick smoke grow from the spot on the melt, showing the temperature of the plate reaching the boiling point of iron. Whereas when an iron or a tungsten rod is faced to an iron plate, smoky flames are not observed and the spot on the plate is considered as being in temperatures below the boiling point. Further, when cadmium is used as the plate smoky flame rises

strongly from the spot showing rapid evaporation of the metal for all kinds of the rod used: iron, tungsten and carbon. These phenomena show that the temperature of the cadmium plates reaches the boiling point which is remarkably below the melting points of the rod materials used.

The melting and boiling points of electrode materials are given in Table II for reference. As will be seen from Table I and the descriptions of the last section the arcs burn more steadily in regular order of increasing

Table II. The melting and boiling points of electrode materials.

Material	Cd	Zn	Fe	W	C	(Fe ₃ O ₄)	(Fe ₂ O ₃)	(ZnO)
Melting point (°C)	320.9	419.5	1530	3380	3600	1538	1560	1975
Boiling point (°C)	764	907	3200	5900	4000		(1200)	

melting points of the rod electrodes and of decreasing boiling points of the plate electrodes as far as the present experiment is concerned.

Now, for one or two seconds after the initiation of the arc between iron electrodes, the arc current is alternating one, but gradually reveals rectifying property with rise of temperature of the electrodes and becomes nearly perfect direct current within a few seconds. The initial arc current of alternating property can be explained by a mechanism of spray discharge or field emission. In order to explain by the same idea the fact that there are no initiation of arc between an iron positive plate and an iron negative rod, it will have to be assumed that the positive charges, which cause the spray of electrons, can not accumulate on the white heated cathode owing to evaporation of the insulating surface layer. This assumption seems very plausible for iron electrodes, but can not interpret the arcs of alternating property, which are formed between an iron rod and a cadmium plate or between a carbon rod and an iron plate. For, in these cases, too, presence of the thin layer is hardly conceivable on white glowing iron electrodes. Thus usual theories can not explain these arc phenomena without contradiction.

As already stated, in half cycles in which the iron or zinc plates are in positive potential the arcs initiate more stably when the plate are faced to rod electrodes of higher melting points. To interpret these phenomena it will be sufficient only to assume thermal emission

of electrons from carbon or tungsten rod. This assumption, however, fails in explaining other arc phenomena: a negative tungsten rod keeps arc stably, after interruption of the superposition, in the cases of a zinc or cadmium positive plate, but does not for a positive iron plate. As there are such several arc phenomena that can not be explained by the usual theories, conditions for stability of arcs are necessary to be investigated taking these experimental results into consideration.

Before proceeding to the interpretation of the arc initiation, it must be noted that arcs formed on negative carbon rod is due to the thermal electron emission and that the arc which kindles on a tungsten cathode after the electrode is heated white by arc current is also the thermal type. Such arcs of thermal type are distinguished from others by the large value of the arc current and also by the current osillogram of *b*-type of Fig. 2.

Now, the conditions necessary to explain the experimental facts can be reduced to two. The first is that one of the electrodes at least is in boiling state to supply thick metal vapour in which the arc can start. The second is that the ionization potential *E* of the evaporating electrode materials must be larger than two times the work function ϕ of the cathode, enabling every positive ion to draw out two electrons from the cathode, one electron to neutralize itself and another to maintain the arc. This second condition proves of great use as stability criterion.

The values of E and ϕ of electrode materials are given in Table III as well as in Fig. 3, where E 's are shown with circles and ranges of 2ϕ values⁽⁵⁾ obtained experimentally by various investigators with segments. In order to show validity of the present criterion, the 2ϕ values of liquid state, which may be considered to be smaller than those of solid state, must be used for the interpretation of the experimental results. Since the values of liquid are not yet known, it is required in the first place what ranges of 2ϕ values may satisfy the stability condition, where to E being given the values in Table III. If the ranges of the values thus determined are included in those of solid state or less than them, then it can be said that the 2ϕ values of liquid state are in these ranges determined if they have both the upper and the lower limits, or merely that the 2ϕ values are less than the upper limits determined if any lower limits are not obtained. The second condition of the stability of the arc can be written as

$$E(\text{vapour}) > 2\phi(\text{cathode}),$$

and hence the extinction condition as $E < 2\phi$.

Table III. Maximum and minimum values observed for 2ϕ and E in volts.

Material	C	Cd	Fe	Zn	W
2ϕ max. (V)	9.62	8.20	9.54	8.61	9.38
2ϕ min. (V)	8.00	7.36	7.82	6.16	8.50
E (V)	11.2	8.96	7.83	9.35	8.1

Since the above condition concerns with cathode, each electrode material is discussed as a cathode. The arcs formed on the same material used as an anode are discussed in connection with other cathode materials coupled with this anode.

a) Cadmium cathode

In this case dense cadmium vapour exists in the gap, hence the stability criterion is written as

$$E(\text{Cd}) > 2\phi(\text{Cd}),$$

which is satisfied by the measured E and 2ϕ as shown in Fig. 3. This explains the result that cadmium arc is stable for any anode material.

b) Iron cathode

Arcs do not initiate between iron electrodes unless high frequency oscillations are superposed. Thus either the electrode temperature

must be below the boiling point or the condition $E(\text{Fe}) < 2\phi(\text{Fe})$ must hold, which is actually satisfied as is shown in Fig. 3. Whether the temperature reaches the boiling point or not can not be said immediately, but depends on the anode material.

As the arc between Fe and Cd is stable and cadmium evaporates densely $2\phi(\text{Fe})$ must be less than $E(\text{Cd})=8.96$ volts. This condition is satisfied by the observed values except larger ones of ϕ . Iron-zinc arcs are unstable. The origin may be ascribed to temperature of zinc being below the boiling point or to that zinc is covered by a layer of compounds of higher boiling point. If the zinc temperature were above the boiling point, then the extinction condition would have to hold: $2\phi(\text{Fe}) > E(\text{Zn})=9.35$ volts, which is satisfied only by larger 2ϕ given in Fig. 3. Moreover

Fig. 3. Ionization potential E and two times the work function 2ϕ of the electrode materials.

this limitation of $2\phi(\text{Fe})$ contradicts with that for the iron-cadmium arc, that is, $2\phi(\text{Fe})$ must be smaller than 8.96 volts. It is considered, therefore, that the surface of zinc electrode is below the boiling point due to contamination by its compounds. The extinction of the arc between iron and tungsten can be explained by $2\phi(\text{Fe}) > E(\text{Fe})$ and by the temperature of iron below the boiling point. Stable initiation of arc between iron cathode and carbon anode can be explained by the large value of $E(\text{C})$ considering that carbon can evaporate easily. The iron plate is boiling, but $E(\text{Fe})$ can not explain the stability.

Thus it can be said that arcing between an iron cathode and other materials is explained by taking 2ϕ of iron to be less than 8.96 volts,

although some questions about iron-zinc arcs remain for future investigation.

c) Zinc cathode

Between a zinc cathode and an iron anode arcs do not initiate without the superposition of oscillations. As stated above it will be natural to consider that zinc surface is below the boiling point due to oxide layer. To explain stable arcs between a zinc cathode and tungsten anode zinc must be considered as being above the boiling point considering that tungsten has much higher melting point. Accordingly zinc vapour must be predominant and the relation $2\phi(\text{Zn}) < E(\text{Zn}) = 9.35$ volts well explain the stability. Carbon-zinc arcs are stable. Since both of $E(\text{C})$ and $E(\text{Zn})$ are larger than $2\phi(\text{Zn})$, stability should be very well.

d) Tungsten cathode

Between iron and tungsten electrodes no arcs are initiated unless the high frequency oscillations are superposed. Hence if iron is in boiling state there must be the relation $2\phi(\text{W}) > E(\text{Fe})$, and this is actually satisfied by the measured values. Stable arcs are formed between zinc and tungsten electrodes by the superposition though uncertain initiations are observed when tungsten is the cathode. Considering zinc being above and tungsten below their own boiling points, the condition $2\phi(\text{W}) < E(\text{Zn}) = 9.35$ volts must hold; and this condition is satisfied by main part of $2\phi(\text{W})$ except the largest value 9.38 volts. Cadmium-tungsten arcs are stably formed even after interruption of the superposition. The stability condition is $E(\text{Cd}) > 2\phi(\text{W})$, which is satisfied only with small values of $2\phi(\text{W})$ according to Fig. 3. In case both electrodes are tungsten, the arc starts by the superposition. After the electrodes glew white by arc current the arc initiates without oscillations, but fades away in a short time as temperature of electrodes is lowered by heat conduction. Fig. 3 shows that $E(\text{W}) < 2\phi(\text{W})$, that is, the tungsten vapour can not account for the arcing. The arc must be accounted for by the thermal emission of electrons from the tungsten cathode. Eventually the experiments on the tungsten cathode arc show that 2ϕ value of tungsten must be less than $E(\text{Cd}) = 8.96$ and larger than $E(\text{Fe}) = 7.83$ volts.

e) Carbon cathode

Between a carbon cathode and any metal

examined arcs kindle stably even after the excitation is ceased. The initiation of the arc, when the carbon electrode is cathode, can be explained by thermal emission of electrons from white heated carbon and also by the stability conditions $E(\text{C}) > 2\phi(\text{C})$, $E(\text{Cd}) > 2\phi(\text{C})$ and $E(\text{Zn}) > 2\phi(\text{C})$, which are satisfied by the known values of E and ϕ . For iron anode, however, it can be explained by the thermal emission. Since the arc formed on a carbon cathode can be interpreted by thermal emission, much can not be said about the work function of carbon.

§ 5. Discussion

As stated above the initiation of the arc can be explained by the proposed stability criterion. The high frequency current between the electrodes may be due to the field emission of electrons as usually considered. Since the instantaneous value of this high frequency current must be considerably large estimating from the duration ($\sim 1\mu\text{s}$) of its first impulse, the condenser capacity (2000 pF) and the secondary voltage of the neon-transformer (6 kV), and since the area of the discharge spots on the electrodes are very small, the spot of either one of the electrodes at least will soon reach its boiling point and will supply considerable amount of neutral particles. These particles are ionized between the electrodes, beat the cathode and are to release electrons therefrom. If the above mentioned stability condition is fulfilled, the arc current will build up with the temperature rise of electrodes, and when either cathode or anode begins heavy evaporation by boiling the arc will continue to kindle even after the superposition is ceased.

According to the general conception of arc discharges ratio of number of electrons liberated from the cathode by the impinging positive ions to those drawn out by the field of positive space charges is considered to be small. However, the present experiments show that the electrons of the former origin play an important part in the initiation of the arc.

The values of the work function used in the present interpretation are those obtained for solid state. Although the work function is known as being nearly independent of temperature,⁶⁾ the values for liquid state are more desirable for the present purpose, about

which anything is not yet known. However, if the present criterion is valid it may be said that 2ϕ values of the materials in the melted state lie within the limits obtained by the present experiment. While it is likely to happen that the surfaces of melted metals are covered by thin layers of oxides, which must also affect the work function. In this respect experimental investigations on the stability of vacuum arcs are desirable. At present, accordingly, it will not be adequate to discuss in more detail about the effect of the work function on the arc initiation.

In conclusion the author's thanks are due to Prof. K. Honda of Tokyo University for his kind advices.

The Thermoluminescence of Glasses

By Takeo KIKUCHI

Institute of Polytechnics, Osaka City University

(Received January 30, 1958)

The thermoluminescence of soda-silicate glass and fused quartz, as well as crystalline quartz, were observed below room temperature. The glow curves of glasses have broad bands without any structure. The luminescence shows the slow decay continuing for more than ten minutes at any fixed temperature between 100°K and 350°K. The dependence of these curves on the irradiation temperature and on the X-ray dose, and the effect of the heat treatments were studied. The decay curves, which do not obey the simple monomolecular or bimolecular law, are analysed by the model that the trapping levels are distributed continuously and uniformly beneath the conduction band. The discussions on the relation between the trapping centers and the random network structure of the glasses are presented.

§ 1. Introduction

In the work of the thermoluminescence for fused quartz, R. Yokota has observed that the glow curve of fused quartz has the broad band, and suggested that this represents the characteristic features of the glassy states.¹⁾ The author has found soda-silicate glass shows the glow curve with two broad bands, one at the temperature above the room temperature, and the other at the temperature below it.²⁾ And he has pointed out that these two groups of the bands indicate the existence of two groups of the electron trapping levels, deep and shallow, in glass, corresponding to the model for the electronic structure of the amorphous substances proposed by H. Förhlich with regards to the theory of the dielectric

breakdown.³⁾ In the present paper we shall describe the experiments on the thermal glow and the decay of the luminescence for soda-silicate glass, fused quartz and crystalline quartz irradiated previously with X-ray at low temperatures. And from these results we shall discuss the electron trapping levels in the glassy states.

§ 2. Experimental Procedure

The specimens were soda-silicate glass, fused quartz and crystalline quartz, which were kindly offered by R. Yokota. The molecular formula of soda-silicate glass is $0.6\text{Na}_2\text{O} \cdot 2\text{SiO}_2$. Each specimen has the surface of about 1cm^2 and the thickness of about 0.5 mm, which was attached on the

copper block of the cryostat at the distance of 20 mm from the window of the X-ray tube. At a constant temperature, the specimen was irradiated with X-ray (W-target) of a constant intensity (40 kv, 16 ma, unless especially denoted).

The measurements of the luminescence intensity were performed by the use of the photomultiplier 931A, dc amplifier and a recorder. During the X-ray irradiation, the intensity of the luminescence emitted by the specimen reached the saturation value in a few minutes. As soon as the irradiation was ceased, the intensity dropped quickly by a considerable amount and then decayed more or less slowly. After the observation of the decay for about 10 or 20 minutes, the temperature of the specimen was raised with a constant speed, the glow curve being recorded.

§ 3. Results

(1) Glasses and Crystal

The glow curves of each specimen are shown in Fig. 1. At a lower temperature, the

Fig. 1. Glow curves of glasses and crystal. (a) and (b); irradiated with X-ray for 32 minutes. (c); irradiated with X-ray for 11 hours.

broad bands are found in the glow curves for soda-silicate glass and fused quartz, while such a band is not found for the crystal. This seems to indicate that the shallow electron traps associated with the broad band at low temperature are characteristic to the glassy states.

(2) Temperature Dependence

The glow curves of glasses irradiated at various temperatures are shown in Fig. 2. We see each curve has a nearly similar slope at the side of higher temperature, and the peak shifts to the lower temperature indefinitely, as the irradiation temperature is lowered. This shows that a band of the glow curve is not due to one type of trapping center, but due to many trapping centers whose levels are distributed over the wide range.

Fig. 2. Glow curves of glasses irradiated (a); for 2 minutes, at 1; 102°K, 2; 114°K, 3; 123°K, 4; 142°K, 5; 166°K, (b); for 10 minutes at 1; 102°K, 2; 118°K, 3; 149°K, 4; 160°K.

Fig. 3. Decay curves of glasses irradiated (a); for 2 minutes, at 1; 102°K, 2; 123°K, 3; 166°K, (b); for 10 minutes, at 1; 102°K, 2; 290°K.

Fig. 3 shows the time decay of the luminescence of soda-silicate glass and fused quartz at various temperatures. The ordinate indicates the ratio of the luminescence intensity I to the intensity I_0 immediately after the cease of the irradiation. The lumines-

science intensity decays rapidly at first and then decays more slowly. These decay curves do not obey the simple mono- or bimolecular law. The temperature dependence of the decay time is not found for fused quartz and is very small even for soda-silicate glass compared with the conventional model in which only one or a few trapping levels are assumed. As discussed later, these facts are well understood by considering many trapping levels which are assumed to be in the glasses.

(3) Dependence on the X-ray Dose

To examine the dependence of the decay on the X-ray intensity, the X-ray current is changed from 3 ma to 20 ma at 40 kv. The decay curves are similar to those shown in Fig. 3 independent of the X-ray intensity in this range. This fact indicates that the present phenomena are not due to the bimolecular processes.

On the other hand, if the duration of the X-ray irradiation is changed, the X-ray current being fixed, the decay time changes. This is shown in Fig. 4. The more the

Fig. 4. Decay curves of soda-silicate glass irradiated for 1; 128 minutes, 2; 32 minutes, 3; 8 minutes, 4; 2 minutes, 5; 0.5 minutes at 102°K.

duration of the X-ray irradiation, the slower is the decay. This suggests that during the irradiation the redistribution of the trapped electrons are allowed to tend to the equilibrium distribution which favors the deeper traps. The shape of the glow curve is independent of the duration of the irradiation, though the luminescence intensity rises as the duration increases.

(4) The Effect of Heat Treatment

In Fig. 5 the decay curves of the luminescence intensities for the specimens of soda-silicate glasses are shown. These specimens are prepared by different heat treatments;

Fig. 5. Decay curves of soda-silicate glass irradiated for 32 minutes at 102°K. 1; annealed at 550°C for 15 hours, 2; quenched after heated at 800°C for 10 minutes.

that is, one is annealed at 550°C for about 15 hours, and the other quenched after heated at 800°C for about 10 minutes. The quenched specimen shows the slightly rapid decay compared with the annealed one. As for the experiments of the glow curves, these two specimens show nearly the same shape.

§ 4. Discussion

Now we shall consider the processes which will contribute to the phenomena of the thermoluminescence of the glasses described in the last section, and the distribution and structure of the electron trapping centers of the glasses. As already suggested in 3. (2) from the dependence of the glow curves on the temperature of the X-ray irradiation, many trapping levels are presumed to be distributed continuously beneath the conduction band. And the fact that the decay curve does not depend on the X-ray intensity, as described in 3. (3), shows that the decay is mainly determined by the rate at which electrons are released thermally from many trapping levels. Hence the processes in which we are interested are to be that the electrons ionized to the conduction band, are trapped in the trapping centers whose energy levels are distributed continuously beneath the conduction band, and after the irradiation is ceased, these electrons are released ther-

mally and then rapidly recombine.

Now the features of the luminescence decay may be interpreted as follows. If the depth of a trapping level from the bottom of the conduction band is ε and the density of the trapping level occupied by the electrons in the range from ε to $\varepsilon+d\varepsilon$ immediately after the cease of X-ray irradiation is $Z(\varepsilon)d\varepsilon$, the intensity of the luminescence $I(t)$ at a time t after the irradiation is ceased may be expressed as

$$I(t) = \int_0^{\infty} Cb \exp(-bt e^{-\varepsilon/kT}) Z(\varepsilon) d\varepsilon, \quad (1)$$

where b is the frequency factor, k the Boltzmann's constant, T the absolute temperature and C a constant. Although $Z(\varepsilon)$ could be obtained directly by analysing the decay curves, we shall rather assume the form of $Z(\varepsilon)$ at first and calculate $I(t)$ according to Eq. (1), which is to be compared with experimental curves. We assume, for simplicity, that the trapped electrons are distributed uniformly from the levels E_a to E_s , as shown in Fig. 6. That is,

$$\begin{aligned} 0 < \varepsilon < E_s, & \quad Z(\varepsilon) = 0 \\ E_s \leq \varepsilon \leq E_a, & \quad Z(\varepsilon) = A \\ E_a < \varepsilon, & \quad Z(\varepsilon) = 0. \end{aligned} \quad (2)$$

Fig. 6. Distribution of trapped electrons. E_s is the most shallow occupied level. E_a is the deepest occupied level. It is assumed that electrons uniformly and continuously occupy the levels from E_s to E_a .

In this equation, E_s and E_a are the most shallow and the deepest trapping levels occupied by the electrons respectively, at $t=0$. Substituting Eq. (2) in Eq. (1), we obtain

$$\begin{aligned} I(t) &= \int_{E_s}^{E_a} A \cdot Cb e^{-\varepsilon/kT} \exp(-bt e^{-\varepsilon/kT}) d\varepsilon \quad (3) \\ &= I_0 \cdot \frac{\exp(-bx_a t) \{1 - \exp[-b(x_s - x_a)t]\}}{b(x_s - x_a)t}, \end{aligned} \quad (4)$$

where

$$x_s = \exp(-E_s/kT), \quad x_a = \exp(-E_a/kT) \quad (5)$$

and I_0 is the luminescence intensity at $t=0$. Since $x_s \gg x_a$ in general, Eq. (4) may be written approximately as follows,

$$I(t) \simeq I_0 \cdot \frac{1 - \exp(-bx_s t)}{bx_s t}. \quad (6)$$

In this equation, we should notice that the factors determining the decay time are E_s and T , if b is assumed to be fixed. The curves of Eq. (6) are shown in Fig. 7 in the broken lines. In this figure, the solid curves are the same as the observed ones shown in Fig. 3. Although the agreements of both curves are not sufficiently well, the following estimations may be possible. Assuming b to be 10^{10} sec^{-1} , from Fig. 7 we can estimate for soda-silicate glass the approximate values of E_s to be 0.21 eV and 0.33 eV at the temperature of 102°K and 165°K respectively. For fused quartz, the value of E_s changes considerably with temperature, i.e. E_s are 0.22 eV and 0.66 eV at 102°K and 300°K respectively.

Fig. 7. Decay curves of glasses.

Experimental, 1; fused quartz irradiated at 102°K for 10 minutes, 2; soda-silicate glass irradiated at 102°K for 2 minutes, 3; irradiated at 166°K for 2 minutes.

Calculated, 1'; $bx_s=0.02$, 2'; $bx_s=0.05$, 3'; $bx_s=0.1$.

The results described in 3. (3) that the decay time of luminescence is independent of X-ray intensity show that the value of E_s does not change with the intensity of the X-ray. On the other hand, the decay time is considerably dependent upon the duration of the X-ray irradiation. In fact, for soda-silicate glass at 102°K the values of E_s are estimated to be 0.22 eV in the case of the irradiation of 128 minutes and to be 0.20 eV in the case of the irradiation of 0.5 minutes. We shall make some speculation with respect

to these points. If we assume that the number of trapping centers is far more than the number of electrons available and that the probability for the electron to be captured by the trap is independent of the depth of the trap, the electrons ionized by X-ray may be captured uniformly by each trapping level. Therefore, the dose rate of X-ray does not affect the distribution of the trapped electrons. Since, during the irradiation, the electrons trapped in the upper trapping levels will be released thermally more rapidly than those in the lower levels, the distribution of the trapped electrons will tend to be dense in the lower levels with the increase of the duration of the irradiation. A part of electrons released thermally may recombine rapidly and the other part of those may be captured again by the lower trapping levels. This retrapping processes may greatly promote such a redistribution of trapped electrons. Due to these trapping processes, the level E_s , which divides the trapping levels into empty and uniformly occupied, may be expected to be lowered with the increase of the duration of the X-ray irradiation.

As is well known, the depth of the occupied trapping level ε is obtained from the glow curve according to the approximate equation,

$$\varepsilon \simeq kT_g \ln\left(\frac{bT_g}{\beta}\right), \quad (7)$$

where T_g is the temperature corresponding to the maximum of the glow curve and β is the speed of the temperature rise. Assuming b to be 10^{10} sec^{-1} as before, we may obtain from Fig. 1 the values of ε to be ranged from 0.22 eV to 0.40 eV for soda-silicate glass and from 0.22 eV to 0.54 eV for fused quartz, in the case that each specimen is irradiated at 102°K . We find the least ones of these values approximately agree with the values of E_s estimated from the decay curves.

Next we shall discuss briefly the model of the shallow trapping centers of electrons, the detail of which were previously manifested by the author.⁴⁾ According to the theory of random network structure of glasses, we may expect the existence of the volume fluctuation or the local volume dilations and compressions in glasses which is to be associated with the randomness of the Si-O-Si bond angle. The effective potential $V(r)$ for an electron may be assumed to be proportional

to the volume dilation $\Delta(r)$ and may be expressed as

$$V(r) = E_1 \Delta(r), \quad (8)$$

where E_1 is a proportional constant. In this equation $\Delta(r)$ may be determined by the randomness of the glass structure, or its thermal history of the specimen which defines the fictive temperature τ .⁵⁾ We shall assume that the volume dilations are confined within the spheres of a certain radius. These dilated spheres may form trapping centers for conduction electrons. Using Eq. (8) we can obtain the energy level ε of the traps as the function of E_1 , τ and a the radius of the dilated sphere. ε may be found to increase with τ and E_1 and to decrease with a . The values of the trapping level ε estimated from our experiments are obtained from the appropriate values of them; that is, for τ from 1000°K to 1500°K which are considered to be the fictive temperature of our specimens, and for a around $10 \text{ \AA}$ and for E_1 around 20 eV which seem to be reasonable values in the model adopted here.

Interpreting the experimental results of the heat treatments seems to be difficult. The quenched specimen has a higher fictive temperature, probably near 1000°K , than the annealed one, whose fictive temperature is considered to be about 823°K . The experimental results described in 3. (4) show that this difference of the fictive temperature of the specimens has less effects than expected from the model above mentioned.

§ 5. Summary

We have observed the thermoluminescence of glasses and examined its dependence on the temperature and the X-ray dose. From the glow curves the electrons ionized by X-ray are found to be trapped in the levels from nearly 0.2 eV to 0.5 eV. The decay curves exhibits slow decays continuing for more than ten minutes, and the decay times are considerably affected by the duration of the X-ray irradiation. These phenomena are well understood by the terms of the electron trapping levels which are uniformly and continuously distributed beneath the conduction band. The distribution of the trapped electrons or the highest level occupied by the electrons E_s is determined by the temperature and the duration of X-ray irradiation.

The model of the trapping center was proposed which is based on the glass structure, essentially affected by the fictive temperature of the specimen. The values of the trapping levels obtained from this model fit approximately with the observed ones. In order to interpret the effect of the heat treatments of the specimens, the more profound considerations are desirable.

§ 6. Acknowledgement

The author wishes to thank Dr. R. Yokota for his offering the valuable specimens, and

he also wishes to thank Professor H. Kawamura for his guidance throughout the course of this work.

Orientation Dependence of the Uniaxial Ferromagnetic Anisotropy Induced by Magnetic Annealing in 20% Co-Ni Single Crystals

By Keizō AOYAGI, Satoshi TANIGUCHI
and Mikio YAMAMOTO

*The Research Institute for Iron, Steel and
Other Metals, Tôhoku University, Sendai*

(Received January 13, 1958)

Previously, We¹⁾ and, independently, Néel²⁾ developed a theory of uniaxial ferromagnetic anisotropy induced by magnetic annealing in cubic solid solutions by assuming that the energy of atom pairs depends both on their kinds and on the orientation of the magnetization vector, and obtained results which agree qualitatively well with the experimental results available at that time. In order to check the theory more precisely, we have measured the induced uniaxial anisotropy as dependent on the alloy composition, annealing temperature, annealing time, orientation of magnetic field applied during annealing, etc. for polycrystalline and monocrystalline Ni-Co alloys. We shall present here the results concerning the orientation dependence of the uniaxial anisotropy induced in 20%Co-Ni single crystals.

The specimen used was a (110) circular disk of 15.26 mm in diameter and 0.61 mm in thickness. The anisotropy measurement was made by using

a torque magnetometer, which was designed to allow the repetition of heat treatment and torque measurement without removing the specimen, so that the torque curve associated with the induced uniaxial anisotropy can be obtained as a difference between curves of the states annealed with and without magnetic field. After finishing the measurement of the curve for the annealing without magnetic field, the specimen was annealed at 650°C (above the Curie temperature) for 30 minutes, cooled down to 450°C at the rate of about 30°C/min., held at that temperature for 15 minutes and consecutively for 5 hours in the presence of magnetic field of about 1500 Oe directed along a desired crystallographic direction, and then rapidly cooled to the room temperature. In this way, the uniaxial anisotropy constant, K_u , and its easy direction, θ_0 , were determined as functions of the direction of the magnetic field applied during annealing, θ_T .

In Figs. 1 (a) and (b), $K_u/K_{u[111]}$ and $\Delta\theta = \theta_0 - \theta_T$ are plotted against θ_T , in comparison with the theoretical formula for the induced uniaxial anisotropy, E_u :

$$E_u = -K(k_1 \sum_i \alpha_i^2 \beta_i^2 + k_2 \sum_{i,j} \alpha_i \alpha_j \beta_i \beta_j),$$

where K , k_1 and k_2 are the constants and α_i 's and β_i 's are the direction cosines of the magnetization vector and magnetic field applied during annealing, respectively. The figures clearly show that the experimental results agree completely with the theoretical formula by taking the value of k_2/k_1 as 3, while the theoretical value of k_2/k_1 under the nearest neighbour assumption is 4.

Fig. 1. Uniaxial ferromagnetic anisotropy constant relative to that in the [111] direction, $K_u/K_{u[111]}$, and the deviation of its direction of easy magnetization from that of magnetic field applied during annealing, $\Delta\theta$, as dependent on the direction of annealing field, θ_T .

Chikazumi³⁾ recently made a similar measurement with a Ni_3Fe single crystal and found that his result was fitted to the theoretical formula by taking a rather large value, about 8.5, of k_2/k_1 . It does not seem, however, that the large discrepancy between theory and experiment with Ni_3Fe single crystal is originated from the geometrical coordination of lattice points in face-centered cubic crystal as proposed by Chikazumi³⁾, since 20% Co-Ni single crystal has also the face-centered cubic lattice. We are now pursuing the discrepancies between theory and experiment for Ni-Co and Ni_3Fe crystals.

Pits on Germanium Surface Formed by Molten Indium

By Sei-ichi DENDA

Electrotechnical Laboratory, Tokyo, Japan

(Received March 1, 1958)

It is well known that small pits are formed on germanium surface when a strong acid etching solution is used. Recently we have been observed the same kind of pits which appears on germanium when it is immersed into molten indium.

The small piece of slice of *n*-type germanium single crystal with (111) surface is polished with emery paper, and is soldered by the pellet of indium with diluted $\text{ZnCl}_2 + \text{HCl}$ as a flux, and then immersed into a large volume of molten indium with some agitation at 350°C . In 2 minutes it is suddenly picked out of indium, and the indium remaining on the surface is removed by Hg.

Fig. 1 and Fig. 2 show the photographs of the treated germanium surface on which pits pattern appears. This is not obtained on the whole wetted region but on the small portion of that region. The density of these pits is nearly the same as that of the etch pits on the specimen which is cut out of a same single crystal. Fig. 2 also shows different kind of type of very small pits whose density is one order of magnitude greater than that of the big one. However, its properties are not known yet.

If the temperature of molten indium is 200°C , Fig. 3 which shows triangles, characteristic structure of (111) plane, is obtained.

Pits in Fig. 1 and Fig. 2 resemble the etch pits

Fig. 1.

Fig. 2.

Fig. 3.

formed by CP-4 which is a strong etching solution, and the situation in Fig. 3 is seen on the surface treated by superoxol which is a weak etchant. Thus there is a close analogy between chemical etching and metallic dissolution of germanium.

It has been visualized that the edge dislocation affects the flatness and uniformity of the alloyed *p-n* junction which is important in the transistor fabrication¹⁾.

J. PHYS. SOC. JAPAN **13** (1958) 534**Stepped Structure in Moiré Fringe**

By Hatsujiro HASHIMOTO

*Kyoto Technical University, Matsugasaki,
Sakyoku, Kyoto, Japan*

(Received February 28, 1958)

The moiré fringes of crystal lattice were observed¹⁾ in the electron microscopic images of two crystalline films superposed. Such fringes appear only on the extinction contour bands due to Bragg reflections. The dislocation in moiré fringe was shown²⁾ to reveal the dislocation in crystal lattice. The present author observed stepped structures in moiré fringes of CuS and ZnS films as shown in Figs. 1, 3 and 4.

Fig. 1 is a moiré fringe formed on a single contour band of Bragg reflection in which stepped

Fig. 1. (a) is moiré fringe of CuS with a guide (b) ($\times 300,000$).

Fig. 2. Optical analogues demonstrating moiré pattern.

Fig. 3. (a) is moiré fringe of CuS film with a guide (b) ($\times 400,000$). (c) Optical demonstration of cross-stepped structure.

structures of steps of $1/2$ and 1 spacing can be seen. Such structure may be interpreted by light optical analogue as follows. Fig. 2 (a) is a grating containing a disorder in spacing near its center whose amount is half the spacing in total and its range covers 5 lines. Fig. 2 (b) is a perfect grating. Fig. 2 (c) is a moiré pattern obtained by superposing (a) and (b) with small twist angle in which a structure of the steps of $1/2$ spacing is formed. Fig. 2 (d) is also a moiré pattern obtained by similar method, which shows a stepped structure of 1 spacing. Fig. 3, which is a fringe on a single contour band, indicates two crossed fringes. Each of which may be interpreted as the combination of two edge dislocations of the same sign as is shown in Fig. 3 (c).

Fig. 4 is a moiré fringe on two extinction bands

Fig. 4. Moiré fringe on two extinction bands ($\times 300,000$)

due to principal maxima of $(h\ k\ 0)$ and $(\bar{h}\ \bar{k}\ 0)$ reflections. Between two parts of the fringe, we can detect similar stepped structure described above. Such structure was observed on almost every coupled extinction bands but the amount of shift of steps was different in each case. In moiré fringes on the two extinction bands which seem to be due to a principal and its subsidiary maxima or the first and the second Bragg reflections, we also observed stepped structures. These structures may not be interpreted as the disorder of original lattice because the structures moved with the movement of extinction bands and therefore the structures are expected to have no relation with disorder in original lattice. These structures seem to be due to the dynamical interaction of electron with crystal.

The author expresses his sincere thanks to Prof. K. Tanaka of Kyoto University and Prof. R. Uyeda of Nagoya University for their kind discussions.

J. PHYS. SOC. JAPAN **13** (1958) 535On the Superstructure of the Alloy Au_3Mn

By Denjiro WATANABE

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received February, 23, 1958)

It was found by Raub *et al.*¹⁾ that the alloy Au_3Mn has an ordered structure with tetragonal symmetry below 625°C ., but its atomic arrangement has not yet been determined. On the other hand, it was elucidated by Meyer²⁾ that the ordered alloy is metamagnetic like Au_2Mn , having the Néel point of antiferromagnetism at about 145°K . A full explanation of the above magnetic property, however, has not been given due to lack of information on the crystal structure. The present author was able to determine the complex ordered structure of Au_3Mn by electron diffraction.

Fig. 1 shows a diffraction pattern of a thin alloy film containing about 25 atomic % Mn, which was slowly cooled from 450°C . after annealing at $450\sim 500^\circ\text{C}$. for 2 hrs. The pattern resembles that of the ordered alloy Cu_3Pd ³⁾ in the splitting of superlattice reflections. In order to explain this splitting, a model of a two-dimensional anti-phase domain structure was proposed, as shown in Fig. 2. In this model, it can be seen that the fundamental lattice is a face-centred orthorhombic one with an atomic arrangement similar to Cu_3Au but that the stepshifts, $\pm\frac{1}{2}(\vec{a}_2\pm\vec{a}_3)$ and $\pm\frac{1}{2}(\vec{a}_3\pm\vec{a}_1)$, occur at

every cell and at every two cells of the fundamental lattice along the x and y directions respectively. The lattice constants of the fundamental lattice are: $a_1=4.08$, $a_2=4.05$, $a_3=4.03\text{\AA}$. It is noticeable that both types of shifts belong to the first kind³⁾ and, therefore, the present two-dimensional anti-phase domain structure is different from that found in Cu_3Pd ³⁾.

The intensity distribution in reciprocal space corresponding to the model in Fig. 2 can well explain the details of the pattern in Fig. 1, except the following two points.

(1) Strictly speaking, the positions of the split superlattice reflections do not coincide with those expected from the above model. This disagreement is attributable to the fact that the extensions of the domain along the x and y directions are not a_1 and $2a_2$, as considered in Fig. 2, but are $1.2a_1$ and $2.2a_2$, respectively. This fractional property of domain size means a mixture of different sizes of domains in the actual lattice⁴⁾. Thus, it should be noticed that the model in Fig. 2 corresponds to an idealized lattice of the ordered Au_3Mn , and for the actual, fractional domain size an enormous unit cell will have to be taken as an exact unit cell.

The lattice spacings obtained from an X-ray Debye photograph of 26.5 atomic % Mn alloy by Raub *et al.*¹⁾ are almost explained by the present model with the domain size, $1.0a_1$ and $2.2a_2$.

(2) In Fig. 1 satellites are observed around the intense normal spots, while their intensities cannot be derived from the present model. The circumstance is the same as in CuAu(II) ⁵⁾ and Cu_3Pd ⁴⁾.

Fig. 1. Electron diffraction pattern of the ordered Au_3Mn film; normal incidence. Indices assigned to normal reflections are referred to the disordered cubic lattice.

Fig. 2. The Au_3Mn superstructure, viewed along $[001]_{\text{cub}}$. Stepshifts occur at places indicated by arrows.

It is sure that the satellites arise from the lattice modulation, such as a periodic change of the lattice spacing or of the scattering factor, with the same period as that of anti-phase domains, but the explanation of the origin of such a modulation has not yet been given. The author measured the intensities of diffraction spots photometrically and tried Fourier analysis for the potential distribution, in order to obtain more information about the nature of the lattice modulation, and he succeeded in getting a clue to the solution.

A full report will be published elsewhere.

The author wishes to express his sincere thanks to Prof. S. Ogawa for his kind guidance.

Ultrasonic Velocity and Adiabatic Compressibility of Mixture of Sulfuric Acid and Water

By Yoshio ISHIDA

Faculty of Education, Shimane University, Matsue

(Received February 7, 1958)

The ultrasonic velocity in aqueous solution of the sulfuric acid was measured at the frequency of 5 Mc/sec and at two temperatures 30°C and 15°C, by use of the rotary grating method^{1,2,3)} which is a variation of the Debye-Sears light diffraction method⁴⁾.

After finishing it, the author was informed about the publication by Porosorow⁵⁾ and very glad to have an opportunity to make comparison as shown in Table I.

Table I.

In Fig. 1, the concentration is expressed in the mole fraction of the sulfuric acid and the adiabatic compressibility is computed by the formula $1/\rho V^2$. The velocity-curves have maxima, while the compressibility-curves minima. The position of maximum of the velocity-curve shifts to the

higher-concentration side as the temperature decreases. The position of minimum of the compressibility-curve does not shift appreciably, but the

Fig. 1. Ultrasonic velocity and adiabatic compressibility versus concentration.

value of minimum decreases with the temperature.

The feature that velocity-curve has maximum is common to all of the mixtures of methyl alcohol-water⁷⁾, ethyl alcohol-water⁶⁾, acetone-water⁶⁾, pyridine-water⁷⁾, formic acid-water³⁾, acetic acid-water^{9,7)}, nitric acid-water⁵⁾, carbon tetrachloride-liquid paraffin¹⁰⁾ and others. We ascertained that the volume contraction always took place when these mixtures were prepared. Since the sulfuric acid-water mixture shows both of the volume contraction and the above-mentioned ultrasonic feature, it belongs to the group of these mixtures. Thus, there is a relation between the volume contraction and the existence of minimum in the compressibility curve.

Supported by a scholarship of the Ministry of Education in 1957, the present research was performed at the Department of Physics, Faculty of Science, Kyoto University. The author wishes to thank Professor I. Takahashi for his continual encouragement and valuable discussions. His thanks are also due to Professor M. Ishibashi of the same University for his kind guidance in the technique of acidimetry.

**Excitation of π Electrons in Benzene by Fast
Electron According to FE Model**

By Mitio INOKUTI

*Department of Applied Physics, Faculty
of Engineering, University of Tokyo,
Tokyo*

(Received February 17, 1958)

It has been empirically known that an aromatic hydrocarbon undergoes strikingly little chemical change under high energy radiations as compared with other organic compounds.¹⁾ The radiation-insensitivity of aromatic hydrocarbons seems to have not received clear-cut explanation, though some proposed to attribute it to easy transfers of excitations.²⁾ However, it is also desirous to examine primary excitation processes due to radiations, and so we tried an estimation of cross sections for excitation of π electrons in benzene by impact of a fast electron.

We adopt a simple FE model to describe the molecule, whose skeleton is represented by a circular ring of radius a . ($a=2.767$ atomic unit, adjusted by observed 1st excitation energy.) Then an EF orbital is

$$u_m(\chi)=(2\pi)^{-1/2}e^{im\chi}, \quad m=0, \pm 1, \pm 2, \dots \quad (1)$$

where χ is the electronic angular coordinate. Born approximation gives the differential cross section I for excitation $i \rightarrow f$ as*

$$I=4\langle k'/k \rangle K^{-4} |(f|T|i)|^2,$$
$$T=\sum_{s=1}^6 \exp(i\mathbf{K} \cdot \mathbf{r}_s), \quad (2)$$

where $\mathbf{r}_s$ ($s=1, 2, \dots, 6$) are electronic positions, $\mathbf{k}$ and $\mathbf{k}'$ momentum of the colliding electron before and after scattering respectively and $\mathbf{K}=\mathbf{k}'-\mathbf{k}$. If $\mathbf{k}$ is perpendicular to the molecular plane,** we can integrate (2) to get the total cross sections $Q_m^{(0)}$ and $Q_m^{(4)}$ for the formation of the excited states where a π electron is excited into the levels $\pm m$ from the levels ± 1 or the level 0, respectively, as

$$Q_m^{(0)}=2q(1, m)+2q(-1, m),$$

* The Hartree atomic unit is used in all the expressions.

** Cases with other incident directions, offering mathematical complexities, have not been treated exactly, but seem never to yield features essentially different from the simple case closely examined.

$$Q_m^{(4)}=2q(0, m), \quad m=2, 3, 4, \dots, \quad (3)$$

where

$$q(n, m)=(8\pi a^2/k^2) \int_0^w J_{n-m}^2(z) z^{-3} dz,$$
$$v, w=ka \mp \sqrt{(ka)^2 - m^2 + n^2}. \quad (4)$$

The integral in (4) can be evaluated analytically for $|m-n|>1$, while it must be computed numerically for $|m-n|=1$.

Table

incident energy (ev)	$Q_2^{(0)}$	$Q_2^{(4)}$	$\sum_{m \geq 3} (Q_m^{(0)} + Q_m^{(4)})$
(π atomic unit)			
100	11.457	0.684	1.562
200	6.451	0.345	0.781
300	4.582	0.230	0.561
400	3.586	0.173	0.391
700	2.216	0.099	0.223
1000	1.625	0.069	0.156
1500	1.140	0.046	0.104

Numerical results, given in Table, show that π electrons are very apt to be excited to the lowest excited level; it is physically expected on account of the mobile character of π electrons. For comparison we remark that the cross section for excitation of σ electrons, roughly estimated by means of the additivity-hypothesis³⁾ that the cross section of a molecule is nearly the sum of those of the constituent atoms, amounts only about 10% of $Q_2^{(0)}$. As we disregarded exchange collisions, the excited levels concerned are singlets and so they may be deactivated by fluorescence or collisional deactivation in a short period, so that they may contribute little to initiation of secondary processes leading to over-all radiation effects. On the basis of the above argument we can interpret the radiation-insensitivity of benzene in terms of the large cross section for excitation of π electrons at least qualitatively.

With the present result we can point out that primary excitation processes sometimes become dependent on molecular structure and significant in radiation chemistry, contrary to current ideas. Excitation to lower triplet states deserves examination also, but it is difficult as exchange collisions generally become important at low energies where Born approximation is inapplicable.

The author is grateful to Prof. A. Amemiya for his discussions and encouragements throughout the work.

Contact Behavior of Metals to CdSe, CdTe, ZnSe and ZnTe

By HIROSI TUBOTA and HIROMICHI SUZUKI
General Education Department,
Kyusyu University

(Received February 25, 1958)

Behavior of the contact between metals and II-VI intermetallic compounds such as CdSe, CdTe, ZnSe and ZnTe were studied. These compounds were prepared as polycrystalline materials by a dry method in our laboratory. CdSe was *n*-type and had the hexagonal structure, while the others were *p*-type and had the cubic structure. Cu, Ag, Au, Zn, Cd, In and Pb were used as contact metals.

The ingots of these compounds were cut and

polished up into a parallelepiped and cleaned. Then, a film of the metal mentioned above was evaporated onto two opposite surfaces with the largest area as the electrodes. The dc current-voltage characteristics were obtained by a usual method at room temperature in the dark. From these characteristic curves, we observed the linearity and obtained the threshold voltage (V_0) for zero current. This voltage is defined as the extrapolation of the linear part of the characteristic curve to zero current, and this magnitude may be used as a measure of deviation from the ohmic behavior. The results are shown in the following table, and also the typical curves of current-voltage characteristics in In-CdSe and Au-CdSe are shown in Fig. 1.

In the case of CdSe, measurements were made with many samples. Particularly, in In-CdSe, about one dozen of samples were tried and it was

Observed values of the threshold voltage (V_0)

	ZnTe (<i>p</i>)	0.05	—	—	—	—	—	—

Fig. 1. Dc current-voltage characteristic curves. (A) for In-CdSe contact, (B) for Au-CdSe contact.

found that V_0 were very close to zero for all of the samples and the linearity were very good up to several volts. It is of interest that the result is in agreement with the fact observed in In-CdS and Ga-CdS by Smith.¹⁾

In the cases of CdTe, ZnSe and ZnTe, measurements were made with several samples and no metals were found to present the good ohmic behavior. Furthermore, in ZnSe and ZnTe, almost all metals used showed such poor linearity that the

threshold voltages could not be determined.

If the barrier height in metal-semiconductor contact is determined only by the work function difference between metal and semiconductor, it should be expected that, as the work function of metal becomes larger, so does the deviation from the ohmic behavior, and hence the threshold voltage increases in *n*-type materials. This expectation seems to be satisfied qualitatively in CdSe as shown in the table. On the other hand, as the reverse is the case in *p*-type, the results obtained in the case of CdTe seem qualitatively explicable on the same way.

In order to explain the ohmic behavior by the model of the conductive layer formed by diffusion of metal into semiconductor, we must have more sufficient knowledge of the diffusion of the present materials. However, at least, in the case of In-CdSe contact showing a good ohmic behavior, it seems that there may be a strongly *n*-type conductive layer formed in CdSe next to the electrodes, as proposed by F. A. Kröger²⁾ for In-CdS and Ga-CdS contacts.

The authors wish to express their sincere thanks to Prof. A. Okazaki for his continual advice and encouragement.

Gamma Rays from the Proton Bombardment of Silicon

By Eiji OKADA, Iwao MIURA, Tetsuo WAKATSUKI
and Yasuo HIRAO

*Department of Physics and the Laboratory of Nuclear Studies,
Faculty of Science, Osaka University, Osaka*

(Received February 10, 1958)

Gamma ray spectrum from silicon bombarded by 5.7 MeV protons has been studied by a scintillation spectrometer. The following gamma rays due to inelastic scattering of protons were observed. 1.78 MeV (^{28}Si 1st—ground), 1.28 MeV (^{28}Si 1st—ground), 2.03 MeV (^{28}Si 2nd—ground), 2.43 MeV (^{28}Si 3rd—ground), 2.24 MeV (^{30}Si 1st—ground). Excitation curves for the 1.78 MeV gamma rays have been measured in the proton energy range from 2.2 to 5.7 MeV. Resonances were found at 2.9, 3.5, 4.4, 5.0 and 5.4 MeV. At 5.4 MeV, the angular distribution of the 1.78 MeV gamma rays was measured. By comparison with theory, the corresponding compound level of ^{29}P at 7.9 MeV was assigned $d_{5/2}$.

The cross section for this process is 250 mb.

§ I. Introduction

The yield of gamma rays from silicon bombarded with protons has been studied by a number of workers. In the low energy region of proton energies below 2 MeV, the spectrum of gamma ray energies and the yields were measured for the reactions $^{29}\text{Si}(p, \gamma)^{30}\text{P}^{(1)}$ and $^{30}\text{Si}(p, \gamma)^{31}\text{P}^{(2)}$. Many resonances have been found for each reaction. As the proton energy becomes higher, gamma rays following inelastic scattering of protons become predominant. Cohn, Bair, Kington and Willard³⁾, observing 1.78 MeV gamma rays from the first excited state of ^{28}Si due to proton inelastic scattering, found 13 resonances in the range of proton energies from 2.6 to 4.9 MeV.

Bromley, Gove, Paul, Litherland and Almqvist⁴⁾ studied the gamma radiation associated with the $^{29}\text{Si}(p, p'\gamma)^{29}\text{Si}$ inelastic scattering reaction in the proton energy range from 2.5 to 3.0 MeV.

The present paper describes measurements of the energy spectrum, yield and angular distribution of gamma rays following inelastic scattering of protons by natural silicon target at proton energies extending up to 5.7 MeV.

§ 2. Experimental Methods

Molecular ion beam of hydrogen accelerated by 44 inch cyclotron has been used to study the gamma rays following inelastic scattering of protons by silicon. The outer beam of protons passed through a focussing magnet, concrete shield wall 1.5 meter thick and

aluminium absorbers of different thicknesses before reaching a target. The distance from the cyclotron to the target is about 7 meters. The upper limit of the proton energy was 5.7 MeV and the energy was degraded at 0.1 MeV intervals down to 2.2 MeV by the aluminium absorbers placed about 1 meter in front of the target. The intense gamma rays from aluminium by $\text{Al}(p, p'\gamma)$ reaction were shielded by a lead block with a beam hole 1 cm in diameter placed just behind the absorber in a vacuum vessel. But a considerable fraction of gamma rays from aluminium absorbers was observed in a forward direction and a correction was necessary in angular distribution measurement.

The corrections amount to about 100% for 0° , 4% for 135° and 1~2% for all the other angles. The energy of those back ground gamma rays was found to be 1.74 MeV corresponding to the transition from the fourth to the second excited state of ^{27}Al .⁵⁾

The beam was defined by a defining slit made of gold plate 4 mm wide and 10 mm high.

The proton current incident on the target was measured by a current integrater consisting of a highly insulated condenser and a string electrometer. A monitor scintillation counter was also used.

The gamma rays were measured with a sodium iodide crystal spectrometer consisting of a crystal 3 in. in diameter and in length, viewed by a Dumont 6364 photomultiplier.

The pulses were fed from the amplifier to a 20 channel pulse height analyzer. The crystal and the lead shield for the crystal were mounted on a turntable which enabled them to be set at angles between -60° to $+135^\circ$ with respect to the proton beam. The distance from the target to the surface of the crystal was 30 cm. No collimation for the

Fig. 1. Schematic diagram of experimental equipment.

Fig. 2. Gamma ray spectrum from Si bombarded by 5.7 MeV protons observed at 90° with respect to the proton beam.

gamma ray was used for the measurement of the yield and the spectrum, but a lead slit of 3.5 cm in diameter and 7 cm thick was placed in front of the crystal for the measurement of angular distribution to improve the geometrical condition.

The geometry of the system is shown schematically in Fig. 1.

§ 3. Results and Discussions

Fig. 2 shows the gamma ray spectrum observed at right angles to the beam at proton energy of 5.7 MeV. The arrows indicate the positions of the peaks and the energies of the gamma rays expected from the known excited levels of ^{28}Si (abundance 92.2%), ^{29}Si (4.7%) and ^{30}Si (3.1%)⁵⁾ by inelastic scattering.

As is evident from the Fig. 2, the energy of the most intense gamma ray is 1.78 MeV (^{28}Si 1st—ground) corresponding to the deexcitation from the first excited state to the ground state in ^{28}Si . The 2.67 MeV (^{28}Si 2nd—1st) and 3.13 MeV (^{28}Si 3rd—1st) were too weak to be observed. Gamma rays of 1.28, 2.03 and 2.43 MeV were identified as the deexcitation from the first, second and third excited state to the ground state of ^{29}Si . Gamma ray of 2.24 MeV energy corresponding to the transition from the first excited state to the ground state of ^{30}Si has also been observed. The 550 keV gamma ray was ascribed to be due to the gold backing.

Next, the yield of the 1.78 MeV radiation from the reaction $^{28}\text{Si}(p, p'\gamma)^{28}\text{Si}$, as a function of the proton bombarding energy was measured at right angles to the beam. The result is shown in Fig. 3. The resonant yields were

Fig. 3. Yield of the 1.78 MeV radiation from the $^{28}\text{Si}(p, p'\gamma)$ reaction as a function of the bombarding proton energy.

observed at proton energies of 2.9, 3.5, 4.4, 5.0 and 5.4 MeV. As the proton energy was changed by the absorber, the spread of the proton energy is considerably large and the levels spaced closely are not resolved. Thus our value 2.9 MeV can be supposed to include

2.64 and 3.11 MeV resonances, 3.5 MeV includes 3.35, 3.58 and 3.71 MeV resonances, 4.4 MeV includes 4.25 and 4.44 MeV resonances, and 5.0 MeV includes 4.70, 4.82 and 4.86 MeV resonances as reported by Cohn et al.³⁾

Newly found resonance level at 5.4 MeV has very strong intensity and the corresponding level of ^{29}P is 7.9 MeV. To determine the spin of this level, the angular distribution of 1.78 MeV gamma ray was measured at proton energy of 5.4 MeV. The results of this measurement are shown in Fig. 4 and the solid line in this figure represents a curve

Fig. 4. Angular distribution of the 1.78 MeV radiation relative to the direction of the incident protons at proton energy of 5.4 MeV. The solid curve was calculated assuming $5/2^+$ -compound state and $1=1'=2$.

Fig. 5. Angular distribution of the 1.78 MeV radiation at proton energy of 5.7 MeV. The solid curve is a least square fit to the experimental points using even Legendre polynomials up to P_4 .

calculated theoretically as is discussed later.

The measurement was also made at proton energy of 5.7 MeV and the results are shown in Fig. 5. The solid line in this figure represents a least squares fit to the data, using even Legendre polynomials up to P_4 , and is given by

$$W(\theta) = \alpha \{1 + 0.239P_2(\cos \theta) - 0.225P_4(\cos \theta)\}$$

As the spins of the ground and the first excited state at 1.78 MeV of ^{28}Si are known to be 0^+ and 2^+ respectively, the angular distribution of the gamma ray corresponding to the transition from the first excited state to the ground state can be calculated if appropriate spin is assumed for the compound level of ^{29}P . The general expression was given by Kraus, Schiffer, Rösser and Biedenharn⁸⁾ and the numerical coefficient of the Legendre polynomials for the present case can be obtained from Table I in our previous work⁷⁾ for $1, 1' \leq 3$ and except for interference term. (1 and $1'$ are incoming and outgoing angular momentum for protons respectively.) For the resonance level of ^{29}P at 7.9 MeV ($E_p = 5.4$ MeV), the assignment of $5/2^+$ to the level and $1=1'=2$ gives satisfactory agreement with the experiment. In this case the theory gives⁸⁾

$$\begin{aligned} \sigma(\theta) = & a_{3/2} 12(12 - \cos^2 \theta) \\ & + a_{5/2} (151 - 138 \cos^2 \theta + 175 \cos^4 \theta) \\ & + a_{3/2, 5/2} 24(1 - 18 \cos^2 \theta + 25 \cos^4 \theta) \end{aligned}$$

where the first term is that due to $3/2$ channel spin, the second is due to $5/2$ channel spin and the final term is due to interference effects. The solid curve in Fig. 4 represents the theoretical curve with the values $a_{5/2} = 1/2 \cdot a_{3/2}$ and $a_{3/2, 5/2} = 1/2 \cdot a_{3/2}$. The relative values of $a_{5/2}$ or $a_{3/2, 5/2}$ to $a_{3/2}$ other than this choice also explain the experimental curve to some extent. But the value of the spin J other than $5/2^+$ can not give the angular distribution observed by the experiment. The values $J=5/2^+$ $1=1'=2$ are consistent with the observation on the angular distribution of the inelastically scattered protons from the 1.78 MeV level of ^{28}Si at proton energy of 5.4 MeV carried out by Yamabe, Kondo and Yamazaki⁹⁾ in our laboratory.

It is therefore concluded that ^{29}P has $d_{5/2}$ level at 7.9 MeV. But it is not certain that the level is single or not.

The angular distribution of the 1.78 MeV gamma ray at proton energy of 5.7 MeV is

shown in the Fig. 5. General character of the curve seems to be expressed by the theoretical curve assuming compound level $d_{5/2}$ and $l=2$, $l'=0$.

The absolute cross section for the excitation of 1.78 MeV gamma ray at 5.4 MeV proton energy has been measured by comparison of the intensity with that of 1.17 and 1.34 MeV gamma rays from a standard ^{60}Co source* placed at the position of the target. The result is 24 mb/ster. at 90° . From the curve shown in Fig. 4, the total cross section can be calculated as 250 mb.

Magnetic Spectrometer having Inclined Plane Pole-Faces for Low-energy Electrons

By Susumu KATO

*Laboratory for Applied Physics, Faculty of Engineering,
Osaka University, Higashinoda, Osaka, Japan*

(Received January 29, 1958)

A magnetic spectrometer with inclined plane pole-faces has been constructed for the velocity analysis of low-energy electrons. The magnetic field strength H at a point P satisfies

$$H = H_1/r,$$

where H_1 is a constant and r is the distance from the line of intersection of the two pole-planes to P . The momentum dispersion of our spectrometer is about 3 times larger and the solid angle of the collection is more than 10 times wider than those of a conventional semi-circular spectrometer of similar dimensions. The equation which determines the momentum dispersion was obtained and the conditions for focusing were discussed.

§ 1. Introduction

An electron, ejected from one point into a uniform magnetic field in a direction per-

pendicular to the lines of magnetic force, describes a circle whose radius depends on the velocity of the electron and on the strength

of the magnetic field. Thus various momenta may be selected by changing either the radius of the selected paths or the value of the magnetic field. This is the principle of the conventional semi-circular spectrometers. The resolving power of a semi-circular spectrometer is mainly defined by three terms, i.e. the momentum dispersion, broadening of the image of the emitting source focused on the collecting slit and the collecting slit width.

Various attempts have been done for increasing the resolving power.¹⁾ One of the methods which has been used is to give a small amount of departure from uniformity in the magnetic field, for example—by altering the profile of the pole-faces of the magnet. In order to get good reproducibility and ease of construction, the simplest possible profile is evidently desirable.

It is thus of interest to utilize the non-uniform magnetic field between two inclined plane pole-faces. The field is the same as that due to a current flowing along the line of intersection of the two planes, and the lines of force are a family of circular arcs. This kind of field was first discussed by Richardson²⁾ mathematically, and has further been studied in the case of a sector field by several investigators.¹⁾

We have constructed a magnetic spectrometer which has an inclined plane pole-faces magnet. In our spectrometer the whole paths of electrons from the source to the collecting point exist in the magnetic field as in usual semi-circular focusing systems but somewhat different from the paths suggested by Richardson. The spectrometer has the high dispersion and resolving power together with a fairly large solid angle of collection, and the lack of uniformity of the edge of magnetic field does not affect the paths of electrons.

§ 2. The Orbits of Electrons

Let r , z , and ϕ be cylindrical coordinates representing radial, longitudinal and azimuthal displacements with respect to the axis $r=0$ defined by the line of intersection of the two planes which contain the faces of the magnetic pole-pieces. The equipotential planes $\phi=\text{constant}$ all intersect along this axis, on which lie the centers of the circular lines of force. The field H satisfies

$$H=H_1/r, \quad (1)$$

where H_1 is the intensity at $r=1$.

The three-dimensional equations of the orbits from a point source lying in the mid-plane $\phi=0$ at $r=r_s$ were given by Richardson. However the integrands which were used in his equations are not convenient for numerical calculations to design a spectrometer. Fortunately in a spectrometer the image will be formed by the orbits which lie in or near the mid-plane $\phi=0$. In this case, the equations of the family of coplaner orbits are given also by Richardson,

$$r=r_s \cdot \exp \{K(\cos \phi - \cos \phi_s)\}, \quad (2)$$

$$z = -K \cdot r_s \cdot \exp(-K \cos \phi_s) \times \int \cos \phi \cdot \exp(K \cos \phi) d\phi, \quad (3)$$

where, ϕ is the angle between the velocity vector V at a point P on the orbit and a vector through P parallel to the axis $r=0$, pointing in the direction of increasing z and $\phi=\phi_s$ at the source S . K is related to the momentum $m_e \cdot v$ by

$$K = \frac{m_e \cdot v}{H_1 \cdot e_0}. \quad (4)$$

Now we consider the nature of the orbits.

A. Estimation of orbits.

On designing the spectrometer it is convenient to know the approximate forms of the orbits before the rigorous calculations. From the above equations of the orbits, the radius of curvature ρ at a point P on the paths is

$$\rho = Kr. \quad (5)$$

Then, if we know the position of a source S and ϕ_s , we can show a orbit lying in the mid-plane as a series of loops in which the radius of curvature is equal to Kr . r takes a value between $A \exp K$ and $A \exp(-K)$ periodically, with maxima at $\phi=2n\pi$ and minima at $(2n+1)\pi$, where n is an integer and

$$A = r_s \cdot \exp(-K \cos \phi_s).$$

The z -displacement in a complete loop increases rapidly with K . Orbits with the same value of K have the same shapes but different sizes, because both r and z are proportional to $\exp(-K \cos \phi_s)$, which varies with the angle of emission ϕ_s .

For the actual calculation of eq. (3) it will be convenient to use the values of $\int_0^\phi \cos \phi \cdot$

$\exp(K \cos \psi) d\psi$ given by Richardson. A part of his work is shown in Table I.

Table I. Values of $\int_0^\psi \cos \psi \cdot \exp(K \cos \psi) d\psi$
for $K=1$.
(quoted from a part of Richardson's table²⁾)

ψ°	I	ψ°	I

80	2.22688	170	1.83976
90	2.24395	180	1.77550

B. Conditions for focusing.

In spectrometers it is necessary that the rays emitted from a point source with small angular divergence $\Delta\xi_s$ should be converged to a point. However the general conditions for focusing of the rays in the field H of Eq. (1) have not been studied yet. Then we have derived the general condition from Eqs. (2) and (3) as followings,

$$\frac{\partial r}{\partial \psi_s} = rK \sin \psi_s, \quad (6)$$

$$\frac{\partial z}{\partial \psi_s} = K(z \sin \psi_s + r_s \cos \psi_s). \quad (7)$$

Eq. (6) becomes zero when

$$\psi_s = n\pi, \quad (n=0, 1, 2, \dots), \quad (8)$$

and for Eq. (7) the condition which makes it zero is

$$\cos \psi_s = \pm \sqrt{\frac{z^2}{z^2 + r_s^2}} = \pm \sqrt{\frac{w^2}{w^2 + 1}}, \quad (9)$$

where $z = w \cdot r_s$.

Unfortunately we have no ψ_s 's satisfying the conditions (8) and (9) simultaneously except when the emitting source lies on the line of intersection of the two magnetic pole-planes so we can not design such spectrometer. Then we must choose the value of (r, z) which indicates the position of the collecting slit so as to minimize the broadning of the emitted rays estimated from both Eqs. (3) and (9).

The relations between ψ_s and w are shown by the dotted lines in Fig. 1 and the corresponding values of z calculated from Eq. (3)

by full lines. The intersections satisfy both Eqs. (3) and (9). But for perfect focusing Eq. (8) should also be considered, then the points A_1 and A_2 in Fig. 1 are the most suitable ones for spectrometers of this kind.

Fig. 1. Focusing of the orbits lying in the mid-plane for $K=1$. The relations between emitting angle ψ_s and $w=z/r_s$ derived from Eq. (9) are shown with the dotted lines. The corresponding values of z calculated from Eq. (3) are shown by full lines. ψ represent the positions of the collecting slit. The intersecting points satisfy both Eqs. (3) and (9). Among these points A_1 and A_2 are most suitable for the spectrometers.

C. Momentum dispersion and resolving power

In the conventional semi-circular spectrometer the distance from the source to the image z_i is,

$$z_i = 2\rho = \frac{2p}{H \cdot e_0},$$

where p is the momentum of an electron. Thus

$$p \frac{dz_i}{dp} = \frac{2p}{H \cdot e_0} = z_i.$$

The dispersion is proportional to the length of the spectrometer. With inclined poles Richardson calculated the dispersion of z -direction for only a case when K is near to or greater than unity and ψ_s is near to π . However to obtain the best dispersion available in this type of magnetic field we must calculate for both r and z -directions in the

general case. We have derived following Eqs. of momentum dispersion.

From Eq. (2)

$$p \frac{dr}{dp} = K \frac{dr}{dK} = Kr(\cos \psi - \cos \psi_s) . \tag{10}$$

The maximum value of Eq. (10) is $2r$ when $K=1$, which represents two times the dispersion of a semi-circular spectrometer of the same length. The dispersion of z -direction is given from Eq. (3)

$$p \frac{dz}{dp} = K \frac{dz}{dK} = z \left\{ 1 - K \cos \psi_s + \frac{K(\partial I / \partial K)}{I} \right\} , \tag{11}$$

where

$$I = \int_{\psi_s}^{\psi} \cos \phi \cdot \exp (K \cos \phi) d\phi , \tag{12}$$

thus

$$\frac{\partial I}{\partial K} = \int_{\psi_s}^{\psi} \cos^2 \phi \cdot \exp (K \cos \phi) d\phi . \tag{13)*}$$

Values of $\partial I / \partial K$ are given in Table II. for $K=1$. The momentum dispersion for z -direction derived from Eq. (11) is shown in

Table II. Values of $\frac{\partial I}{\partial K} = \int_0^{\psi} \cos^2 \psi \cdot \exp (K \cos \psi) d\psi$ for $K=1$.

ψ°	$\partial I / \partial K$	ψ°	$\partial I / \partial K$

80	1.858	170	2.138
90	1.860	180	2.202

Fig. 2. The maximum value occurs near at $\psi=450^\circ$, $\psi_s=180^\circ$ and fortunately this is in the neighbourhood of points A_1 and A_2 indicated in Fig. 1. The dispersion in this point is larger than semi-circular spectrometer by more than 3 times. Orbits in the mid-plane of our spectrometer and the arrangement of the electrodes are shown in Fig. 3. The axis

* Differentiation with respect to K was done under the assumption that the both limits of the integral were constants. When the width of the beam of the emitted rays is not so wide the error caused by this assumption is negligibly small.

of the collecting slit i.e. the perpendicular line of the baffles of our spectrometer is sat normal to the z -axis but the direction of the perpendicular line of the spectrometer which was suggested by Richardson is arranged normal to the r -axis. From the point of view of adjustment our slit system is more con-

Fig. 2. Momentum dispersions. The values were calculated from Eq. (11) and shown in full lines. The dotted line corresponds to the momentum dispersion for conventional semi-circular spectrometers.

Fig. 3. Orbits in the mid-plane between inclined plane pole-faces in our spectrometer. The positions of the centers of the two baffles and the collecting slit are adjusted for the values $\psi=270^\circ$, 360° and 450° of the orbit with $K=1$, $\psi_s=185^\circ$ which was represented as pt. A_2 in Fig. 1 and 2.

venient than the Richardson's one. In his paper he described that his spectrometer has 4.24 times the dispersion of a semi-circular spectrometer of the same length but when we calculated his case with both his equation and our Eq. (11) we have not obtained 4.24 but 3.24.

D. Solid angle of collection.

Richardson has found that the inclined pole spectrograph which was suggested by him has a solid angle of collection about 16.5 times that of a parallel pole spectrograph with a slit of equal width using the same

source-image distance. In our spectrometer the angle has been calculated according to Richardson's method and the results was better 10 times or more compared to the semi-circular spectrometer of the same length.

§ 3. Construction of a Spectrometer

We have constructed a spectrometer with inclined pole-faces magnet. The orbits of electrons in the mid-plane of the spectrometer are shown in Fig. 3. The source to slit distance is 11.10 cm. The momentum dispersion is $3.0z$ which is about 3 times the dispersion of a semi-circular spectrometer of the same length and the displacement of z -direction was 1.65 mm/volt for 100 volts electrons.

A vacuum box has been constructed by soldering brass plates of 1 cm in thickness. The collecting slit has been assembled so that its position and width can be adjusted from the outside of the box, two O-rings being used for this purpose. The box was evacuated by a high speed oil diffusion pump and pressures of about 1×10^{-5} mm H_g could be obtained.

Fig. 4. Magnetic spectrometer having inclined plane pole-faces. The main purpose of the construction of this apparatus is to analyse the velocity distributions of the photoelectrons which were ejected by soft X-rays or ultra-violet rays. The spectrometer (right) and the soft X-ray tube (left) are shown.

The magnet has been constructed with two 20 cm square silicon steel. The narrowest gap near the intersecting line of the plates was 4 mm and for low energy electrons, i.e. weak magnetic field strength, the approach to saturation of the magnetic induction is not conceivable. The intersecting angle between two pole plates was 90° .

The spectrometer is shown in Fig. 4. The main purpose of the construction of this apparatus is to analyse the velocity distributions of the photoelectrons which are ejected by soft X-rays or ultra-violet rays so the velocity of the electrons is up to about 100 v.

§ 4. Discussion

The inclined plane pole-faces magnetic spectrometer described above has following advantages. The momentum dispersion is about 3 times larger and the solid angle of the collection is more than 10 times wider than those of a conventional semi-circular spectrometer of similar dimension. For example when the source to image distance is 11.10 cm the displacement of the image is 0.555 mm/volt for 100 volts electrons in the case of semi-circular spectrometer, and in our spectrometer the value becomes 1.65 mm/volt with an appropriate solid angle of collection.

One of the disadvantages of this type of spectrometers is that the space near the source and the collecting slit is not so large. But in our spectrometer the space for the slit is somewhat improved from the one suggested by Richardson. Richardson designed a spectrometer of different type in which the inclined planes were bevelled so as to become parallel at their closest parts. But the construction and the adjustment of the apparatus are seemed to be more complicated.

In our spectrometer the gap at the intersecting line of the two pole-faces is very narrow and the flux density at the part is somewhat stronger than in the semi-circular spectrometer for the analysis of electrons of the same momentum. This is not so inconvenient for the spectroscopy of low-energy electrons.

Acknowledgements

The author wishes to acknowledge Professor G. Shinoda for his encouragement and helpful discussion during the course of this work. He is grateful also to Assistant Professor T. Suzuki for his kind advice throughout this calculation.

On the Magnetic Annealing Effect in 2% Cobalt-Copper Alloy

I. Induced Ferromagnetic Anisotropy

By Tadayasu MITUI

*Department of Physics, Faculty of Science, University
of Hokkaido, Sapporo, Japan*

(Received September 26, 1957)

The behavior of ferromagnetic precipitates in copper-cobalt alloy containing ca. 2 wt. % cobalt heat-treated with magnetic field was studied with the object of making clear a physical origin of the induced uniaxial anisotropy observed. The magnitude of magnetic anisotropy induced by magnetic annealing was measured as functions of the aging temperature, aging time, and intensity of magnetic field. It has been found that almost all of the experimental results can be explained by the fine-particle behavior of ferromagnetic precipitates. It is shown that the origin of magnetic annealing can be explained neither by the magneto-elastic anisotropy of directional deformation nor by the magnetocrystal-line anisotropy, but by the shape anisotropy of precipitated particles, which is distributed preferentially along the direction of magnetic field applied during annealing. It is also shown that the magnetic annealing affects remarkably the initial precipitation process rather than the over-growth stage of precipitation.

§ 1. Introduction

Since it has been found that the presence of magnetic field during heat treatment induces a uniaxial magnetic anisotropy in various ferromagnetic alloys and ferrites such as, permalloys, perminvars, Alnico V, and cobalt ferrite, the effectiveness of magnetic heat-treatment has been studied by many investigators for many years and a number of explanations have been proposed.

As for magnetically hard materials, this phenomenon was first found with Alnico II by Oliver and Shedden¹⁾ who observed an increase in residual induction by cooling in the presence of magnetic field. This effect was also found in some other permanent magnetic alloys such as MK Alloy, Alnico V, and Alcomax. Especially, Alnico V has been studied by several investigators for the purpose of clarifying a physical origin of the induced uniaxial anisotropy; Heidenreich and Nesbitt^{2,3)} and Kronenberg⁴⁾ succeeded in the direct observation of various interesting phenomena in precipitation by means of the electron microscope and clarified the mechanism of magnetic annealing in this case. They found that Alnico V was divided into plates of precipitates and that the nuclei grew parallel to the direction of magnetic field applied during heat treatment, which suppressed completely the

nucleation of precipitates perpendicular to its direction. These experimental works confirmed substantially the physical origin of uniaxial anisotropy, in this case, namely the so-called "shape-effect", which has been referred to for the interpretations of the magnetic behavior of precipitation-type alloys^{5,6,7)}. The significant feature of this effect is that the precipitate grows in the form of prolate ellipsoid elongated in the direction of magnetic field applied during heat treatment.

On the other hand, Néel⁸⁾, Chikazumi and Oomura⁹⁾, and Taniguchi and Yamamoto¹⁰⁾ proposed independently a new mechanism based on the idea of "directional order", in terms of which they could explain almost all features of the magnetic annealing effect in high-permeability alloys, such as permalloys and perminvars. This mechanism was also proposed by Néel for the magnetic annealing of Alnico-type alloys, but his interpretation may be only a possible one and has not yet been confirmed experimentally. Although the shape effect is found by the microscopic observation in Alnico V, the mechanisms of directional order and surface anisotropy proposed by Néel may also be possible interpretations of magnetic behavior of precipitation-type alloys. Then, the limit of compatibility

of these mechanisms to precipitation-type alloys should be established.

In precipitation-type alloys which respond to magnetic annealing, magnetic field may affect the precipitation process in some way. However, the origin of the anisotropy of Alnico V is incompletely understood, because the precipitation reaction has not yet been definitely studied and also the composition, magnetic saturation, Curie points, and crystal structures of the phases involved have not yet been established. So, we suppose that, in order to find out contributions of various mechanisms on the origin of the uniaxial anisotropy induced by magnetic annealing in precipitation alloys, it is necessary to use alloys metallographically simpler than Alnico V, which is practically important but rather complex.

For the above-mentioned purpose, we have used copper-cobalt alloy containing ca. 2 wt. % of cobalt, with which we previously discovered¹¹⁾ the magnetic annealing effect. We shall report the measurements of the uniaxial magnetic anisotropy induced during various magnetic heat-treatments in this alloy and discuss the mechanism of the effect on the precipitation process.

§ 2. Preparations of the Specimens and the Apparatus

Tammann and Oelsen¹²⁾ determined by measuring the specific magnetization the solubility of cobalt in copper and Hashimoto¹³⁾ determined in more detail the phase diagram of Cu-Co alloys, which is shown in Fig. 1. As seen from the figure, cobalt is soluble

Fig. 1. Phase diagram of Copper-Cobalt alloy system.

only to the extent of 5% at 1100°C, 3% at 940°C, and 0.3% at 400°C. The Curie temperature of precipitate of cobalt-rich phase (β -phase) is higher than temperatures of solid solubility if cobalt is contained less than about 4%.

With Cu-Co alloys containing less than 5% Co, it is possible to precipitate by aging the ferromagnetic phase containing approximately 10% copper in the non-ferromagnetic matrix, and the content of 2% cobalt is suitable to avoid a very small trace of ferromagnetism due to imperfect quenching from the high-temperature region of solid solution, because nucleation of the precipitates proceeds extremely rapidly at the temperatures studied, perhaps due to the extremely rapid precipitation at grain boundaries or other imperfections.

Alloy specimens containing about 2% Co were made from electrolytic copper of 99.9% purity and cobalt of 99.8% purity. Weighed metals were melted in a hydrogen atmosphere in a Tammann furnace. After casting in an iron mold, the ingot was forged to avoid segregation and internal cavity and then homogenized at about 1000°C for more than 20 hours.

Specimens were cut out from the ingot and were lathe-machined into disks, 13.3 mm in diameter and 5.2 mm in thickness. Then, to eliminate the internal strain due to forging and machining and to disperse grains finely and randomly, they were in a vacuum heated from room temperature to 700°C at the rate of ca. 50°C an hour, kept at 700°C for 5 hours and cooled slowly to room temperature. Chemical analysis of the specimens gave the following values: 97.7% Cu, 2.2% Co, and less than 0.1% other metals.

The specimens used for the study of magnetic annealing were aged at various temperatures for an appropriate time in an externally applied magnetic field, after the solution treatment of ca. 2 hours at ca. 1000°C, in vacuum electric furnace.

The magnetic anisotropy was measured by means of the torque magnetometer as described previously¹¹⁾. The disk-shaped specimens are placed in a strong and uniform magnetic field of ca. 10,000 Oe, and the torques necessary to fix the disk on arbitrary directions are measured. The magnetic field is supplied by

a Weiss-type electromagnet. The specimen holder of the torque magnetometer is supported by a jewel bearing on the lower end of a helical spring made of phosphor-bronze, so that the horizontal displacement of the specimen due to slightly irregular field of the electromagnet can be avoided.

§ 3. Details of the Experimental Procedure

The specimens were solution-heat-treated in a vacuum at ca. 1000°C, rapidly quenched in water, and then aged at 750°C for ca. 20 hours without a magnetic field. For all speci-

The precipitation treatments were conducted in a vacuum electric furnace at various temperatures and all the specimens were quenched into water at suitable intervals of the aging. Measurements of torque were carried out at room temperature. The intensity of magnetic field applied in the measurements was about 10,000 Oe, although this intensity is not yet enough to induce the saturated intensity of the torque maximum, as seen from Fig. 3 showing the dependence of the torque maximum upon the intensity of magnetic field.

§ 4. Experimental Results

(1) Precipitation process affected by magnetic field.

In order to test a possibility that the magnetic field present during aging is able to influence on the initial stage of precipitation rather than on the over-growth stage, we varied the time of magnetic annealing. For the specimens quenched and then aged at 750°C for 4.0 hours with the magnetic field of 1000 Oe, we obtained the value of 4×10^3 ergs/cc for the constant, K_u of the induced anisotropy, which was found to be expressed experimentally as

$$E = -K_u \cos^2 \theta, \quad (1)$$

where θ is the angle between the direction of magnetic field applied during annealing and that of the measuring field, as seen from the torque curve shown in Fig. 4. This in-

Fig. 2. Torque curves of the 2% Co-Cu alloy specimens aged without magnetic field.

Fig. 3. Dependence of the torque maximum upon the intensity of magnetic field in 2% Co-Cu alloy.

mens prepared by the above-mentioned procedure, the parasitic torque due to the irregular distribution of intergrains was preliminarily examined by the torque magnetometer, of which the results are shown in Fig. 2. We have selected the specimens showing a negligibly small specific torque (curve C) of ca. 10^2 dyne/cm², and omitted the specimens having remarkable irregular torque values (curves A and B).

Fig. 4. Torques brought about by magnetic annealing at 750°C in 2% Co-Cu alloy.

dicates that magnetic field applied during aging produces an uniaxial magnetic anisotropy with an easy direction along the field. On the other hand, the value of K_u found for

the specimens quenched and then aged for 20 hours without magnetic field and consecutively for 4 hours with the field of 1000 Oe is only ca. 4×10^3 ergs/cc, as seen from the torque curve shown in Fig. 4, being the same order of magnitude as that at the final stage of 750°C-isothermal treatment with field of 1000 Oe observed in the previous work¹¹⁾. It may thus be concluded that the influence of magnetic field during precipitation process is

only effective for the nucleation and initial precipitation process.

(2) *Change of the induced magnetic anisotropy with the time of magnetic annealing at various temperatures.*

Values of the anisotropy energy induced during aging with the field of 3000 Oe at 750°C, 720°C, 650°C and 550°C are plotted against the aging time in Fig. 5, which in-

Fig. 5. Anisotropy energy as dependent on the time of annealing with an applied field of 3000 Oe in 2% Co-Cu alloy.

indicates the marked increase of the induced anisotropy energy at the early stage and its large decrease at the over-aging stage. Such a change of the induced anisotropy with the time of magnetic annealing has a trend similar to the changes of the hardness and coercive force of the alloy, as will be shown later.

We may expect from Fig. 5 that the change of the anisotropy constant with aging time at the initial stage of aging is a relaxation process. In fact, the logarithm of the relaxation time, τ , is plotted against the reciprocal of the absolute temperature, T , in Fig. 6, from which we obtain, as the temperature dependence of the relaxation time,

$$\tau = \tau_0 \exp(E/kT). \quad (2)$$

The value of the activation energy E , is ca. 36 Kcal/mol, being lower than the value of the activation energy for the diffusion of Co-atom in the Cu-matrix determined with single crystals of Cu-Co which is 55.14 Kcal/mol¹⁴⁾.

This is reasonable if one takes into account the fact that diffusive processes in the precipitation process may, in general, be much

Fig. 6. Relaxation time of the effect of magnetic annealing in a 2% Co-Cu alloy specimen. The activation energy is 36 K cal/mol.

more rapid at grain boundaries and other imperfections than in the interior of the matrix.

(3) *Change of the induced magnetic anisotropy with the strength of magnetic field applied during aging.*

The anisotropy constant as a function of the time of magnetic annealing at 750°C is

Fig. 7. Anisotropy as dependent on the time of magnetic annealing at 750°C in 2% Co-Cu alloy, as determined from the torque curves measured in magnetic field of ca. 10,000 Oe at room temperature.

Fig. 8. Effect of the strength of magnetic field applied during annealing at 750°C on the magnetic anisotropy constant in 2% Co-Cu alloy as determined from the torque curves measured in field of ca. 10,000 Oe at room temperature.

shown in Fig. 7, which shows that the anisotropy constant approaches to the maximum value after ca. 2~3 hours at 750°C, independently of the strength of magnetic field applied during magnetic annealing. The maximum value of the induced anisotropy constant is plotted against the strength of magnetic field applied during magnetic annealing in Fig. 8, which indicates that the maximum value of the anisotropy constant approaches to saturation with increasing field, as was also observed in our previous work¹¹⁾. On the other hand, in order to test the effect of removing the field during magnetic annealing, the specimen was aged at 750°C for one hour under the field of 5000 Oe and then without field for suitable time intervals. Fig. 9 shows that the anisotropy constant

Fig. 9. Magnetic Anisotropy constant of 2% Co-Cu alloy dependent on the time of annealing at 750°C after the field has been removed.

decreases exponentially after the field has been removed.

(4) *Effect of double magnetic annealing.*

To observe the change of magnetic behavior as the relaxation properties caused by different magnetic annealing, the effect of double magnetic annealing was studied.

After the specimen was annealed at 750°C for 4 hours with field of 2000 Oe (initial magnetic annealing) and its torque was measured. It was annealed again at the same temperature for 4 hours with the same field applied newly in the direction orthogonal to the previous one (second magnetic annealing). Although the initial magnetic annealing induced the anisotropy of pure two-fold rotational symmetry containing no four-fold term, the second magnetic annealing induced the anisotropy of four-fold symmetry, as shown in Fig. 10.

Such magnetic annealing was also extended over-aging stage. Curve A of Fig. 11 shows the torque measured after the specimen had been held at 750°C for 4 hours with the field of 2000 Oe, while the torque measured after

90 degrees is shown in curve B. This torque curve obtained after the double magnetic annealing made over the over-aged stage has the two-fold symmetry and has the easy direction of anisotropy along the direction in which the field is applied initially. Thus, the curves obtained after the double magnetic annealing made during the precipitation process show pronounced differences for the initial stage of precipitation from for the over-growth stage.

(5) Effect of cold working

The anisotropy constant obtained with the specimen which was cold-worked by press in the solid-solution state and aged at 750°C for 4 hours isothermally with magnetic field of 1000 Oe is about 10^4 ergs/cc, being greater than the value of 4×10^3 ergs/cc obtained after the same treatment with the uncold-worked specimen, as shown in Fig. 12. This increase

Fig. 10. Torque curves of 2% Co-Cu alloy, obtained after the double magnetic annealing. Curve A shows the effect of the initial magnetic annealing and curves B show the effect of changing the direction of magnetic annealing by 90° degrees from the direction of the former magnetic annealing.

Fig. 11. Torque curves of 2% Co-Cu alloy obtained after the double magnetic annealing extended over the overaging stage.

Fig. 12. Effect of cold-work on the torque curve of 2% Co-Cu alloy.

of the uniaxial anisotropy may naturally be interpreted by the fact that the precipitation rate is rapidly increased by cold-working and the number of precipitates in the cold-worked specimen responsible for the uniaxial anisotropy is greater than those in the uncold-worked one.

§ 5. Discussion of Results

(1) Precipitation process and magnetic behavior of precipitate particles.

There have been many experimental and theoretical works on the magnetic behaviors of precipitated particles depending on their

the same specimen had been held again at the same temperature for 10 hours with the field applied only in the direction changed by

size and shape. Theories on the most interesting aspect of the behavior of fine particles, have been developed by Kittel¹⁵⁾, Néel¹⁶⁾, Stoner and Wohlfarth¹⁷⁾, and Jacobs and Bean¹⁸⁾. Detailed expositions of this field may be found in the survey by Kittel and Galt¹⁹⁾.

During the isothermal aging of Cu-Co solid solution, the following changes might take place; first, Co atoms migrate and aggregate to form small Co-rich regions, and secondly the face-centered cubic Co-rich phase, which is coherent to the matrix, precipitates and consequently each precipitated particle become ferromagnetic. In this stage, however, precipitates are so small that the directions of magnetization fluctuate thermally, and the bulk specimen does not show any ferromagnetic behavior. The phenomenon of this kind in Cu-Co alloy was recently studied by Becker²⁰⁾ and Weil and Gruner²¹⁾ independently, and was termed "super-paramagnetism" by Bean²²⁾. Moreover, with increasing aging time the precipitated particles becomes too large for thermal fluctuation and become the stable single-domain permanent-magnets. For this stage it seems likely that the nucleation comes to an end and the total volume of precipitation become constant, since changes of the electric resistance and of the saturation magnetization have not been observed in this stage, as seen from Fig. 13.

Fig. 13. Precipitation kinetics and magnetic annealing of 2% Co-Cu alloy at 750°C.

When the aging is continued further, the so-called coagulation takes place, i.e., the volume of each precipitate increases and the number of precipitates decreases. The increase of the particle size results in the division of single magnetic domain into two or more domains, which is energetically favorable. Such multi-domain gives rise to

the low coercivity due to the displacements of domain walls in the precipitates. Such characteristics of Cu-Co alloy were found by Bate, Schofield and Sucksmith²³⁾. More recently, Becker²⁴⁾ also showed that there were magnetically three types of precipitated particles in the precipitation process of Cu-Co alloy containing 2% Co. According to his classification, precipitated particles of the type I are those in a stage of nucleation which show a super-paramagnetic behavior. Precipitated particle having the stable single-domain size in a further aging are belonged to the type II, and the type III involves particles precipitated in the multi-domain size stage in which precipitates continue to grow and the coercivity decreases. On this basis Becker showed that it was possible to explain the change in coercive force with aging time at 800°C. Figure 13 demonstrates the similar results obtained by us. Many kinds of measurements on the 750°C isothermal aging give the experimental confirmation of the suggestion that the induced anisotropy as well as the high coercive force arises from fine particle behavior, because the maximum of the anisotropy corresponds to that of the coercive force. Moreover, the result of the magnetic saturation measurement shows that the nucleation stage of precipitation is completed before the rise of the anisotropy to its maximum, since the magnetic saturation corresponds the total amount of ferromagnetic precipitated particles. Accordingly, it seems likely that changes of the induced anisotropy during magnetic annealing are related to a change in particle size in the growth stage of precipitated particles having a constant total amount. Taking into account of single domain precipitates, all of the present experiments may be explained consistently.

(2) Origin of the ferromagnetic anisotropy of precipitated particles.

The above-mentioned relations between the coercive force and aging process suggests that the coercive force of the alloy may be due to the particle anisotropy: hence, an examination of high coercive force of the alloy may simultaneously clarify the origin of the uniaxial anisotropy. On the experimental side, the work of Bate, Schofield and Sucksmith²³⁾ has shown that the high coercive force in Cu-Co alloy arises from fine-particle

behavior of precipitated particles. Accordingly, the discussion in the following paragraph is concerned with the comparison of the observed with the theoretical values of the coercive force.

Generally the high coercive force of finely dispersed particles arises from the crystal anisotropy, the magnetoelastic anisotropy or the shape anisotropy. Now we estimate the coercive forces of the Cu-Co alloy due to these three causes separately. First, the coercive force due to the magnetoelastic origin is expressed by $H_c = 3\lambda T/I_s$, as given by Stoner and Wohlfarth¹⁷⁾. Taking 10^{-5} for λ , the coefficient of magnetostriction, 10^{10} dynes/cm² for T , a reasonable upper limit of the internal stress, and 1300 for I_s , the saturation magnetization, gives ca. 230 Oe for H_c . Accordingly, the magnetoelastic anisotropy does not play the major role, as the maximum coercive force of ca. 1500 Oe was observed by Bate *et al.*²³⁾ Next, the coercive force due to the crystal anisotropy is $H_c = 0.64 K/I_s$ for cubic crystallites oriented at random. Taking 5×10^6 ergs/cc for K , the crystal anisotropy constant, gives only about 250 Oe. Finally, the coercive force due to the shape anisotropy of randomly oriented particles should be $H_c = 0.48(N_t - N_0)I_s$, where N_0 and N_t are the demagnetizing factors of the spheroid along the major and minor axes, respectively, according to the calculation by Stoner and Wohlfarth (1948)¹⁷⁾. The upper limit on the coercive force of highly elongated particle is $(0.48) \times 2\pi I_s = 3700$ Oe. On the other hand, particles with a $N_t - N_0$ of 0.7 which is estimated from the photographs, the coercive force of ca. 1400 Oe is predicted. Thus, the observed coercive force can be reasonably explained by the shape anisotropy.

(3) Possible origin of the uniaxial ferromagnetic anisotropy.

In the Cu-Co alloy, it seems that the induced uniaxial ferromagnetic anisotropy results only from the shape anisotropy of the precipitated particles and the degree to which they are orientated to the direction of applied field during magnetic annealing, since the matrix is non-ferromagnetic and only the precipitated phase is ferromagnetic. In fact, the curve C of Fig. 2 shows no torque for aging without field, because precipitated particles in the polycrystalline specimen are

distributed at random in the orientation, whatever an effective anisotropy of precipitates and interactions between precipitates themselves are. However, if the specimen has anisotropic orientations of crystal grains, it shows an irregular torque curve for aging without field, as seen from curves A and B of Fig. 2. As already stated, we are inclined to explain the uniaxial ferromagnetic anisotropy by the shape of precipitated particles. We must, however, examine possibilities of other origins of the anisotropy: magnetoelastic, magnetocrystalline and of the so called "directional order" together with the shape anisotropy.

The anisotropy energy due to the magnetostrictive strain fixed in the direction of applied field is given by

$$K_u = (3/2)\lambda^2 E, \quad (3)$$

where λ is the coefficient of magnetostriction, and E is Young's modulus. This mechanism gives only the energy of 3×10^2 ergs/cc if λ is 10^{-5} and E is 2×10^{12} dynes/cm². This is much less than ca. 10^6 ergs/cm³ of precipitate and thus it seems unlikely that strain anisotropy plays the major role. As to the crystalline anisotropy, X-ray study has confirmed that the particles precipitated during the aging process show the face-centered cubic structure, as will be shown in Part II, and naturally it makes few contribution to the uniaxial anisotropy.

In order to test the possibility that the anisotropy of the precipitated particles is primarily the shape anisotropy, we have investigated the shape of precipitates directly by electron and light microscopes, as will be shown in Part II.

Thus, as a matter of fact, it seems clear that the particle shape accounts for the uniaxial ferromagnetic anisotropy in Cu-Co alloy. According to the theory of Néel *et al.*, the uniaxial anisotropy constant, K_u , is expressed by

$$K_u = (1/2)N(\Delta I_s)^2 V(1-V), \quad (4)$$

where N is the demagnetizing factor of the precipitate particles, ΔI_s the difference in saturation magnetization between the precipitated phase and the matrix phase, and V the fractional volume of the orientated precipitates. If we take $\Delta I_s = 1300$ which is the saturation magnetization of the precipitates, $V =$

0.01 which is estimated from the photographs, the averaged value $N=0.7$ which is estimated from the photographs, we obtain the induced anisotropy energy of about 5×10^4 ergs/cc which is approximately in agreement with the observed maximum value of $10^4 \sim 8 \times 10^3$ ergs/cc. There are reasons that the observed values are less than predicted, by the same reason in the before-mentioned case of the coercive force of fine particles. In addition, the value of the shape anisotropy constant is in general connected to the amount of the orientated precipitates and unrelated to the total amount of ferromagnetic phase present. Accordingly, $V=0.01$ is perhaps over-estimated, since the volume fraction of the total amount of the phase precipitated completely at the aging temperatures studied is about $0.01 \sim 0.02$ in view of the phase diagram. Consequently, it may be inferred that the induced anisotropy is caused by the precipitates having the anisotropic distribution along the field applied during aging.

The next step in understanding the compatibility of the mechanisms is to discuss the possibilities of the directional order and the surface anisotropy. As we have seen from the experimental results (§ 4, (1), (2) and (4)), it seems unlikely that the directional order plays the major role, since the change of the anisotropy is influenced sensitively by the size of the precipitates and the precipitation process. Especially, the mechanism of directional order cannot interpret the experimental fact regarding the anisotropy of the four-fold symmetry induced by double magnetic annealing, because the dipole-dipole interaction, which depends on the kind of atom pairs and the direction of spontaneous magnetization relative to the axis of the atom pair, yields only the directional equilibrium of solute atom pairs in the precipitated phase. Furthermore, the saturation magnetization reaches a constant value very early before the aging time corresponding to the maximum of the induced anisotropy, as illustrated in Fig. 13. This means that the total volume and the compositions of the precipitates reach to nearly a constant value very early during the initial stage of precipitation. Consequently, it seems that the induced anisotropy does not depend on the concentration of the atom pairs, so that the directional order may

not play the major role. The qualitative disagreements between the observed result and the predicted result from directional order are provided by the effective response to magnetic annealing on the initial precipitation and by the phenomenon of disappearance of induced anisotropy during the over-aging.

On the other hand, although the surface anisotropy of precipitated particle seems attractive, we have few available data supporting it, since the mechanism of surface anisotropy relates sensitively to the size, shape and atomic concentration of precipitated particles and it is difficult to separate the effective part due to this mechanism from the other mechanism.

There are some points of interest in our experimental facts on the effect of magnetic annealing. First, the anisotropy energy rises to the maximum and then falls with increasing time of magnetic annealing at various temperatures, as shown in Fig. 5. Such curious phenomena were found first by the author *et al.*⁽¹¹⁾ and also recently by Becker⁽²⁴⁾ for shorter annealing times at 800°C . In the precipitation process at the various temperatures studied, the maxima of the anisotropy shift to longer aging time with decreasing temperature. This shows that a suitable growth time corresponding to the critical size for precipitated particles of single domain shifts to longer aging time as the aging-temperature is lowered. The critical time corresponding to the single domain formation was known from some properties, such as the coercive force which was considered to be a very sensitive indicator of the average size of precipitated particles. The aging time corresponding to the maximum of the anisotropy coincides approximately with the time of maximum of the coercive forces as shown in Fig. 13. Accordingly, it seems likely that the behavior is due to the formation of single domain and the decreasing anisotropy for the longer time is due to the behavior of multi-domains in larger precipitated particles, just as mentioned above in § 5, (1). Presumably such behavior due to over-aging would also be observed in other alloys of the precipitation type and would be remarked as a characteristic phenomenon of magnetic annealing.

Secondly, Fig. 7 shows that the dependency

of the induced anisotropy on the strength of the applied field is remarkable. Tendency of the saturation of the induced anisotropy suggests that the field applied during aging causes the alignment of precipitated particles to line up in the direction of the field. In general, if the field applied during aging is high enough and the direction of magnetization in precipitated particles orientates to the direction of external field, the induced anisotropy frozen in by the magnetic annealing will be approached to their saturation values and will be independent of field applied during aging. When the direction of the magnetic field coincides no longer with directions of magnetizations of precipitated particles, the consideration for the phenomenon is much more complicated. Presumably the behavior would be decided by interaction between the force of magnetic field acting on the precipitated particle and the crystal force due to the favored coherency of the matrix, just as in the case of Alnico V.

Thirdly, the anisotropy of four-fold symmetry is produced by the double magnetic annealing during initial stage of precipitation, as illustrated in Fig. 10. Such an unusual phenomenon is not fully understood. If the precipitated particles are aligned to favor in the two directions of fields which have been applied in the double magnetic annealing, the torque curve having four-fold symmetry may correspond to the torque curves obtained in the experiment of Nesbitt *et al.*²⁵⁾ However, the maximum torque obtained in Fig. 10 increases with increasing strength of the measured field which is not yet enough to produce magnetic saturation of the precipitates, contrary to the experiments of Nesbitt *et al.* in which the anisotropy diminishes with increasing field strength and is due to the shape anisotropy of the precipitated particle. This behavior of polycrystal can not be due to the shape anisotropy of the precipitates alone and perhaps the consideration of the origin of the other anisotropy and mutual interaction of precipitates are necessary to explain it.

In addition to these, there is the fact that magnetic field is able to influence the nucleation or initial precipitation rather than over-growth stage of precipitates. Recently, Nesbitt and A. G. Williams²⁶⁾ showed that magne-

tic field affects the nucleation process only in Alnico V. They also indicated that the mechanism of Kittel *et al.* was the more important one. Thus, it seems likely that such behavior of the Cu-Co alloy as well as Alnico V is the characteristic of magnetic annealing in the precipitation-type alloys.

From the arguments mentioned above, it may be seen that the shape anisotropy and directional orientation of precipitated particles are the most reasonable origin of the magnetic annealing effect of the Cu-Co alloy.

§ 6. Summary

A number of phenomena of magnetic annealing have been observed during the various precipitation process of 2% Co-Cu alloy. We have examined the possibility of magnetic behavior arising from the particle anisotropy and clarified that the uniaxial anisotropy properties of this alloy are explained by the shape effect proposed by Néel and Kittel *et al.*, as offered to be correct for alnico V. Moreover, it has been observed that magnetic field applied during aging is able to influence the nucleation stage or initial precipitation stage rather than over-growth stage of precipitation, as shown by Nesbitt *et al.* with Alnico V.

The author wishes to express his sincere thanks to Prof. S. Miyahara for his kind guidance. The contributions of the members of our research group are gratefully acknowledged.

A part of this work was financed by the Scientific Research Fund of the Ministry of Education.

Electrical and Optical Properties of GeS

By Tadaichi YABUMOTO

*Institute of Electrical Engineering, Shizuoka University,
Hamamatsu, Japan*

(Received December 12, 1957)

High purity germanium monosulfide was prepared and its semiconducting properties were measured. Samples are obtained by the reaction of germanium and sulfur in vacuum at high temperature and reducing in ammonium gas to remove germanium disulfide. Dark resistivities of evaporated layers and polycrystalline blocks of GeS prepared by the above method are $10^{10} \Omega \text{ cm}$ or more.

1. The thermal activation energy for dark current is 0.74 ~ 1.0 eV and about 0.25 ~ 0.5 eV at higher and lower temperature regions, respectively.

2. The absorption edge is found at about $700 \text{ m}\mu$ from the optical measurements.

3. At room temperature the maximum spectral sensitivity of photoconductivity is observed at the wavelength of about $700 \text{ m}\mu$ in vacuum and of about $800 \text{ m}\mu$ in room air.

4. The sign of the observed thermoelectric power is that of p type at high temperature, and its magnitude is about 1 mV/deg.

§ 1. Introduction

Semiconducting properties of sulfides of the elements in the first and second groups of periodic table have been reported in many literatures, but those of the elements in the elements in the fourth group have hardly been investigated up to the present.

GeS was selected as such an example, and

its main features of electrical and optical properties were measured with high purity samples.

§ 2. Preparation and Purification of Samples

GeS samples used in the experiments were obtained by the reaction of germanium and sulfur powders of about stoichiometric ratio

in an evacuated quartz tube at high temperature.

Germanium powder was prepared by grinding high purity single crystals, and sulfur powder was purified by recrystallization in CS_2 three times or more and then by vacuum distillation.

These germanium and sulfur powders were put into a quartz tube which was kept free from impurities by a previous heat treatment in high vacuum, and then the tube was sealed off after evacuation.

Reaction of germanium and sulfur was done by heating the quartz tube in an electric furnace at about 800°C and then at 1050°C for about six hours each. Since there are some GeS_2 and sulfur as impurities in the samples prepared by this method, they were again treated in ammonium gas. These samples were heated at 800°C for an hour in quartz tube through which pure ammonium gas was slowly passed at the rate of about 2~3 c.c./sec.

GeS was sublimated and crystallized on the wall of the quartz tube at lower temperature in the stream of ammonia gas. In this treatment the purity of these samples was increased, and a very small amount of impurities such as Fe, Al, Cu, was found spectroscopically and high resistivity was observed.

GeS has a lattice structure like stressed rocksalt and the lattice constants are $a=4.29\text{\AA}$, $b=10.42\text{\AA}$ and $c=3.64\text{\AA}$. By means of x-ray analysis it was confirmed that these samples were certainly germanium monosulfides.

§ 3. Experimental Procedure and Results

Measurements described below were made on sandwich type evaporated layers and on polycrystalline blocks of GeS samples prepared by the above mentioned method. Electric current was measured by Du-Bridge Brown's circuit whose current sensitivity is the order of 10^{-14} amperes.

(a) Dark conductivity

GeS is not stable at high temperatures in air, so the measurements were made in high vacuum tubes. Sandwich type samples were composed of an evaporated GeS layer placed between electrodes of sputtered platinum and evaporated aluminium layers as shown in Fig. 1.

The polycrystalline block type samples have

two platinum sputtered layers on opposite surfaces as electrodes. These tubes were heated in an oil bath, and the temperature was measured by copper-constantan thermocouple.

Temperature dependence of dark current was measured for both type samples between room temperature and 200°C .

Figs. 2 and 3 show the data on evaporated layers and on a polycrystalline block respectively.

Fig. 1. Experimental tube to measure the conductivity of sandwich type GeS layer.

From these figures the thermal activation energy for dark conductivity is calculated to be $0.74\sim 1.0\text{ eV}$ and in the case of evaporated of about layers there is lower activation energy portion $0.25\sim 0.5\text{ eV}$ at lower temperature region.

From the results the specific resistance is also calculated to be $10^9\sim 10^{14}\Omega\text{cm}$ for the evaporated layer and $10^{10}\Omega\text{cm}$ or more for the polycrystalline blocks at room temperature.

(b) Optical absorption

Optical absorption was measured with evaporated layers at room temperature. Samples were prepared by evaporation on quartz plates. The thickness of the layers is $0.2\sim 1\mu$ which is determined by optical interference and colorimetric measurement.

Fig. 2. Temperature dependence of dark current in sandwich type samples.

Fig. 3. Temperature dependence of dark current in polycrystalline block type sample.

A tungsten filament was used for the light source, and the radiation was made to monochromatic light by a Beckmann type monochromator or a minimum dispersion type spectrometer. After passing through the layer, the monochromatic light was detected by an antimony- cesium photo-tube or a photo-multiplier. A curve of absorption coefficient calculated from the absorption experiments is shown against the wavelength in Fig. 4. From

Fig. 4. Optical absorption of GeS and GeS₂.

this figure it is seen that the absorption edge of fundamental absorption band lies at about 700 mμ (1.8 ev). In Fig. 4 the similar result obtained with GeS₂ is also plotted. Its absorption edge lies at about 540 mμ (2.3 ev).

(c) Photoconductivity

Experimental results on spectral sensitivity of photo-current at room temperature are shown in Fig. 5. Sandwich type samples are composed of thin evaporated GeS layer placed between transmitting electrode and evaporated aluminium electrode. Nesa coating was used as the transmitting electrode on the quartz glass. Polycrystalline block sample has two evaporated gold layers as electrodes.

Light source and monochromator are similar to those used in the absorption experiment, and the detection of light intensity was made by thermopile.

As seen from this figure there is a maximum of sensitivity at about 700 mμ in wavelength for both type samples. On the polycrystalline

block the maximum shifts to about $800\text{ m}\mu$ in room air. As the curves (1), (2), (3) of this figure show the order of measurement, it is

Fig. 5. Spectral photocurrent for equal energy illumination.

Fig. 6. Temperature dependence of thermoelectric power.

seen that the shift of its maximum is reversible.

It will be interesting to study this phenomena further. It is also seen from this figure

that the sensitivity rapidly increases below the wavelength of about $550\text{ m}\mu$.

This wavelength is almost the same as that of the absorption edge in GeS_2 , but it seems that the increase is not related to GeS_2 , because no photocurrent was observed in GeS_2 with the irradiation of 100 watt tungsten lamp and high pressure mercury arc lamp.

(d) Thermoelectromotive force

Thermoelectromotive force was measured between the temperature of 70° and 160°C with a potentiometer, and the temperature was measured by copper-constantan thermocouples. In Fig. 6 the results are plotted against temperature. For temperatures below 100°C the accuracy of data is low because of the high resistance of samples.

Although it seems that the conduction process is intrinsic above 100°C as seen from Figs. 2 and 3, the sign of the electromotive force observed is that of p type ones.

The magnitude of thermo electric power is about 1 mv/deg.

§ 4. Conclusions and Acknowledgements

In this paper some electrical and optical properties of GeS are described. High purity GeS samples were obtained by heating in the stream of ammonia gas after being prepared by heat treatment of germanium and sulfur in quartz tube. The energy gap of GeS is calculated as $1.5\sim 2.0\text{ eV}$ from thermal activation energy, about 1.8 eV from the maximum of photoconductivity and these values are in good agreement with each other. Dark resistivity of GeS as high as $10^{10}\ \Omega\text{cm}$ or more is obtained at room temperature.

In evaporated layers there is a conduction of lower activation energy which seems to come from some impurity centre. It is interesting that the sign of thermoelectromotive force is that of holes at higher temperature region where intrinsic conduction seems to take place.

The author wishes to express his sincere thanks to Mr. Sakio Suzuki, Mr. Shoji Yamada and Dr. Shinichiro Narita for their contributions in making the samples and taking the experimental data of this work.

Electronic Structure and Diamagnetism of Graphite

By Shoichi MASE

Department of General Education, University of Nagoya

(Received December 17, 1957)

We studied the electronic energy bands of graphite by the Bloch method and then calculated the diamagnetic susceptibility. The calculated value of the main term in Peierls' constant susceptibility (parallel component to c -axis) is about 0.3 times the experimental value, and the theoretical value of periods (on the basis of Onsager's theory) of two types with regard to the de Haas-van Alphen effect is about 2.5 times the experimental value. The cause of such discrepancy is discussed.

§ 1. Introduction

As is well known, in a strong diamagnetic substance like graphite or bismuth or antimony, conduction electrons, i.e. so-called de Haas-van Alphen electrons, cause a non-periodic part of susceptibility which is fairly small compared with the experimental value.¹⁾ Blackman²⁾ suggested that the periodic part and most of the non-periodic part of the susceptibility of bismuth are caused by electrons found in separate places in the Brillouin zone. However, it is difficult to explain why the electrons giving rise to a large non-periodic part of susceptibility do not so appreciably to the periodic part. Hence on the basis of Blackman's suggestion, we have to expect an extreme anisotropy in energy bands.

According to Wallace,³⁾ Coulson⁴⁾ and others, the electrons and holes in graphite occupy the corner states of the Brillouin zone of hexagonal prism and there is no energy gap between the lower and the upper bands. Then, since the characteristic quantities of the electrons and holes are estimated as nearly equal, there is no reason to assume two types of energy pockets, as Blackman did, and we must consider that the electrons causing the periodic and non-periodic susceptibilities are electrons of the same type.

In this paper we study the relation between the diamagnetic susceptibility and the energy bands. For the purpose of determining the values of the parameters required in later sections, in § 2 we consider how the energy integrals in the Bloch method are affected by the inclusion of the overlapping of wave functions. In § 3 the exact secular equation for the π -electron in three dimensional lattice is set up and the energy distribution is in-

vestigated in detail on the basis of this equation. In § 4 the constant diamagnetic susceptibility is calculated by using the parameters which were determined in § 2 and § 3. In § 4 it is shown that, in the magnetic field parallel to the c -axis, the c -axis component of the ordinary main term of the Landau-Peierls' diamagnetism is only about 30 % of the experimental value and that the perpendicular component is also much smaller than the susceptibility of diamond. Hence we conclude that the observed value of the perpendicular component consists mostly of atomic susceptibility. In § 5 the de Haas-van Alphen effect is analysed. It is shown there that correct value of periods can not be obtained within the limits of either π -electron or the one band model.

§ 2. π -bands of Two Dimensional Lattice. Effect of the Overlapping of Wave Functions

In the Bloch method, the overlapping of wave functions is usually neglected to simplify the calculation. Wallace³⁾ worked along this line. Coulson and Tayler,⁴⁾ however, took into account the overlapping of wave functions between nearest neighbours and calculated the state density, and obtained a result differing remarkably from Wallace's. From Table I, however, we suppose that the overlapping of higher orders gives rise to an effect of the same order as the overlapping of lower order when proceeding to a higher approximation, since the distance to a higher neighbour is not very much longer than that to the nearest neighbour; that is to say, it is possible that the effect of the overlapping was wrongly estimated in the first step of

the approximation. We shall therefore take into account the effect of the overlapping of wave functions more fully.

Fig. 1. Crystal structure of two dimensional lattice.

Table I. Classes of neighbouring atoms; a is the atomic distance to nearest neighbour. (Cf. Fig. 1.)

Type	Distance R/a	Number in a class	$(a/R)^4$
σ_1	1	3	1
ρ_1	$\sqrt{3}$	6	1/9
σ_2	2	3	1/16
σ_3	$\sqrt{7}$	6	1/49
ρ_2	3	6	1/81
ρ_3	$2\sqrt{3}$	6	1/144

We show in Fig. 1 the crystal lattice of two dimensional graphite composed of two sublattices, A and B, as marked there. Defining ϕ as the atomic $2p_z$ function, and φ as Löwdin's orthogonalized atomic function, we have

$$\left. \begin{aligned} \varphi(\mathbf{r}-\mathbf{r}_j) &= \sum_i \phi_i (1+\mathbf{S})_{ij}^{-1/2}, \\ S_{ij} &= \int \phi_i^* \phi_j d\tau. \end{aligned} \right\} \quad (2.1)$$

Using the orthogonalized function φ instead of the usual non-orthogonalized function ϕ for the Bloch sums ψ_A and ψ_B corresponding to types A and B respectively of atoms in a unit cell, energy eigenvalues are given by

$$E = H_{AA} \pm |H_{BA}|, \quad (2.2)$$

where the matrix elements are

$$H_{AA} = E(0) + \sum_{\mu} E(\rho_{\mu}) a_{\mu}^{\rho}(\mathbf{k}), \quad (2.3a)$$

$$H_{BA} = \sum_{\nu} E(\sigma_{\nu}) a_{\nu}^{\sigma}(\mathbf{k}), \quad (2.3b)$$

and where

$$a_{\mu}^{\rho}(\mathbf{k}) = \sum_j \exp(-2\pi i \mathbf{k} \cdot \boldsymbol{\rho}_{\mu}^j),$$

$$a_{\nu}^{\sigma}(\mathbf{k}) = \sum_j \exp(-2\pi i \mathbf{k} \cdot \boldsymbol{\sigma}_{\nu}^j).$$

We make use of symbols $\boldsymbol{\rho}$ and $\boldsymbol{\sigma}$ to denote

the distance vectors from the referred atom to atoms of the same type and of different type; the suffix μ and ν denote the μ - and ν -th neighbours in each species, and j is to distinguish an atom from those in the same neighbouring order; $E(0)$, $E(\rho_{\mu})$ and $E(\sigma_{\nu})$ are integrals

$$E(0) = \int \varphi^*(\mathbf{r}) H \varphi(\mathbf{r}) d\tau, \quad (2.4a)$$

$$E(\rho_{\mu}) = \int \varphi^*(\mathbf{r}-\boldsymbol{\rho}_{\mu}) H \varphi(\mathbf{r}) d\tau, \quad (2.4b)$$

$$E(\sigma_{\nu}) = \int \varphi^*(\mathbf{r}-\boldsymbol{\sigma}_{\nu}) H \varphi(\mathbf{r}) d\tau. \quad (2.4c)$$

Fig. 2. The Brillouin zones for two dimensional lattice.

Now, to calculate the electric and magnetic properties, we study the electronic states in the neighbourhood of point P shown in Fig. 2. We use an expansion in a power series of wave vectors, $\mathbf{k}' = \mathbf{k} - \mathbf{k}_P$ ($|\mathbf{k}'| \ll |\mathbf{k}|$)

$$\begin{aligned} a_{\nu}^{\sigma}(\mathbf{k}) &= \sum_j \exp(-2\pi i \mathbf{k}_P \cdot \boldsymbol{\sigma}_{\nu}^j) \\ &\times \left\{ 1 - 2\pi i \mathbf{k}' \cdot \boldsymbol{\sigma}_{\nu}^j - \frac{1}{2} (2\pi \mathbf{k}' \cdot \boldsymbol{\sigma}_{\nu}^j)^2 + \dots \right\}. \end{aligned}$$

Since for any number of ν we can show that $a_{\nu}^{\sigma}(P) = 0$, H_{BA} identically vanishes at P . Further, we have

$$\begin{aligned} a_{\mu}^{\rho}(\mathbf{k}) &= \sum_j \cos 2\pi \mathbf{k}_P \cdot \boldsymbol{\rho}_{\mu}^j \\ &- \frac{1}{2} \sum_j (2\pi \mathbf{k}' \cdot \boldsymbol{\rho}_{\mu}^j)^2 \cos 2\pi \mathbf{k}_P \cdot \boldsymbol{\rho}_{\mu}^j + \dots \end{aligned}$$

Because the first term H_{AA} of (2.2) is quadratic in $\mathbf{k}'$ and the second term H_{BA} giving rise to splitting into two bands is linear in $\mathbf{k}'$, the two bands have no overlapping in the neighbourhood of P . The energy value $E_P(\mathbf{k})$ in the neighbourhood of P is then given by

$$\begin{aligned} E_P(\mathbf{k}) &= E(0) - 3(E(\rho_1) - 2E(\rho_2) + E(\rho_3) + \dots) \\ &\pm 3\pi a(-E(\sigma_1) + 2E(\sigma_2) + E(\sigma_3) + \dots) |\mathbf{k} - \mathbf{k}_P|. \end{aligned} \quad (2.5)$$

This formula shows that the shapes of the

two bands are symmetric as regards P . This fact is due to the crystal symmetry. The widths of the lower and the upper bands, $\Delta E_L = E(P) - E(\Gamma)$ and $\Delta E_U = E(R) - E(P)$, where $E(\Gamma)$ and $E(R)$ are respectively the energy at points Γ and R , are given by

$$\Delta E_L = - \sum_{\nu} a_{\nu}^{\sigma}(\Gamma) E(\sigma_{\nu}) + \sum_{\mu} (a_{\mu}^{\rho}(P) - a_{\mu}^{\rho}(\Gamma)) E(\rho_{\mu}), \quad (2.6a)$$

$$\Delta E_U = - \sum_{\nu} a_{\nu}^{\sigma}(\Gamma) E(\sigma_{\nu}) - \sum_{\mu} (a_{\mu}^{\rho}(P) - a_{\mu}^{\rho}(\Gamma)) E(\rho_{\mu}). \quad (2.6b)$$

By writing integrals (2.4) in terms of the non-orthogonalized functions, we can investigate the effect of the overlapping of wave functions on the width of the energy band.

Defining $S(n)$, $\bar{E}(0)$ and $\bar{E}(n)$ as

$$S(n) = \int \phi^*(\mathbf{r} - \mathbf{r}_n) \phi(\mathbf{r}) d\tau, \quad (2.7a)$$

$$\bar{E}(0) = \int \phi^*(\mathbf{r}) (V - U) \phi(\mathbf{r}) d\tau, \quad (2.7b)$$

$$\bar{E}(n) = \int \phi^*(\mathbf{r} - \mathbf{r}_n) (V - U) \phi(\mathbf{r}) d\tau, \quad (2.7c)$$

where V is the crystal potential and U the potential of an isolated atom, we can rewrite $E(\sigma_1)$ etc. in terms of (2.7). Thus we obtain

$$\begin{aligned} E(\sigma_1) = & (1 + 5S^2(\sigma_1) + 31S^4(\sigma_1) + 213S^6(\sigma_1))\beta(\sigma_1) \\ & - 2(S(\sigma_1)\beta(\rho_1) + S(\rho_1)\beta(\sigma_1)) \\ & + 2S(\sigma_1)(2S(\sigma_2)\beta(\sigma_1) + S(\sigma_1)\beta(\sigma_2)) + \dots, \end{aligned} \quad (2.8a)$$

$$\begin{aligned} E(\rho_1) = & -S(\sigma_1)(1 + 8S^2(\sigma_1) + 60S^4(\sigma_1))\beta(\sigma_1) \\ & + (\beta(\rho_1) + 10S(\sigma_1)S(\rho_1)\beta(\sigma_1) \\ & - 2S(\rho_1)\beta(\rho_1) + 5S^2(\sigma_1)\beta(\rho_1)) \\ & - (S(\sigma_2)\beta(\sigma_1) + S(\sigma_1)\beta(\sigma_2)) \\ & - (S(\sigma_3)\beta(\sigma_1) + S(\sigma_1)\beta(\sigma_3)) + \dots, \end{aligned} \quad (2.8b)$$

where

$$\beta(\sigma_{\nu}) = \bar{E}(\sigma_{\nu}) - S(\sigma_{\nu})\bar{E}(0),$$

$$\beta(\rho_{\mu}) = \bar{E}(\rho_{\mu}) - S(\rho_{\mu})\bar{E}(0).$$

The width of lower band is

$$\begin{aligned} \Delta E_L = & (1 + \sum_{\nu} a_{\nu}^{\sigma}(\Gamma)S(\sigma_{\nu}) + \sum_{\mu} a_{\mu}^{\rho}(\Gamma)S(\rho_{\mu}))^{-1} (1 + \sum_{\mu} a_{\mu}^{\rho}(P)S(\rho_{\mu}))^{-1} \{ - \sum_{\nu} a_{\nu}^{\sigma}(\Gamma)\beta(\sigma_{\nu}) \\ & + \sum_{\mu} (a_{\mu}^{\rho}(P) - a_{\mu}^{\rho}(\Gamma))\beta(\rho_{\mu}) + (\sum_{\mu, \mu'} a_{\mu}^{\rho}(P)\beta(\rho_{\mu})a_{\mu'}^{\rho}(\Gamma)S(\rho_{\mu'}) - \sum_{\mu, \mu'} a_{\mu}^{\rho}(\Gamma)\beta(\rho_{\mu})a_{\mu'}^{\rho}(P)S(\rho_{\mu'})) \\ & + (\sum_{\mu, \nu} a_{\mu}^{\rho}(P)\beta(\rho_{\mu})a_{\nu}^{\sigma}(\Gamma)S(\sigma_{\nu}) - \sum_{\mu, \nu} a_{\mu}^{\rho}(P)S(\rho_{\mu})a_{\nu}^{\sigma}(\Gamma)\beta(\sigma_{\nu})) \}. \end{aligned} \quad (2.6)'$$

To find the order of magnitude, we assume that the resonance integral is proportional to the overlapping integral $S(n)$, and that $S(n)$ is inversely proportional to the fourth power of distance. Then we have

$$\beta(R) = \frac{S(R)}{S(\sigma_1)} \beta(\sigma_1) = \left(\frac{a}{R}\right)^4 \beta(\sigma_1),$$

and

$$\Delta E_L = - \frac{\beta(\sigma_1)}{S(\sigma_1)} \times \frac{(1 + \sum_{\nu} a_{\nu}^{\sigma}(\Gamma)S(\sigma_{\nu}) + \sum_{\mu} a_{\mu}^{\rho}(\Gamma)S(\rho_{\mu})) - (1 + \sum_{\mu} a_{\mu}^{\rho}(P)S(\rho_{\mu}))}{(1 + \sum_{\nu} a_{\nu}^{\sigma}(\Gamma)S(\sigma_{\nu}) + \sum_{\mu} a_{\mu}^{\rho}(\Gamma)S(\rho_{\mu}))(1 + \sum_{\mu} a_{\mu}^{\rho}(P)S(\rho_{\mu}))}. \quad (2.6)''$$

Adopting the values 1/4 and -3.0 ev. for $S(\sigma_1)$ and $\beta(\sigma_1)$ respectively, as proposed by Coulson and Tayler, we study how the magnitude of the calculated band width is affected, taking into account the contribution of higher neighbours; results are given in Table II. Naturally in the approximation of nearest neighbours, (2.6)' agrees with the result of Coulson and Tayler. Potential $V - U$ is large half way between any two atoms, and then the overlapping of wave functions in this neighbourhood contributes largely to $E(0)$ and

$\bar{E}(\sigma_1)$. Therefore we may suppose that $E(0)$ and $\bar{E}(\sigma_1)$ are of the same order. Hence we have a value -4.0 ev. for $E(\sigma_1)$. Neglecting the overlapping of wave functions and taking into account the contribution of the nearest neighbours alone, we have 12 ev. as the width of the lower band. Although the contribution of $S(\sigma_1)$ considerably reduces the width of the lower band, the effect is cancelled fairly well by the contributions of $S(\rho_1)$ and $\bar{E}(\rho_1)$. Thus the final value converges into some

value between the value of zeroth approximation (12 ev.) given in the second column in Table II, and that of nearest neighbour approximation (5.1 ev.). While $E(\sigma_1)$ is found to be nearly equal to the value of the lowest approximation in which the overlapping is not included, $E(\rho_1)$ is much more affected than $E(\sigma_1)$ and the sign is the opposite of the sign expected from the two-centre approximation. The absolute value of $E(\rho_1)$, however, is fairly small as compared with $E(\sigma_1)$. Hence, when overlapping is neglected, the theoretical result is wrong even when the resonance integrals of higher neighbours are taken into account. However, when only the nearest neighbours are taken into account, no good result can be obtained even should the overlapping be calculated exactly, since many other terms of comparable order are neglected. As to these points, Wohlfarth⁶⁾ got similar results by calculating the effect of overlapping for a simple one-dimensional lattice.

Table II. The overlapping effect on energy integrals in units of ev. The first row shows the distance to the farthest neighbouring atom whose contribution is taken into account.

	$\sigma_1(S(\sigma_1)=0)$	σ_1	ρ_1	σ_2	$R=\infty$
ΔE_L	12.0	5.1	6.8	7.0	7.6
	$E(\sigma_1)$		$E(\rho_1)$		
$S=0$	-4.0		-0.4		
$S \neq 0$	~ -4.2		~ 1.3		

§ 3. π -bands of Three Dimensional Lattice

In three dimensional lattice, the binding only between the successive layers (the layer distance $c=3.35$ Å) is extremely weak (the binding energy is about 4 kcal/mole)⁷⁾ and so the feature of stacking can be easily changed by something such as mechanical treatments.⁸⁾

Therefore it is possible that the observed electric and magnetic properties are not those of a uniformly stacked lattice but are those of a mixture of various stackings.

There are three types of stacking, viz, aa type, ab type and abc type. The difference between the electronic structures of these three types is ordinarily not so remarkable, but it does have an important effect on the electronic properties at low temperatures. For example, in abc type the total number of electronic states per atom in the lowest B.Z. is 0.998. This type of lattice, therefore, would be expected to behave like a metal. Compared with the number of conduction electrons in graphite ($\sim 10^{-6}$ per atom at 0°K) as estimated from experiments on Hall effect and others, the number 0.002 in the abc type of lattice is considerably large. There are experimental reports that some crystals contain abc type of lattice to about 15%.⁹⁾ Depending on whether this abc type is contained in large blocks or in small pieces in the background of the ab type, the effect on diamagnetic property differs very much, i.e. the effect is far smaller in the latter case. According to Brennan,⁷⁾ the cohesive energy for ab type is lower than that for aa type by about 0.36 kcal/mole. Although the cohesive energy has not been compared for abc and ab types, it is probable that abc type is energetically more stable than aa type. However, it is not probable that abc type is contained in the form of a large block in crystals. In the present paper we consider only regular lattice of ab type.

Taking orthogonal atomic wave functions φ for the four atoms A, B, A' and B' respectively in a unit cell, and taking into account that the circumstances around the A and B sites are the same as those around the B' and A' sites, we construct four Bloch sums from these functions which then give the following matrix elements:

$$H_{AA} = E_{zz}(0) + \sum_{\mu} E_{zz}(\rho_{\mu}, 0) \cdot a_{\mu}^p(\mathbf{k}) + 2 \sum_n E_{zz}(0, 2nc) \cdot \cos 4\pi nck_z \\ + 2 \sum_{n, \mu} E_{zz}(\rho_{\mu}, 2nc) \cdot a_{\mu}^p(\mathbf{k}) \cdot \cos 4\pi nck_z, \quad (3.1a)$$

$$H_{BB} = E_{zz}^-(0) + \sum_{\mu} E_{zz}^-(\rho_{\mu}, 0) \cdot a_{\mu}^p(\mathbf{k}) + 2 \sum_n E_{zz}^-(0, 2nc) \cdot \cos 4\pi nck_z \\ + 2 \sum_{n, \mu} E_{zz}^-(\rho_{\mu}, 2nc) \cdot a_{\mu}^p(\mathbf{k}) \cdot \cos 4\pi nck_z, \quad (3.1b)$$

$$H_{BA} = \sum_{\nu} E_{zz}(\sigma_{\nu}, 0) \cdot a_{\nu}^{\sigma}(\mathbf{k}) + 2 \sum_{n, \nu} E_{zz}(\sigma_{\nu}, 2nc) \cdot a_{\nu}^{\sigma}(\mathbf{k}) \cdot \cos 4\pi nck_z, \quad (3.1c)$$

$$H_{B'A} = 2 \sum_n E_{zz}(0, (2n-1)c) \cdot \cos 2\pi(2n-1)ck_z + 2 \sum_{n,\mu} E_{zz}(\rho_\mu, (2n-1)c) \cdot a_{\mu}^p(\mathbf{k}) \cdot \cos 2\pi(2n-1)ck_z, \quad (3.1d)$$

$$H_{A'A} = 2 \sum_{n,\nu} E_{zz}(\sigma_\nu, (2n-1)c) \cdot a_{\nu}^s(\mathbf{k})^* \cdot \cos 2\pi(2n-1)ck_z, \quad (3.1e)$$

$$H_{A'B} = 2 \sum_{n,\nu} E_{zz}(\sigma_\nu, (2n-1)c) \cdot a_{\nu}^s(\mathbf{k}) \cdot \cos 2\pi(2n-1)ck_z, \quad (3.1f)$$

where n denotes the number of layers and other indices have the same meaning as in the preceding section. It is noted that $\mathbf{k}$ is a two-dimensional wave vector. The secular equation is written

$$\begin{vmatrix} H_{AA}-E & H_{BA}^* & H_{B'A} & H_{A'A}^* \\ H_{BA} & H_{BB}-E & H_{A'A}^* & H_{A'B}^* \\ H_{B'A} & H_{A'A} & H_{AA}-E & H_{BA} \\ H_{A'A} & H_{A'B} & H_{BA}^* & H_{BB}-E \end{vmatrix} = 0. \quad (3.2)$$

Fig. 3. The Brillouin zones which contain one electron per atom.

Since it can be seen from an approximate solution of this equation that the position of the highest energy in the lower zone and that of the lowest energy in the upper zone are on line $\overline{PH}$ in Fig. 3, we shall investigate the neighbourhood of this line only. Because $a_{\nu}^s(P)=0$, as was seen in § 2, $H_{A'A}$ and $H_{A'B}$ are negligibly small compared with $H_{B'A}$ and are of the order of about 1/10 of H_{BA} .

Hence these terms are neglected here. In this approximation, the solution of the secular equation is in form the same as obtained by Carter and Krumhansle,¹⁰⁾ i.e.

$$E = H_{BB} - \frac{1}{2}(H_{BB} - H_{AA} + H_{B'A}) \pm \left\{ |H_{BA}|^2 + \frac{1}{4}(H_{BA} - H_{AA} + H_{B'A})^2 \right\}^{1/2}. \quad (3.3)$$

The two bands touch at point Q , where $H_{BB} - H_{AA} + H_{B'A} = 0$, and on lines $\overline{QH}$ and $\overline{PQ}$ we have exactly $E = H_{BB}(\mathbf{k}_P, k_z)$. The value of $|k_z|$ at Q , where the two bands contact is somewhat larger than $1/4c$. As seen from (3.1), the leading term among the terms depending on k_z in $H_{BB}(\mathbf{k}_P, k_z)$ is $2E_{zz}(0, 2c) \cos 4\pi ck_z$. Then if $E_{zz}(0, 2c) > 0$, as expected from the two-centre approximation, $H_{BB}(\mathbf{k}_P, k_z)$ has its maximum value at $k_z = 0$, $k_z = \pm 1/2c$ and minimum value at $k_z = \pm 1/4c$. The difference is $4E_{zz}(0, 2c)$. Hence the lower and upper bands overlap by $4E_{zz}(0, 2c)$.¹¹⁾ We measure the energy in the lower band from its top, that in the upper band from its bottom, and write them as ϵ_h and ϵ_e respectively. Further we neglect in the matrix elements terms other than the leading terms. Then we can rewrite (3.3)

$$\epsilon_h = 9\pi^2 a^2 \gamma_0' k^2 + 4\gamma_1' (\cos^2 2\pi ck_z - 1) - \frac{\delta}{2} - \gamma_1 \cos 2\pi ck_z - \left\{ 9\pi^2 a^2 \gamma_0'^2 k^2 + \frac{1}{4}(\delta + 2\gamma_1 \cos 2\pi ck_z)^2 \right\}^{1/2}, \quad (3.4a)$$

$$\epsilon_e = 9\pi^2 a^2 \gamma_0' k^2 + 4\gamma_1' \cos^2 2\pi ck_z - \frac{\delta}{2} - \gamma_1 \cos 2\pi ck_z + \left\{ 9\pi^2 a^2 \gamma_0'^2 k^2 + \frac{1}{4}(\delta + 2\gamma_1 \cos 2\pi ck_z)^2 \right\}^{1/2}, \quad (3.4b)$$

where

$$\gamma_0 = E_{zz}(\sigma_1, 0), \quad \gamma_0' = \frac{1}{2}(E_{zz}(\rho_1, 0) + E_{zz}(\rho_1, 0)), \quad \gamma_1 = E_{zz}(0, c), \\ \gamma_1' = E_{zz}(0, 2c), \quad \delta = E_{zz}(0) - 3E_{zz}(\rho_1, 0) - E_{zz}(0) + 3E_{zz}(\rho_1, 0).$$

The area of cross-section perpendicular to k_z -axis of the reduced energy surface is denoted

by $A(k_z)$. Then, $A(k_z)$ for the upper band and the lower band is given respectively by

$$A_h(k_z) = \frac{1}{9\pi a^2 \gamma_0^2} \{ \epsilon_h^{\max} + 4\gamma_1'(1 - \cos^2 2\pi c k_z) \} \{ \epsilon_h^{\max} + 4\gamma_1'(1 - \cos^2 2\pi c k_z) + \delta + 2\gamma_1 \cos 2\pi c k_z \}, \quad (3.5a)$$

$$A_e(k_z) = \frac{1}{9\pi a^2 \gamma_0^2} (\epsilon_e^{\max} - 4\gamma_1' \cos^2 2\pi c k_z) \{ \epsilon_e^{\max} - 4\gamma_1' \cos^2 2\pi c k_z + \delta + 2\gamma_1 \cos 2\pi c k_z \}. \quad (3.5b)$$

In the region $k_z \geq 0$, $A_h(k_z)$ takes the maximum value at $k_z = 1/2c$

$$A_h^{\max}(1/2c) = -\frac{2\epsilon_h^{\max}\gamma_1}{9\pi a^2 \gamma_0^2} \left(1 - \frac{\epsilon_h^{\max}}{2\gamma_1} - \frac{\delta}{2\gamma_1} \right). \quad (3.6)$$

The value of k_z for which $A_h(k_z) = 0$, is obtained from the formula,

$$\cos 2\pi c k_z = -(1 - |\epsilon_h^{\max}|/4\gamma_1')^{1/2}.$$

Thus, $k_z \sim 3/8c$, by $|\epsilon_h^{\max}| \sim 2\gamma_1'$. On the other hand, the values of k_z for which $A_e(k_z) = 0$, are determined from formulas

$$\cos 2\pi c k_z \approx -\frac{\epsilon_e^{\max} + \delta}{2\gamma_1},$$

$$\cos 2\pi c k_z = \left(\frac{\epsilon_e^{\max}}{4\gamma_1'} \right)^{1/2}.$$

Consequently, by assuming that $\epsilon_e^{\max} + \delta \sim 0.2\gamma_1$, we obtain $k_z = 1/4c + \Delta k_z$ ($\Delta k_z \sim 0.016/c$), and $k_z \sim 1/8c$. Accordingly, the number of energy pockets of electrons is twice that of holes. Now, we must calculate the number of states to evaluate the chemical potentials ζ_{0e} , ζ_{0h} of electrons and holes. Denoting the number of occupied states of electrons and holes per unit volume by n_{0e} , n_{0h} , we determine ζ_{0e} , ζ_{0h} from the following

$$\left. \begin{aligned} \zeta_{0e} + \zeta_{0h} &= 4E_{zz}(0, 2c), \\ n_{0e} &= n_{0h}. \end{aligned} \right\} \quad (3.7)$$

We should have used the formula (3.4) to calculate the value of n_0 , but the calculation is cumbersome on account of the presence of the term containing γ_1' . Therefore, for the present, we investigate the qualitative features by means of an approximate calculation. If we approximate the constant energy surfaces of the electrons and holes by ellipsoids, we have the relation

$$A_h^{\max} K_{zh} = A_e^{\max} K_{ze}, \quad (3.8)$$

where K_{zh} is the length of k_z from point H to the point at which $A_h(k_z) = 0$ and where K_{ze} is the difference between two values of

k_z so that $A_e(k_z) = 0$. Since $A_e^{\max}$ becomes considerably smaller than $A_h^{\max}$ because of the appearance of γ_1' , we have $K_{ze} > K_{zh}$. Thus the points where $A_h(k_z) = 0$, $A_e(k_z) = 0$, are given by $k_z \gtrsim 3/8c$, $k_z \lesssim 1/8c$ respectively, we have the relation $\zeta_{0e} \gtrsim \zeta_{0h}$. Next, we make a rough estimation of the orders of ζ_{0e} and ζ_{0h} , which as seen from (3.7), are of the order of $2E_{zz}(0, 2c)$. Assuming that the resonance integral is inversely proportional to the fourth power of the distance, as in § 2, we obtain $E_{zz}(0, 2c) \sim 1/16 \cdot E_{zz}(0, c)$. Taking the value 0.09 ev. for $E_{zz}(0, c)$ as was given by Coulson, we obtain the value 0.011 ev. for ζ_0 , i.e. 128°K in terms of degeneracy temperature. This temperature is in good agreement with the result obtained from the analysis of the de Haas-van Alphen effect.

Based on the above qualitative discussion, we assume the values for the energy integrals as shown in Table III, where T_{0e} and T_{0h} are the degeneracy temperatures obtained from two periods of the de Haas-van Alphen effect. The values of $E_{zz}(\sigma_1, 0)$ and $E_{zz}(\rho_1, 0)$ are determined on the basis of the calculation in § 2 so that the calculated width of π -band is in agreement with the estimated value from the experiment. Carter and Krumhansl gave the value $\gtrsim 0.01$ ev. for δ but we take here a somewhat larger value. With use of Table III, the maximum value of $A_e(k_z)$ is found at $k_z \sim 0.18/c$ and is given by

$$A_{0e}^{\max} \left(\frac{0.18}{c} \right) = 0.351 \times \frac{2\zeta_{0e}\gamma_1}{9\pi a^2 \gamma_0^2}. \quad (3.9)$$

Thus we obtain the result $A_{0e}^{\max}/A_{0h}^{\max} = 0.54$. In Fig. 4, we show schematically the electron distribution in the Brillouin zone at 0°K. The shape of the constant energy surface looks

like an ellipsoid but $A(k_z)$ varies as a function of k_z more gently than in an ellipsoid. In a certain sense, this energy surface has the intermediate character of ellipsoid and cylinder.

Fig. 4. Schematic representation of the distribution of electrons and holes at 0°K.

Table III. Estimated values of energy integrals in units of ev.			
ζ_{0e}	0.015 ($T_{0e}=169^\circ K$)	$E_{zz}(0, c)$	0.20
ζ_{0h}	0.010 ($T_{0h}=116^\circ K$)	$E_{zz}(0, 2c)$	0.0063
$E_{zz}(\sigma_1, 0)$	-3.20	δ	0.02
$E_{zz}(\rho_1, 0)$	0.33		

It is seen in (3.5), that in our approximation, the integrals between the second nearest neighbours do not contribute to $A(k_z)$. Hove¹²⁾ calculated the density of state using a formula neglecting r_1' and δ in (3.4) and obtained the result that the density of the upper band becomes higher than that of the lower band owing to the contribution of the term containing r_0' . It is noted, however, that the value of parameter r_0' should take the sign opposite to that expected from the two-centre approximation. Thus, we may say that the effect of r_0' term is the reverse of that concluded by Hove. Furthermore, the ratio $\pi r_0' r_1 / 2 r_0^2$ of the first term of the correction arising from r_0' term to the main term is estimated as 0.01 by using Table III. As this could be 0.05 at most, we may neglect the effect of r_0' term. This is our ground for the expression (3.5).

Now we study whether the characteristic features of the constant energy surface of electrons and holes, as shown in Fig. 4, remain the same after neglecting the r_1' term. If this term is neglected, both degeneracy temperatures reduce to 0°K and there is no way to explain various properties at low temperatures. Therefore, we assume here finite degeneracy temperatures, although we neglect r_1' and r_0' terms in (3.4). In such an approximation, two separate parts for the distribution of electrons in which energies are the lowest at $k_z=\pm 1/4c$, contact each other and the shape of the energy surface becomes similar to a cylinder, and the numbers of pockets of electrons and holes become equal. The numbers n_{0e} and n_{0h} are given by

$$\left. \begin{aligned} n_{0e} &= \frac{8\gamma_1\zeta_{0e}}{9\pi^2a^2c\gamma_0^2} \left\{ 1 + \frac{\pi}{4} \frac{\delta}{\gamma_1} + \frac{1}{8} \left(\frac{\delta}{\gamma_1} \right)^2 + \frac{\pi}{4} \left(\frac{\zeta_{0e}}{\gamma_1} \right) + \frac{1}{8} \left(\frac{\zeta_{0e}}{\gamma_1} \right)^2 + \frac{1}{4} \frac{\zeta_{0e}\delta}{\gamma_1^2} + \dots \right\}, \\ n_{0h} &= \frac{8\gamma_1\zeta_{0h}}{9\pi^2a^2c\gamma_0^2} \left\{ 1 - \frac{\pi}{4} \frac{\delta}{\gamma_1} + \frac{1}{8} \left(\frac{\delta}{\gamma_1} \right)^2 + \frac{\pi}{4} \left(\frac{\zeta_{0h}}{\gamma_1} \right) + \frac{1}{8} \left(\frac{\zeta_{0h}}{\gamma_1} \right)^2 - \frac{1}{4} \frac{\zeta_{0h}\delta}{\gamma_1^2} + \dots \right\}. \end{aligned} \right\} \quad (3.10)$$

By using Table III, these become $n_{0e}=4.4 \times 10^{18}/\text{cc}$, $n_{0h}=2.5 \times 10^{18}/\text{cc}$. Kinchin¹³⁾ estimated the number of conduction electrons from his measurements of Hall coefficient. His results are $n_e \approx n_h = 1.2 \times 10^{18}/\text{cc}$ at 4°K and $6.2 \times 10^{18}/\text{cc}$ at room temperature. Since at low temperatures the Hall coefficient depends on the magnetic field anomalously, we can not apply any simple theory to calculate

the number of conduction electrons but for the present we will suppose that n_0 is of the order of $1 \sim 4 \times 10^{18}/\text{cc}$ at 0°K. Hence we may say that the above theoretical values are of the right order of magnitude. Since, however, the number of electrons and holes should be equal, we calculate the degeneracy temperatures by taking $n_{0e}=n_{0h}$. The result becomes $T_{0e} < T_{0h}$, which is contrary to that in Table

III. It is essential that we take into account the γ_1' term in order to clarify the difference in the behaviour of electrons and holes.

§ 4. Anisotropy of Constant Diamagnetic Susceptibility

As is well known, the diamagnetic susceptibility of graphite is very large and shows an extremely large anisotropy. Wallace concluded in his paper that the anisotropy in both magnetism and conductivity have the same

order of magnitude. In this section, we make clear how the anisotropy is related to the structure of the energy band.

According to Peierls,¹⁴⁾ the diamagnetic susceptibility per gram originating from quasi-bound electrons is composed of three terms $\chi^{(1)}$, $\chi^{(2)}$ and $\chi^{(3)}$ where $\chi^{(2)}$ is the atomic-like susceptibility and $\chi^{(3)}$ is the term which has its analogue in neither the susceptibility of atom nor in that of free electron. Here $\chi^{(1)}$, which is normally an important term, is given by

$$\chi_z^{(1)} = \frac{(e/2\hbar\bar{c})^2}{12\pi^2\rho} \iint_{(S)} \left\{ \frac{\partial^2 \mathcal{E}}{\partial k_x^2} \frac{\partial^2 \mathcal{E}}{\partial k_y^2} - \left(\frac{\partial^2 \mathcal{E}}{\partial k_x \partial k_y} \right)^2 \right\} \frac{2dS}{|\text{grad } \mathcal{E}|} \frac{\partial f_0}{\partial \mathcal{E}} d\mathcal{E}, \quad (4.1)$$

where ρ is the density and $\bar{c}$ the light velocity. Since, as was mentioned in § 3, the right order of magnitude of the effective number of electrons can be obtained even in the approximation neglecting γ_1' term in (3.4), we take the same approximation as used in the calculation of n_0 . In this approximation, we can also obtain the right order of magnitude of the susceptibility. Then we get

$$\mathcal{E} = -\frac{\delta}{2} - \gamma_1 \cos 2\pi c k_x \pm \left\{ \gamma_0^2 x + \frac{1}{4} (\delta + 2\gamma_1 \cos 2\pi c k_x)^2 \right\}^{1/2}, \quad (4.2)$$

where $x = 9\pi^2 a^2 (k_x^2 + k_y^2)$. We denote the susceptibility in the magnetic field parallel and perpendicular to the c -axis by $\chi_{\parallel}$ and $\chi_{\perp}$ respectively.

(1) $\chi_{\parallel}^{(1)}$

The bracket in the integrand of (4.1) becomes

$$\frac{\partial^2 \mathcal{E}}{\partial k_x^2} \frac{\partial^2 \mathcal{E}}{\partial k_y^2} - \left(\frac{\partial^2 \mathcal{E}}{\partial k_x \partial k_y} \right)^2 = 4\mathcal{E}^2 (9\pi^2 a^2 \gamma_0^2)^2 \cdot \frac{(\gamma_0^2 x - \mathcal{E}^2)^2}{(\gamma_0^2 x + \mathcal{E}^2)^4}. \quad (4.3)$$

Substituting this into (4.1) and using the suffix e to mean the upper band, we obtain

$$\begin{aligned} \chi_{\parallel e}^{(1)}(\mathcal{E}) &= \frac{4(e/2\hbar\bar{c})^2 (9\pi^2 a^2 \gamma_0^2)^2 4\mathcal{E}^2}{12\pi^2 \rho \cdot 18\pi^2 a^2 c \mathcal{E}} \int_0^{(z^2 + \varepsilon(\delta + 2\gamma_1))/\gamma_0^2} \frac{(\gamma_0^2 x - \mathcal{E}^2)^2 dx}{(\gamma_0^2 x + \mathcal{E}^2)^3 \{ \gamma_1^2 \mathcal{E}^2 - (\gamma_0^2 x - \mathcal{E}^2 - \mathcal{E}\delta)^2 / 4 \}^{1/2}} \\ &= \frac{6a^2 \gamma_0^2 (e/2\hbar\bar{c})^2}{c \gamma_1 \rho} \left[\left\{ \left(1 + \frac{\eta^2}{8} \right) \log 4 - 2 - \frac{\eta^2}{2} \right\} J_1 - \left(1 + \frac{\eta^2}{8} \right) \log \xi - \frac{3}{2} \left(\frac{5}{2} - \log 4 \right) \eta \xi \right. \\ &\quad \left. - \frac{3}{2} \eta \xi \log \xi - 3 \left(\frac{85}{48} - \log 4 \right) \xi^2 - 3 \xi^2 \log \xi + \dots \right], \end{aligned} \quad (4.4)$$

where $\xi = \mathcal{E}/\gamma_1$, $\eta = \delta/\gamma_1$. Integrating over $\mathcal{E}$, the limits are 0 and γ_1 , but we can replace the upper limit γ_1 by the infinity without giving rise to a serious error if $kT \ll \gamma_1$. Then we get

$$\begin{aligned} \chi_{\parallel e}^{(1)} &= \frac{6a^2 \gamma_0^2 (e/2\hbar\bar{c})^2}{c \gamma_1 \rho} \left[\left\{ \left(1 + \frac{\eta^2}{8} \right) \log 4 - 2 - \frac{\eta^2}{2} \right\} J_1 - \left(1 + \frac{\eta^2}{8} \right) J_2 - \frac{3}{2} \left(\frac{5}{2} - \log 4 \right) \eta J_3 \right. \\ &\quad \left. - \frac{3}{2} \eta J_4 - 3 \left(\frac{85}{48} - \log 4 \right) J_5 - 3 J_6 \right], \end{aligned} \quad (4.5)$$

where

$$J_1 = -\frac{1}{\exp(-\zeta_e/kT) + 1},$$

$$\begin{aligned}
J_2 &= -\frac{\log \xi_e/r_1}{\exp(-\xi_e/kT)+1} - C \left(1 - \frac{1}{\exp(-\xi_e/kT)+1} \right) + \sum_r (-1)^{r+1} \exp(-r\xi_e/kT) \\
&\quad \times \{ \text{Ei}(r\xi_e/kT) - \log(r\xi_e/kT) \} + \sum_r (-1)^{r+1} \exp(r\xi_e/kT) \text{Ei}(-r\xi_e/kT), \\
J_3 &= -\frac{\xi_e}{r_1} - \frac{kT}{r_1} \log(1 + \exp(-\xi_e/kT)), \\
J_4 &= -\log\left(\frac{\xi_e}{r_1}\right) \left\{ \frac{\xi_e}{r_1} + \frac{kT}{r_1} \log(1 + \exp(-\xi_e/kT)) \right\} - \frac{kT}{r_1} \log(1 + \exp(-\xi_e/kT)) \\
&\quad + \frac{kT}{r_1} \sum_r (-1)^{r+1} \frac{1}{r} \exp(r\xi_e/kT) \text{Ei}(-r\xi_e/kT) - \left(\frac{kT}{r_1} \right) \sum_r \frac{(-1)^{r+1}}{r} \exp(-r\xi_e/kT) \\
&\quad \times \{ \text{Ei}(r\xi_e/kT) - \log(r\xi_e/kT) \} + C \left(\frac{kT}{r_1} \right) \log(1 + \exp(-\xi_e/kT)), \\
J_5 &= -\left(\frac{\xi_e}{r_1} \right)^2 - \frac{\pi^2}{3} \left(\frac{kT}{r_1} \right)^2 + 2 \left(\frac{kT}{r_1} \right)^2 \sum_r \frac{(-1)^{r+1}}{r^2} \exp(-r\xi_e/kT), \\
J_6 &= -\log\left(\frac{\xi_e}{r_1}\right) \left\{ \left(\frac{\xi_e}{r_1} \right)^2 + \frac{\pi^2}{3} \left(\frac{kT}{r_1} \right)^2 - 2 \left(\frac{kT}{r_1} \right)^2 \sum_r \frac{(-1)^{r+1}}{r^2} \exp(-r\xi_e/kT) \right\} \\
&\quad - \left[\frac{\pi^2}{2} \left(\frac{kT}{r_1} \right)^2 - 3 \left(\frac{kT}{r_1} \right)^2 \sum_r \frac{(-1)^{r+1}}{r^2} \exp(-r\xi_e/kT) - 2 \left(\frac{kT}{r_1} \right)^2 \sum_r \frac{(-1)^{r+1}}{r^2} \exp(r\xi_e/kT) \right. \\
&\quad \times \text{Ei}(-r\xi_e/kT) - 2 \left(\frac{kT}{r_1} \right)^2 \sum_r \frac{(-1)^{r+1}}{r^2} \exp(-r\xi_e/kT) \{ \text{Ei}(r\xi_e/kT) - \log(r\xi_e/kT) \} \\
&\quad \left. + 2C \left(\frac{kT}{r_1} \right)^2 \sum_r \frac{(-1)^{r+1}}{r^2} \exp(-r\xi_e/kT) \right].
\end{aligned}$$

Here C is Euler's constant and Ei is exponential integral. By replacing ξ_e and η by ξ_h and $-\eta$, we get a similar expression for the positive holes. From the condition $n_e = n_h$, ξ_e and ξ_h are determined. While formula (4.5) is rather complicated, nevertheless in the regions $\xi_e/k \gg T$, we can obtain

$$\begin{aligned}
\chi_{||e}^{(1)} &= -\frac{6a^2 r_0^2 (e/2\hbar c)^2}{c r_1 \rho} \left[\left\{ 1 + \frac{3}{2} \eta \frac{\xi_{0e}}{r_1} + \frac{\eta^2}{8} + 3 \left(\frac{\xi_{0e}}{r_1} \right)^2 \right\} \log \frac{1}{\xi_{0e}/r_1} \right. \\
&\quad \left. - 2 \left\{ 1 + \frac{\eta^2}{4} - \left(1 + \frac{\eta^2}{8} \right) \log 2 \right\} - 3 \left(\frac{5}{4} - \log 2 \right) \eta \frac{\xi_{0e}}{r_1} - 6 \left(\frac{85}{96} - \log 2 \right) \left(\frac{\xi_{0e}}{r_1} \right)^2 \right]. \quad (4.6)
\end{aligned}$$

A similar expression is obtained for holes.

(2) $\chi_{\perp}^{(1)}$

Since the Landau-Peierls' term is very small compared with the atomic susceptibility, as will be seen later, for convenience we calculate by assuming $\eta = 0$. Substituting the expression

$$\frac{\partial^2 \mathcal{E}}{\partial k_x^2} \frac{\partial^2 \mathcal{E}}{\partial k_y^2} - \left(\frac{\partial^2 \mathcal{E}}{\partial k_x \partial k_y} \right)^2 = 8\pi^2 c^2 (9\pi^2 a^2 r_0^2) \mathcal{E}^4 \left\{ \frac{(\gamma_0^2 x - \mathcal{E}^2)}{(\gamma_0^2 x + \mathcal{E}^2)^3} + \frac{4\gamma_1^2 r_0^2 x}{(\gamma_0^2 x + \mathcal{E}^2)^4} \right\} \quad (4.7)$$

into (4.1), we have

$$\chi_{\perp}^{(1)}(\mathcal{E}) = \frac{8c r_1 (e/2\hbar c)^2}{3\rho} \left\{ 1 - \frac{3}{4} \xi^2 \log \frac{4}{\xi} + \frac{11}{8} \xi^2 + \dots \right\}. \quad (4.8)$$

By integrating (4.8), we obtain

$$\chi_{\perp}^{(1)} = \frac{16c r_1 (e/2\hbar c)^2}{3\rho} \left\{ J_1(\xi) + \left(\frac{11}{8} - \frac{3}{2} \log 2 \right) J_5(\xi) + \frac{3}{4} J_6(\xi) \right\}, \quad (4.9)$$

where $J_1(\xi)$, $J_5(\xi)$ and $J_6(\xi)$ have already been defined. In the temperature range $T \ll \xi/k$, (4.9) becomes

$$\chi_{\perp}^{(1)} = -\frac{16c\gamma_1(e/2h\bar{c})^2}{3\rho} \left\{ 1 - \frac{3}{4} \left(\frac{\zeta_0}{r_1} \right)^2 \log \frac{4}{\zeta_0/r_1} + \frac{11}{8} \left(\frac{\zeta_0}{r_1} \right)^2 + \dots \right\}. \quad (4.10)$$

(3) Comparison with experiments

Adopting the values of parameters γ_0 and others as given in Table III, we get $\chi_{||e}^{(1)} = -3.9 \times 10^{-6}$, $\chi_{||h}^{(1)} = -4.6 \times 10^{-6}$ and then $\chi_{||}^{(1)} = -8.5 \times 10^{-6}$. According to Krishnan and Ganguli's experiment,¹⁵⁾ $\chi_{||}$ is -30×10^{-6} , independent of temperatures below about 90°K. The contribution from the corner electrons, as just calculated, at most is 30 % of this experimental value. If we take the larger value for γ_0 and the smaller value for γ_1 so that the calculated value approaches the experimental, we get too small a value for n_0 and too large a value for the width of the π -band, values which contradict the experimental values. Thus this disagreement can not be removed by taking appropriate values for parameters. We then think that either the basic equation (4.2) is wrong or $\chi_{||}^{(3)}$ can not be neglected. Within the limits of π -electron, (4.2) is an approximate but adequate formula. Jonston¹¹⁾ calculated the effect of the mixing of σ - and π -orbitals on the Fermi surface and got new results on the overlapping of energy bands, results which differ from ours in the energy distribution of the upper band. Since, by estimating the effect of the mixing based on his evaluation, it seems that the new effect would not be so serious as to affect the qualitative aspect of our result, we must look for another cause of the discrepancy in $\chi_{||}$, i.e. we must look in other terms which are not taken into account in usual Peierls' formula.

Now it is noteworthy that (4.5) and $\chi_{||h}^{(1)}$ are in fair accord with the experimental fact that the diamagnetic susceptibility decreases with the adding of impurities;¹⁶⁾ but, first, the above statement is meaningless because $\chi_{||}^{(1)}$ is too small, and, second, it is useless to study the temperature dependence¹⁷⁾ on the basis of (4.5) or on its approximate formula unless we calculate $\chi_{||}^{(3)}$.

On the other hand, $\chi_{\perp}^{(1)}$ is $\sim -3.7 \times 10^{-8}$ for $T \ll \zeta/k$. Therefore $\chi_{\perp}^{(2)}$ and $\chi_{\perp}^{(3)}$ can not be neglected when calculating $\chi_{\perp}$. The susceptibility of carbon per gram is -0.5×10^{-6} and consequently it is expected that $\chi_{\perp}$ for graphite will be of the same order of magni-

tude, which actually agrees well with the experiment. Then it is expected that $\chi_{\perp}$ is almost constant in the whole temperature region.

§ 5. de Haas-van Alphen Effect and Summary

The calculation in the previous section, based upon Peierls' theory can not be used in the low temperature region. For the free electron model, exact expressions of susceptibility have been given by several authors. The periodic part of the susceptibility is

$$\chi \propto \sum_r \frac{(-1)^r \sin(\pi r \zeta / \beta^* H - \pi/4)}{r^{1/2} \sinh(\pi^2 r k T / \beta^* H)}.$$

If we make use of the cylindrical energy surface which is a simple approximate form of (3.4), we get essentially the same period and temperature dependence of the amplitude as in the expression for the susceptibility obtained by using the ellipsoidal model, although it gives rise to a difference in the phase as well as in the field dependency of the amplitude. The shape of the energy surface is known from the determination of the values of ζ and β . Onsager¹⁸⁾ gave a more general form for the period, which is given by a quantity instead of $2\beta/\zeta$, and which can be given by

$$\frac{2\beta}{\zeta} \rightarrow \frac{e}{hcA^{\max}}. \quad (5.1)$$

Then the ratio of the period of electrons and holes can be given by

$$\frac{2\beta_h/\zeta_h}{2\beta_e/\zeta_e} \rightarrow \frac{A_e^{\max}}{A_h^{\max}} = 0.54. \quad (5.2)$$

Onsager's theory is essentially the one-band model.

According to Shoenberg,¹⁾ two independent periods are observed in graphite. The result of his analysis based upon the assumption of ellipsoidal energy surfaces is given in Table IV. For comparison, the result of our calculation is listed in Table V. We must conclude that the first component $T_0 = 169^\circ\text{K}$ in Table IV comes from the electrons and that the second component $T_0' \sim 116^\circ\text{K}$ comes from the holes. As we can see by comparing Tables IV and V, the theoretical and experimental

values of various parameters are in fair accord but not perfectly so. Particularly, there is a considerable difference between the values given in the second column of Table IV and of Table V. If we took the value of $A^{\max}$ 2~3 times that in Table V, we should be able to eliminate this difference. As is

known from (3.6), (3.9), and (3.10), however, this would result in too large a value for n_0 which is approximately proportional to $A^{\max}$, and therefore in too small a value for $\chi_{||}^{(1)}$. This discrepancy is significant because the calculation of $A^{\max}$ is based upon an adequate energy formula.

Table IV. Experimental values of parameters derived under the assumption of ellipsoidal energy surface (after Shoenberg).

$T_0=169^\circ K$	$2\beta/\zeta=2.20 \times 10^{-5}$	$2\beta'/\zeta'=0.75$	$n=3.88 \times 10^{18}/cc$	$\chi_{ }^{(1)}=-3.4 \times 10^{-6}$	$m_{\perp}/m=0.036$
$T_0 \sim 116^\circ K$	$2\beta'/\zeta'=1.65 \times 10^{-5}$	$2\beta/\zeta$	$n'=1.6 \sim 7.98 \times 10^{18}/cc$	$\chi_{ }^{(1)}=-0.4 \sim -2.6 \times 10^{-6}$	$m'_{\perp}/m \sim 0.07$

Table V. Theoretical values of periods, etc.

Formula	(5.1)	(5.2)	(3.10)	(4.6)
T_{0e}	$2\beta_e/\zeta_e=6.7 \times 10^{-5}$	$2\beta_h/\zeta_h=0.54$ $2\beta_e/\zeta_e$	$n_e \sim 4.4 \times 10^{18}/cc$	$\chi_{ e}^{(1)} \sim -3.9 \times 10^{-6}$
T_{0h}	$2\beta_h/\zeta_h=3.6 \times 10^{-5}$		$n_h \sim 2.5 \times 10^{18}/cc$	$\chi_{ h}^{(1)} \sim -4.6 \times 10^{-6}$

From the above consideration, we confirmed that the agreement between theory and experiment can be obtained in neither non-periodic nor periodic parts of susceptibility without the inclusion of a non-diagonal term.

Adams¹⁹⁾ showed that in some cases the non-diagonal term is of comparable order of magnitude to the usual Peierls' term and that it becomes larger accordingly as the energy gap becomes smaller. As was seen in §3, the energy gap between the lower and upper bands, which are nearly full and nearly empty respectively, is very small in the neighbourhood of Q at which these two bands are in contact. Since the non-diagonal term may be more sensitively dependent on the feature of the band structure, 2s and higher states having a slight effect on the energy band structure found here should be taken into account in the calculation of the non-diagonal term which is a very complicated problem.

The writer acknowledges his debt to Professor K. Ariyama for his valuable guidance and expresses his appreciation to Professor H. Nakano for his helpful discussions.

Electron Spin Resonance of Z_1 -centers in Potassium Chloride

By Hazimu KAWAMURA and Keiko ISHIWATARI

Department of Physics, Osaka City University, Osaka

(Received January 18, 1958)

The paramagnetic resonance due to a Z_1 -center electrons in potassium chloride is investigated. Since Z_1 -centers are always accompanied by F -centers, the contribution from F -centers ought to be subtracted from the resultant curve in order to get the absorption curve due to Z_1 -center alone, which is found to be Gaussian with the half width of 79 oersteds and g value of 1.999. The result is analyzed according to the model that an electron is trapped by a divalent cation substituted for a cation of the bulk crystal.

§ 1. Introduction

Pick¹⁾ has found a prominent absorption band which is called Z_1 -band on the longer wave length side of the F -band in additively colored specimens of KCl and NaCl to which divalent ions have been introduced. His work has been followed by several authors²⁾³⁾⁴⁾, and it is now accepted that the model for the Z_1 -center is one electron trapped by a divalent cation substituted for a cation of the bulk crystal as shown in Fig. 1, which first proposed by Seitz⁵⁾.

Fig. 1. The model for Z_1 -center consisting of an electron bound to a divalent ion substituted for cation.

Since the divalent ion such as calcium, strontium or barium has no nuclear magnetic moment, only the spins of the neighboring nuclei have strong magnetic coupling with the trapped electron. Hence the situations are quite similar to those of the F -center, except that the nearest neighbors are anion nuclei instead of cation ones. The broadening of the electron spin resonance of Z_1 -center will, therefore, be mainly due to hyperfine coupling with the nuclear moments of the nearest anions, and will give some information about

the electronic structure of the center just as in the case of F -center.

§ 2. Experimental Procedure

Single crystals of potassium chloride were grown from the melt which contained about 10^{-3} mole fraction of calcium chloride or strontium chloride. Although we did not measure the actual concentration of the divalent ions in the crystal, it would at most be $1/10$ of the initial concentration in the melt. The crystals were then additively colored by heating them at 580°C for five hours in the sodium vapor. The specimens for spin resonance measurements with the dimension of $2 \times 6 \times 9 \text{ mm}^3$ were cut from the colored crystals. In this stage the specimens contain many complex centers beside F - and Z_1 -centers. So by heating them at 400°C for 20 seconds and quenching on a copper block kept at room temperature, we got crystals purely with F -centers. Finally, the F -centers were converted into Z_1 -centers, by irradiating with a sodium lamp whose spectrum lies in the F -band.

The details of the equipment for electron spin resonance were described in the last paper⁶⁾. The microwave of 9500 Mc/sec generated by 2K25 reflex klystron was fed to a rectangular cavity through a coaxial cable. The transmitted power was detected by 1N23 crystal. The magnetic field was modulated at 455 Kc/sec through a small coil wound directly around the specimen. The detected power was resonant amplified and lock-in detected. Although the spin density was as small as $5 \times 10^{16} \text{ cm}^{-3}$, the S/N ratio at the peak was larger than 10 as shown in Fig. 2 by virtue of the high frequency modulation,

and, therefore, we can speak of the curve shape in detail by repeating the run.

After the spin resonance experiment was over, the same specimen was further cleaved to the thickness of about 0.5mm and the optical absorption was measured at -150°C .

Fig. 2. An example of the record for spin resonance absorption curve of specimen No. 1 which contains both Z_1 -centers and F -centers.

§ 3. Experimental Results

The measurments were done with two specimens; one was doped with calcium chloride and the other with strontium chloride. First we shall describe the optical measurements which reveal the characteristic features of the specimens. Fig. 3a shows the plots of the optical density of a quenched crystal as the function of wave numbers in ev measured at -150°C . It has a simple F -band at 2.30 ev with the half width of 0.25 ev followed by a trace of band on the shorter wave length

Fig. 3a. Optical absorption band of KCl doped with Sr, additively colored, and quenched. Only F -band appears.

side. When the specimens were irradiated with sodium lamp from the distance of 10 cm for 20 minutes, the Z_1 -band grows up at the expense of the F -band as shown in Fig. 3b and Fig. 3c. The shape and position of the Z_1 -band alone can be determined uniquely by subtracting the contribution from the F -band as shown in these figures. The peak position and the half width are almost equal for Ca

Z_1 -center and Sr Z_1 -center within the experimental errors as shown in Table I. The densities N_{Z_1} of Z_1 -centers in both cases were calculated employing the value 0.84 for the oscillator strength of Z_1 -center, which was obtained by Camagni *et al.*⁴⁾ These are also shown in the Table with the densities N_F of remaining F -centers in each specimen.

Fig. 4a and Fig. 4b are the plots of the

derivatives of the spin resonance absorption curves reproduced from the records, where in 4a the result for the specimen No. 1 with Ca Z_1 -center and in 4b No. 2 with Sr Z_1 -center are shown. The peak to peak separations and g values* at the absorption peak for these specimens are clearly different from those for F -center alone as indicated in Table II, the

Table II.

specimen	peak to peak (oersteds)	g	N_{Z_1}/N_F (optical)
No. 1 (Ca)	57 ± 3	1.9959 ± 0.0005	1.7
No. 2 (Sr)	57 ± 3	1.9953 ± 0.0005	1.2
F -center alone	49.5	1.994	

latter being reproduced from our last paper³). Since we know the ratio of the density of Z_1 -centers to that of F -centers in addition to

* g value was determined being referred to the sharp line of diphenyl trinitrophenyl hydrazyl, a small speck of which was attached on the modulating coil.

the shape and the position of the absorption curve of F -center, we can, as indicated in Fig. 4, obtain uniquely the absorption curve due to Z_1 -center alone by subtracting the definite contribution due to F -center, so that the ratio of $(\Delta H)^2 \times D$ for the component curves** is equal to the ratio N_{Z_1}/N_F which is determined optically, where D is the peak value of the each component curve and ΔH the peak to peak separation. The resulting curves for both cases are Gaussian with half width of 79 ± 8 oersteds and situated at $g = 1.9991 \pm 0.005$. We could not recognize any difference beyond experimental error between Z_1 -centers doped with calcium and strontium.

§ 4. Discussion

Now we shall discuss the electronic structure of the Z_1 -center according to the model shown in Fig. 1. There is no paramagnetic electron except the Z_1 -center electron, since all ions may have the closed shell configurations.

** Of course, we assume the shape of both component curves is Gaussian.

Further, we can safely neglect the magnetic effect of the nuclei of the divalent ions at the centers, since Ca^{40} whose abundance is 96.92% has no nuclear magnetic moment and the isotope of strontium with nonzero moment is only Sr^{87} whose abundance is 6.96%. Hence we shall be able to assume that the broadening of the spin resonance absorption is mainly due to the hyperfine coupling between the Z_1 -electron and the nuclear spins of the surrounding chlorine ions. The effect of the potassium ions at the position of the next nearest neighbors may be neglected as shown later.

The Hamiltonian for the hyperfine interaction between the nucleus with magnetic moment operator μ_n and the electron with spin magnetic moment μ_s and wave function $\psi(\mathbf{r})$ is given by

$$\mathcal{H} = (8\pi/3) |\psi(\mathbf{R})|^2 \mu_n \mu_s, \quad (1)$$

where $\mathbf{R}$ is the position of the nucleus. Thus the nucleus produces an additional magnetic field

$$\Delta H_m = -(8\pi/3) (\mu/I) m |\psi(\mathbf{R})|^2, \quad (2)$$

where μ and I are the values of the magnetic moment and the spin of the nucleus and m is the eigenvalue of the z -component of the nuclear spin. Since each of the six nearest neighbors gives the contribution given by (2), the mean square deviation of the magnetic field is given by

$$\langle \Delta H^2 \rangle = \langle \sum_i (8\pi/3)^2 (\mu_i/I_i)^2 |\psi(\mathbf{R}_i)|^4 \langle m_i^2 \rangle \rangle, \quad (3)$$

where $\langle m_i^2 \rangle = \langle I_{iz}^2 \rangle = (1/3) I_i(I_i + 1)$. Since all μ_i 's and I_i 's are equal and further $\psi(\mathbf{R}_i)$'s are equal to each other for a spherically or cubically symmetric wave function, we have

$$\langle \Delta H^2 \rangle = (128/9) \pi^2 [(I+1)/I] [\mu |\psi(\mathbf{R})|^2]^2. \quad (4)$$

As indicated by Kip *et al.*⁷⁾, the shape of the line resulting from the distribution of four possible values of m to the six nearest nuclei is nearly Gaussian. Hence, the half width of the resonance line is given by 2.35 times of $\langle \Delta H^2 \rangle^{1/2}$, which is to be compared with 79 oersteds obtained by the experiment. Taking I to be 3/2 and μ to be 0.790 in nuclear magnetons, which is the root of weighted mean square value for natural chlorines, we find

$$|\psi(\text{Cl})|^2 = 0.55 \times 10^{24} \text{ cm}^{-3}. \quad (5)$$

Now for the purpose of order estimation

we shall take the effective mass approximation and assume that the wave function of the Z_1 -center is given by

$$\psi(\mathbf{r}) = F(\mathbf{r}) \psi_0(\mathbf{r}), \quad (6)$$

where $\psi_0(\mathbf{r})$ is the Bloch function for the conduction electron at the bottom of the band, and $F(\mathbf{r})$ is a solution of the effective mass equation for the periodic field perturbed by the substituted divalent ions. For $\psi_0(\mathbf{r})$ we shall employ the solution obtained by one of us making use of cellular method for $\text{KCl}^{(8)}$. Unfortunately the solution is not orthogonal to the inner core s -state. However, a fairly good $\psi_0(\mathbf{r})$ may be obtained by orthogonalizing this solution to $1s$, $2s$ and $3s$ electrons of a free chlorine ion by making use of the Schmidt method. Further, $\psi_0(\mathbf{r})$ employed in (6) must be normalized so that integration of $|\psi_0(\mathbf{r})|^2$ over unit cell is equal to the volume of unit cell. Thus we find;

$$|\psi_0(\text{Cl})|^2 = 320. \quad (7)$$

Just likewise the value of $|\psi_0(\mathbf{r})|^2$ at the position of potassium is found to be

$$|\psi_0(\text{K})|^2 = 470. \quad (8)$$

As for the effective mass equation we shall take electron mass as effective mass and $1/\kappa^* r$ as the perturbing potential, where κ^* is the effective dielectric constant. Even this crude assumption would indeed be rather sensible for the calcium Z_1 -center, since calcium ion has the same configuration with potassium ion; but it may considerably distort the true aspect for the strontium Z_1 -center. We shall, however, go ahead with this, being encouraged by the experimental fact the behaviors of optical absorptions and spin resonances are the same for the calcium and strontium Z_1 -centers. The solution of this effective mass equation is given by

$$F(\mathbf{r}) = (1/\pi \alpha^3)^{1/2} \exp(-r/\alpha) \quad (9)$$

$$\alpha = \kappa^* a_0,$$

where a_0 is the Bohr radius. Since Z_1 -electron is fairly concentrated about the center and hence the displacement of ion may be very small, we may take the optical dielectric constant as κ^* for rough estimation. Inserting $\kappa^* = 2.2$ and $r = 3.14 \text{ \AA}$, we get

$$|F(\text{Cl})|^2 = 0.92 \times 10^{21} \text{ cm}^{-3}. \quad (10)$$

Thus finally we obtain

$$|\psi(\text{Cl})|^2 = |F(\text{Cl})| \cdot |\psi_0(\text{Cl})|^2 = 0.30 \times 10^{24} \text{ cm}^{-3}, \quad (11)$$

which is to be compared with the experimental value of $0.55 \times 10^{24} \text{ cm}^{-3}$. The value of $|F(r)|^2$ at the next nearest neighbors becomes $9.3 \times 10^{19} \text{ cm}^{-3}$. Hence combining with (8) we get $|\psi(\text{K})|^2 = 0.044 \times 10^{24} \text{ cm}^{-3}$. This contribute $0.71 (\text{oersted})^2$ to $\langle \Delta H^2 \rangle$, which can be neglected compared with the contribution from the nearest chlorines, since the latter is found to be $340 (\text{oersted})^2$ from (4) and (11). Further the energy of the optical absorption due to the transition $1s-2p$ is given by $13.6 \times (1/\kappa^*)^2 [1 - (1/2)^2] = 2.1 \text{ ev}$. However, it may not so reasonable to compare this value with the experimental value of the absorption peak position, since the validity of the effective mass approximation is quite suspicious because the electron density is distributed only over a small number of ions.

So far we have dealt with the Z_1 -center upon the model due to Seitz as shown in Fig. 1. However, Pick¹⁾ had proposed a different model. He considered that an electron is bound by a divalent ion accompanied by a positive ion vacancy. If this is the case, the bound electron may be found preferentially near the two chlorine ions which are at the opposite side of the positive ion vacancy. In this case the resonance line may be triangular in shape. Although this triangle may be rounded off due to the distribution of the elec-

tron cloud to the other ions, our result that the resonance line is Gaussian may favor the model due to Seitz.

While the donor level of silicon crystal varies from 0.049 ev to 0.039 ev as the doping element is changed from As to Sb, the choice of divalent ion, calcium or strontium, does make difference less than few percent in the position of Z_1 -band. This is rather surprising, since the Z_1 -electron is far more concentrated and hence its energy is expected to be much more affected by the core potential of central ion compared with the donor electron in Si.

This work was partly supported by the Grant for Scientific Research from the Ministry of Education.

Magnetic Anisotropy Measurements of NiO Single Crystal*

By Hisamoto KONDOH, Enji UCHIDA,

Department of Physics, University of Osaka Prefecture

Yoshihide NAKAZUMI

Tochigi Chemical Industrial Co., Ltd., Osaka

and Takeo NAGAMIYA

Department of Physics, Osaka University

(Received February 5, 1958)

The magnetic anisotropy of NiO single crystal grown by the Verneuil method was measured using a torque balance. An X-ray study showed that the crystal, despite its outward appearance of a single crystal, is composed of small rhombohedral domains twinned through {100} planes. By applying a pressure along one of the [111] axes of the crystal during annealing from above the Néel temperature, the twin structure was partly removed. Torque measurements in a homogeneous magnetic field and their analysis showed that in pressure-annealed crystals domains with trigonal axis pointing along the direction of the pressure dominate but antiferromagnetic domains in each crystallite are distributed at random. The spin axis was found to be in the plane perpendicular to the trigonal axis within $\pm 16^\circ$.

§ 1. Introduction

From powder measurements of the magnetic susceptibility by Trombe¹⁾, Foëx and Blanchetais²⁾ and Bizette³⁾, the monoxide of nickel is known to be antiferromagnetic with a Néel point in the region of 523°K to 600°K. The neutron diffraction study of NiO first made by Shull et al⁴⁾ showed that it has a so-called Néel type magnetic superstructure, with alternating (111) sheets of plus spins and minus spins. The direction of the spins was found to be one of the cubic principal axis, but Kaplan⁵⁾ inferred, by calculating the dipolar interaction energy, that (111) would be the easy plane of magnetization. Keffer and O'Sullivan⁶⁾ showed that there are certain infinite number of orientational configurations of spins on the four sublattices with equal minimum dipolar energy, if the crystal were strictly cubic, but he suggested that the actually observed^{7), 8)} small rhombohedral distortion would make (111) the easy plane of magnetization. Kanamori⁹⁾ considered the small rhombohedral contraction to be due to the balance between a decrease in exchange energy and an increase in elastic energy. Roth's new¹⁰⁾ measurements of the neutron diffraction line intensities appear to

support that the (111) plane is the easy plane. Singer¹¹⁾ measured the magnetic susceptibility of a single crystal grown by the Verneuil method and cooled through the Néel point applying a pressure along one of the [111] directions. He found that the spin direction can not be along one of the cubic principal axes and that it probably is in the (111) plane. The present writers independently carried out similar experiments measuring torque, instead of magnetic susceptibility, and have come to the same conclusion. Later the susceptibility measurements were also made, but since the results do not go beyond those of Singer, they will not be reported here.

Crystals grown by Verneuil method (flame fusion method) are apparently single crystals but they have twin structures consisting of small rhombohedral crystallographic domains, as the crystals become rhombohedral below the Néel point. More domains can be made aligned along a chosen [111] direction by growing the crystal from a seed which is suitably oriented, or by cooling the crystal with application of a pressure along a chosen [111] direction, or even by giving a mechanical shock or a supersonic to the crystal. After developing the technique of growing good crystals and applying these methods of aligning domains, we could get crystals with domains

* This paper has been read at the annual meeting of the Phys. Soc. of Japan, Nov. 24th 1956 at Osaka University.

aligned at maximum by 76 percent (assuming the sublattice magnetizations to lie in the (111) plane). In Singer's experiment, he could obtain an alignment of 50 percent. It can be shown that no accurate determination of the direction of the sublattice magnetizations can be made before a completely aligned crystal is obtained, but some interesting experimental results and their interpretation will be reported in the present paper.

§ 2. Experimental

Single crystals of NiO were grown¹²⁾ by the Verneuil (flame fusion) method. They have bullet-like shapes as shown in Fig. 1 and can be cleaved along {100} to rectangular parallelepipeds. The Laue back reflection X-ray patterns and the oscillation photograph of reflections from a (422) plane showed¹³⁾ that their structure is of NaCl type slightly deformed rhombohedrally and that, despite their outward appearance as single crystals, they are composed of fine crystallographic domains with a repeated twin structure, the twin planes being {100}. Crystals prepared in three different ways, which we shall designate as A, B and C, were used in the present measurements. Crystals of kind A were grown with no seeds, crystals of kind B with seeds which were so placed that their [001] axis points vertically, i.e. along the direction in which the specimens grew, and crystals of kind C with seeds whose [111] axis pointed vertically. In Fig. 1 their crystallographic orientations can be recognized by the shapes of their tops and by the inclinations of the cleavage planes at their bottoms. These different kinds of crystals show different anisotropic properties, as we shall see later.

From X-ray studies made by Rooksby⁸⁾ and Shimomura and Nishiyama⁷⁾ we know that NiO crystals have cubic symmetry above their Néel temperature but suffer a slight rhombohedral contraction below this temperature. This deformation should be responsible for the twinning observed at room temperature. By applying a pressure along one of the [111] directions while cooling slowly from above the Néel temperature, we may expect a partial removal of this twinning. We prepared samples of a shape shown in Fig. 2(b), a column of regular hexagon whose basal planes are (111) and lateral planes {112}. This shape is

convenient for the purpose of giving a homogeneous stress and for the purpose of getting clear marks of crystal orientations. The misorientations of the surfaces were confirmed to be within 3° by observing X-ray pictures for perpendicular incidence. In the early stage of our experiment, only a set of parallel (111) planes were ground from a cleavage cube of

Fig. 1. The vertical and horizontal views of NiO crystals grown by the Verneuil method. Crystals of kind A have circular tops, those of kind B rectangular tops, and those of kind C triangular tops. Cleavage planes at the bottom are (100) planes.

Fig. 2. Made out shapes of the samples. The cubes represent mother crystals.

edges of about 1 cm length, so that the samples had a shape shown in Fig. 2(a). This shape was less satisfactory in removing twin structures. Fig. 3 schematically represents our device of stress-annealing; weight up to 45 kg was applied on the crystal.

Magnetic torque measurements were made by using a torsion balance. The apparatus and the method are almost the same with those developed by Stout and Griffel¹⁴⁾ in their

magnetic anisotropy measurements of $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$. The torsion fiber is a ribbon wire of phosphor bronze, 1 mm wide and 0.03 mm thick. For the suspension ribbon of a length of 15 cm, the torsion constant was $3.35 \text{ dyn cm radian}^{-1}$. No significant change of this value with temperature and time has been observed during the measurements. In order to mount the sample with a desired orientation, the leg

Fig. 3. The schematical representation of stress-annealing device. B: brass cylinder, S: sample, H: heating coil, C: thermocouple.

of the suspension was made of a silica rod of 7.1 mm in diameter whose bottom surface was ground flat with a suitable inclination to the axis of rotation, and the sample was glued to

it with collodion cement. The angular position of the freely hung crystal, relative to the pole pieces of the magnet, was checked by observations with a telescope and read at the torsion head. The magnitude of the torque which the sample underwent in the homogeneous horizontal magnetic field was measured by reading the rotation of the torsion head which is necessary to bring the sample back to its normal position in zero field.

The results for this torque, T , could be summarized within experimental errors by a formula

$$T = C \cos 2(\theta + \varepsilon) \quad (1)$$

where C is the amplitude, θ the angle between a fixed horizontal axis of the crystal and the field direction, and ε a phase constant. If the centering of the suspension and sample is not done correctly, the field exerts an additional torque on the suspension itself, which varies approximately as $\cos \theta$. Care was taken to eliminate this effect up to about 8000 oe, which was the usual field intensity in the present measurements.

§ 3. Results

Singer¹¹⁾ reports that unstressed crystal shows an almost isotropic susceptibility. Our annealed but unstressed crystals of kind A

Fig. 4. Magnetic torque data obtained with an unstressed crystal of kind A. Arrows indicate crystallographic direction in which the torque attains its maximum and minimum values, the lengths of the arrows representing their relative values. Broken lines are positions of vanishing torque.

showed anisotropy without exception; an example of torque measurements for them is shown in Fig. 4, in which the attached indices of planes represent the planes of rotation in the respective series of experiments, θ measures the angle of the magnetic field relative to the crystal, arrows indicate the position of maximum (positive) and minimum (negative) torques, and a broken line the stable position of zero torque; there is another unstable position of zero torque which is perpendicular to that indicated by this broken line. These positions and torque amplitude varied from sample to sample. Crystals of kind B showed even stronger anisotropy without stress-annealing and the results of their torque measurements when the samples were made into the shape shown by Fig. 2(b)* were similar to those represented by Fig. 6, which corresponds to a stress-annealed crystal of kind A (the same sample with that which gave Fig. 4 without stress). Crystals of kind C, if unstressed, showed no anisotropy.

Stress annealing from 800°K produces a unique anisotropic character of the crystal but a subsequent re-annealing at 1000°K without applying a force recovers the original anisotropy.

The amplitude of torque, C , for the sample corresponding to Fig. 4 and 6 is plotted in Fig. 5 as a function of the force applied during the process of annealing. The shape of the sample was somewhat like that shown in Fig. 2(a) but the [111] corners were not so much cut off as this; the edge length of the cube from which the sample was cut out was 0.74 cm, the triangular cut-out surfaces had edges of a length of 0.75 cm and the thickness was 0.44 cm. In obtaining these plots the crystal was restored to its original state each time before annealing under a stress. The amplitude clearly increases with increasing weight but shows a saturation beyond approximately 30 kg (120 kg/cm²), except for the amplitude of torque for the plane (111) which merely fluctuates. Excessive weight of >70 kg rather diminished the torque amplitude. The unique characteristic of the stress-annealed crystals of kind A and particularly of kind B can be summarized as follows:

- 1) The directions of maximum, minimum,

* The mechanical shocks in the process of working out seem to endow or enhance the anisotropy.

and zero torques are definite crystallographic directions, as shown in Fig. 6.

- 2) The ratio of the amplitudes for different planes of rotation is constant, independent of the magnitude of the applied stress.

- 3) In the (111) plane, i.e. the plane perpendicular to the stress axis, the crystal is almost isotropic, yielding no torque.

Fig. 5. Plots of the torque amplitude against the magnitude of the applied pressure during annealing. Each point at saturation for the rotation plane of (100) represents the mean of the three values obtained for (100), (010) and (001). These three values are equal to one another when there is no torque in the (111) plane.

- 4) If (111) is the plane of rotation, the torque vanishes when the (111) surfaces of the sample become perpendicular to the magnetic field.

Crystals of kind B made into the shape of Fig. 2(b) possess these characteristics even before receiving stress annealing, possibly due to the effect of grinding out (see § 5).

The amplitudes corresponding to Fig. 6 and their ratio are listed in Table I, together with the phase angles, ϵ . We shall theoretically interpret these ratio and phase angles in the next paragraph, and the results obtained are also included in this Table.

Fig. 7 shows the temperature dependence of the torque amplitude for the plane (111).

The Néel temperature estimated from this curve is 523°K.

§ 4. Interpretation of the Results

Our samples consist of twinned crystallographic domains of four kinds with rhombohedral

axis along four possible body diagonals. Furthermore, it is conceivable that each of these domains is subdivided into three kinds of antiferromagnetic domains with three different directions of sublattice magnetizations since each crystallographic domain has a trigonal

Fig. 6. Magnetic torque data obtained with a stress-annealed crystal of kind A.
